The tail is deeply forked, the middle rays less than half the length of the longest ray of the same fin; the second ray of the dorsal fin, a little longer than the base of that fin; the scales are large, oval, and very deciduous, placed in fifteen rows between the dorsal and ventral fins. Most authors suppose that the belly of the herring is not serrated in any stage of its growth, which is said to form a good specific distinction between it and the sprat; but it will be found that this is not the case, for a herring less than six inches in length is as distinctly serrated on the belly with thirty-six teeth, between the ventral and anal fins, as a sprat of equal size; but as the herring increases in size, so the serratures become obliterated, and, by the time the fish reaches to the length of eight inches, the belly will be found to be no longer serrated, but carinated.

The most prominent specific distinction of the herring, from the sprat, white-bait, and pilchard, is in the position of the dorsal fin, which is placed exactly in the middle of the fish, half way between the point of the upper jaw, and the end of the longest caudal ray.

Dr Knox considers the food of the herring, while inhabiting the depths of the ocean, to consist principally of minute entomostracous animals; but it is certainly less choice (adds Mr Yarrell) in its selection when near the shore. Dr Neill found five young herrings in the stomach of a large female herring; he has also known them to be taken by the fishermen on their lines, the hooks of which were baited with limpets. The young of the white-bait and small shrimps are often found in the stomach of herrings when they are not in roe; but when they are about to spawn, their stomachs (as is observed in most other fishes at that period,) appear as if empty and destitute of any perceptible food. On the authority of Dr Fleming the fry have even been caught with a trout-fly.

On the coasts of the West Highlands, herrings for many years past have been taken with the rod, the hook dressed with a white feather (generally from some of the gulls.) Near Oban, and upon the shores of Mull and Jura, twelve dozen are sometimes taken by a single boat during the evening.

Mode of taking and curing Herrings.—The herring-fishery is only carried on during the spawning season, when the fish are in the highest perfection. The Yarmouth herring-fishery commences about the middle of September, but the season varies at different parts of the coast. On the coast of Sutherland the early herring-fishery commences in June; the late fishery about the middle of July, and continues until September. On the coast of Cromarty large shoals appear as early as the month of May. The great object is to obtain a supply for the purpose of curing, although, in the early part of the season, large numbers of fresh herrings are brought to the London market from Yarmouth; and the consumption at Norwich and other places, which are not at a great distance from the coast, is also considerable. The fish are sometimes so rich in the early part of the season as to be unfit for curing, and on this account they are brought into the market for immediate

of the water, which assumed a tincture from the shoals beneath. By these means, they sometimes take twelve or fifteen hundred barrels of pilchards at a draught; and they place them in heaps on the shore.—It often happens that the quantity caught exceeds the salt or the utensils for curing them; and they then are carried off to serve for the purposes

consumption. The spawning season being over by the end of October or the beginning of November, the fishing terminates, as the herrings are then in a poor and exhausted condition.

The description of vessel fitted out for the herring-fishery on the eastern and western coasts of Scotland is called a "buss," of from fifty to eighty tons burden, cutter built. They ply from loch to loch in pursuit of the herrings, and come to anchor in the nearest harbour when the fish appear. A man or two is left on board the buss to take charge of her, and the rest go out in the boats, each manned with four hands, for the purpose of setting the nets. Each boat has two trains of nets, 230 or 240 yards long, and from eleven to twelve yards deep. In deep water both trains are tied together by the back-rope, one end to windward and the other to leeward. The boats are fastened at each end and allowed to drive to leeward with the nets. Every half-hour, or oftener, the men endeavour to ascertain if there are any herrings in the net. This they do by following along the line of the back-rope, and here and there raising a piece of netting. By this means they not only find when they are upon good fishing-ground, but learn whether the herrings swim high or low, and they raise or sink the nets accordingly, by shortening or lengthening the buoys by which the nets are kept up. Sometimes they traverse ten or twenty miles in a night, setting their nets ten or twelve times in different places. The fishing is never carried on but in the night, and the darkest nights, accompanied by a slight breeze, are the most propitious. In the morning, at daylight, the fishermen take their cargo to their respective busses. When the herrings are in great numbers, their labours are comparatively light. The nets are set in the evening, a small anchor is fixed to each end of the train, and they are not hauled or raised until morning. In this case the trains are not joined together, but are set separately, and near the buss, on board of which the men sleep. The crews of the busses are engaged by the month, and a great proportion of them are landsmen, pursuing other labours when the fishing season is over. Each man receives, in addition to his wages, a certain quantity of herrings, when the season is a good one, and a smaller proportion when it is unfavourable.

The Dutch Herring Fishery.—Mr William Chambers, in his Recollections of a Continental Tour, gives an interesting description of the Dutch herring fishery. "The Dutch greatly excel," he says, "in the art of curing herrings. The herring in a salted state is the animal delicacy of Holland, and enjoys a very different estimation from that of the common salt herring in Britain. Yet the fish of both countries are the same, being caught in the same fishing-grounds; and there is no reason why our herrings should be in any respect inferior in quality and mercantile value. There are about eighty vessels employed in the Dutch herring fishery, nearly all of which belong to Vlaardingen and Maas-sluis, two ports on the Maas, situated between Rotterdam and the sea. The fishing is conducted on an organized plan. All the vessels set sail on a fixed day, namely, the 15th of June, which is held as a day of rejoicing and merriment. They are accompanied by a vessel of war, which carries a chaplain for the fleet; and to this vessel, at the beat of drum, the fishermen proceed on Sundays for public worship. The fishing-grounds are towards the northern coasts of Scotland; but agreeably to a law of old standing, no vessel is expected to approach within three leagues of the shore. The first day that nets are allowed to be hauled is the 24th of June, when the fishing at once commences in all its vigour. The whole process of curing is conducted on shipboard. Immediately on being caught, the herrings are bled, gutted, cleaned, salted, and barrelled. The bleeding is effected by cutting them across the back of the neck, and then hanging them up for a few seconds by the tail. By being thus relieved of the blood, the fish retain a certain sweetness of flavour or delicacy of flesh which unbled herrings cannot possibly possess. The rapidity of the process of curing must likewise aid in preserving the native delicacy of the animal, for the herring is salted and in the barrel in a very few minutes after it has been swimming in the water. The superiority of the Dutch herrings, I was assured, is solely ascribable to this mode of curing, though it is not unlikely that something is also owing to the nature of the salt employed, as I have somewhere seen it mentioned that the salt in use, in reference to other processes of curing in Holland, is of a less bitter quality than that which is commonly employed in this country. The first herrings caught and cured, to the extent of two or three barrels, are instantly dispatched by a fast-sailing vessel for Holland, where their arrival is anxiously expected. On landing at Maas-sluis, one barrel, decorated with flowers and with flags flying, is dispatched to the Hague as an offering to his majesty, who on this occasion presents the fortunate fishers with 1000 guilders. The other barrels are sold by public auction, and generally fetch from 900 to 1100 guilders. These precious barrels are then subdivided among the dealers, who retail them at a high price. A single herring of this first importation brings one and a half to two guilders—that is, half a crown to three shillings and fourpence each. So highly are they esteemed, that a single herring is considered a handsome present; and it is a custom to make such gifts to friends and acquaintances on this auspicious occasion. Livery servants may be seen passing through the streets with a plate, on which lie one or two herrings, covered with a fine white cloth and a neat card of presentation. When a second importation takes place, the price falls perhaps to a guilder, to half a guilder, to fivepence, and, finally, to a penny each. The period of my visit was shortly after the early importations of the herrings from the Dutch fleet, and I observed some shops still decorated with the gaudy crowns of flowers with which their exterior had been invested a few weeks before. Both in Holland and in the countries up the Rhine, I had an opportunity of seeing these delicious Dutch herrings brought to table. Two or three of them form a dish at dinner, and are partaken of as an entremet, or something tasteful between the courses. I observed that some persons at the table-d'hôtes began their meals by taking a small piece of them. They are always brought to the table raw, and cut across, as if crimped. At Rotterdam, on asking for one boiled, I shocked the feelings of our domestic attendant, who expressed no small degree of surprise at so singular a proposition."

The *Pilchard*, (*Clupea pilchardus*,) is a species of the herring-tribe, and differs from the common herring,

chiefly, in being rather shorter in the head, and thicker in the body, and in having its dorsal or back-fin, somewhat forwarder: but it may be more readily distinguished

of manure. This fishery employs not only great numbers of men at sea, training them to naval affairs, but also numbers of women and children at land, in salting and curing the fish; in making boats, nets, ropes, and casks, for the purposes of taking or fitting them for sale. The poor are fed with the superfluity of the capture; the land is manured with the

---

by its scales, which are nearly half as large again as those of a herring of the same size. It is found, during the months of August and September, in great shoals, or *schools*, as they are called by the fishermen, on the south-west coast of England, and afford employment, for a time, to a great number of boats and men, belonging to the fishing-towns of Cornwall. This fish is also met with off the French coast, and other parts of Europe, but its chief place of resort appears to be the coasts of Cornwall and Devon. The pilchard is rarely met with in the London markets, but there is a fish, found sparingly among the sprats, which has obtained its name, which in reality, is merely a small, and we believe, undescribed species of herring. The value of this fishery was well known as long back as the reign of Elizabeth, when an act of parliament, containing the following clause, was passed :—"No stranger should transport beyond seas, any pilcherd or other fish in cask, vnlesse hee did bring into the realme for every sixe tunnes, two hundred of clap boord fit to make cask, and so rateably, vpon payne of forfeiting the said pilcherd or fish." The reason the *stranger* was obliged to bring in a certain quantity of wood, appears to have arisen from the circumstance of Cornwall being nearly without timber of any kind.

There are several signs by which the presence of a shoal of pilchards may be known; the luminous appearance of the sea at night, the number of birds of prey which accompany it, and, when seen from a moderate distance, the appearance of the water, which seems for miles around to be, as it were, boiling or bubbling.

When the annual visit of the pilchards is expected, to prevent their passing unnoticed, men are continually on the alert, watching from all the elevated spots on the coast, from which stations they are also able by signs to direct the operations of their friends at sea, so that they may be enabled to enclose as many of the fish as possible. The largest net which is employed, is called a *sean*, and is upwards of sixty fathoms (three hundred and sixty feet,) in length, and thirty-six feet in depth; the lower part of this net is kept down by means of leaden weights, while the upper floats on the surface, being rigged out with a number of corks; if one of these nets is found to be insufficient for the purpose of surrounding the shoal, a second, or even a third, is attached to it. The *sean* now forms a kind of wall, within which the fish are enclosed, and the object of the fishermen is to bring this net as near as possible to the shore, so that at low water, the fish shall have all means of escape cut off, except by overleaping the net. As soon as the tide is out, a net called a *truck-net*, which differs from the *sean* in being smaller, and without leads, is cast among the pilchards, and, cords being attached to its four corners, it is hauled on shore, along with as many fish as it may happen to contain; and this is repeated until the whole of them are taken or have made their escape.

While these means are employed for the capture of the larger quantity, other boats are engaged in taking the scattered parts of the shoal by means of driving-nets. The boats and nets of the *seaners* being very expensive, are generally provided by some capitalist or company of proprietors, and the men during the season are paid a small weekly sum, and also a certain portion of the captured fish. As soon as they are brought on shore, they are carried off in baskets to the curing-house, where they are carefully laid in rows one above the other, with alternate layers of salt, till a pile of considerable height is formed. They are said now to be in *bulk*, and are allowed to remain in this state from a fortnight to five weeks. During this time a quantity of brime and oil has drained from them, which runs off through gutters in the floor and is carefully collected; they are next thrown into a large wooden trough which contains a false bottom formed of battens or long strips of wood, and are freed from the salt and impurities that are attached to them; they are now very carefully and neatly packed in hogsheads, arranged in circles, one within the other, the heads all pointing inwards.

As soon as the hogshead is full, a circular board is placed on the top of the fish, and they are pressed very closely together by the application of heavy weights, the weights being large blocks of granite. This pressure reduces the bulk of the fish by nearly one third, and the hogshead has to be filled up three times before it is considered well packed. A quantity of pure oil runs off, during this part of the process, through a small hole in the bottom of the cask. It is calculated, that a hogshead of pilchards which weigh about four hundred weight and a quarter, will yield from three to four gallons of oil, worth about £17 a tun, or rather better than 1*s*. 4*d*. a gallon.

The oil is used in the manufacture of cart-grease, and for many other purposes to which the more common kind of whale-oil, called train-oil, is applied. Attempts have been made to purify this oil, so as to render it serviceable to the currier, but hitherto without success, on account of the quantity of salt and glutinous matter which it contains. The pilchards, when thus packed, are exported chiefly to the West Indies, for the use of the slave-population, and to different parts of the Mediterranean and are likewise salted and dried in great quantities for winter-provision, by the poorer classes in Cornwall and Devon.

The myriads of fish that a shoal of pilchards contains, are almost beyond the power of calculation; some of the shoals will form almost solid masses, covering a surface frequently of six square miles, and extending in depth upwards of one hundred feet. In successful times, as many as from five to seven hundred hogsheads have been taken from one shoal. The annual value of the fish that are exported is from fifty to sixty thousand pounds.

The appearance of a shoal of pilchards on a dark night, when enclosed by the nets, is splendid beyond description; struggling and leaping in every direction, to escape from their confinement, or to avoid the attacks of their numerous enemies (particularly the dog-fish,) who are imprisoned along with their victims, they appear like so many flakes of fire, and the sea itself seems like a lake of liquid flame.

The pilchard fisheries, according to evidence laid before a committee of the house of commons, appear, of late years, to have decreased considerably. Several causes have tended to produce this state of the fishery; among others, the removal of a bounty of 8*s*. 6*d*. a hogshead, which had been paid to the exporters till within these five or six years, and the increase of duty at present is as much as 18*s*. 2*d*. a hogshead, imposed by the government at Naples, to which place large quantities were exported.

The fishery is also injured by the illegal practice of employing drift and other nets too near the shore, by which means the shoals are dispersed as they approach. It is likely, however, that the statute of the 14th of Charles II. will soon be more strictly enforced. This Act imposes a fine upon all persons who "shall in any year, from the first of June till the last day of November, presume to take fish in the high sea, or in any bay, port, creek, or coast, of or belonging to Cornwall and Devon, with any drift-net, trammel, or

offals; the merchant finds the gain of commission, and honest commerce; the fisherman a comfortable subsistence from his toil. "Ships," says Dr Borlase, "are often freighted hither with salt, and into foreign countries with the fish, carrying off at the same time a part of our tin. The usual produce of the number of hogsheads exported for ten years, from 1747

stream-net or nets, or any other nets of that sort or kind, unless it be at the distance of one league and a half at least from the respective shores."

The number of boats at present engaged in this fishery is about 1000, giving employment to 3500 men at sea, and upwards of 5000 men, women, and children, on shore.

The *White-bait* (*Clupea alba*,) which is found so plentifully in the Thames, and is so well known in the

neighbourhood of London, as a delicate and well-flavoured fish, was supposed by naturalists to be the young of the shad, until Mr Yarrell, in the Magazine of Natural History, proved it to be a distinct species. In many respects it differs materially from all the other British species of Clupea, not only in specific characters, but also in its habits, and is one as distinctly marked as any of its congeners. From the beginning of April to the end of September, this fish, according to Mr Yarrell, may be caught in the Thames as high up as Woolwich or Blackwall, every flood tide, in considerable quantity; while during the first three months of this period, neither species of the genus Clupea of any age or size, except occasionally a young sprat, can be found. About the end of March, or early in April, white-bait begin to make their appearance in the Thames, and remain till the end of September, when they are no longer to be found in the river. In the months of June, July, and August, provided the weather be fine, immense quantities are consumed by visitors to Greenwich and Blackwall, where epicures of all orders assemble for a white-bait feast. The fishery for these fish is continued in the Thames frequently so late as September, and specimens of young fish of the year, from four to five inches long, are then not uncommon, but mixed, even at this late period of the season, with others of very small size, as if the roe had continued to be deposited throughout the summer.

The white-bait (says Dr Parnell, in a communication in the first volume of the Magazine of Zoology and Botany, to which we are indebted for the present account) is not, as it was formerly considered to be, peculiar to the Thames, as I have found it to inhabit the Frith of Forth in considerable numbers during the summer months. From the beginning of July to the end of September they are found in great abundance in the neighbourhood of Queensferry, and opposite Hopetoun House, where I captured on one dip of a small net, of about a foot and a half square, between two and three hundred fish, the greater part of which were white-bait of small size, not more than two inches in length: the remainder were sprats, young herring, and fry of other fish. In their habits they appear to be similar to the young of the herring, always keeping in shoals, and occasionally swimming near the surface of the water, where they often fall a prey to aquatic birds.

I have no doubt (continues Dr Parnell) that the white-bait will be found to exist in the Frith of Forth* throughout the whole of the year in considerable quantity, and that the fishermen would find it a new source of income, equal or superior to the spirling fishery, did they use the mode of fishing for white-bait that is practised in the Thames. But in consequence of the large extent of the estuary, and of no means being used exclusively for the capture of these fish, we can form but a faint idea of the number that may there exist.

The white-bait net which is used in the Thames is not large; the mouth of it measures only about three feet across, but the mesh of the hoes, or bag-end of the net, is very small. A boat is moored in the tide-way, where the water is from twenty to thirty feet deep; and the net with its wooden frame is fixed to the side of the boat. The tail of the hose, swimming loose, is from time to time brought into the boat, the end untied, and its contents shaken out. The wooden frame forming the mouth of the net does not dip more than four feet below the surface of the water.

The largest specimen of Clupea alba that I have met with, taken from the Frith of Forth, measures five inches in length. The upper part of the back, from the nape to the tail, is of a pale greenish ash-colour, the sides, gill covers, pectoral, ventral, and anal fins, of a beautiful pure white; the dorsal and caudal fins straw colour, minutely spotted with dark brown. The head on the summit in young specimens is marked with a large brown spot, which is divided anteriorly by a white line. Each orbit on the superior margin is tinged with black, as well as the posterior inferior margin, but in a less degree. The shape of the body resembles that of the young herring, but it is more compressed and of a deeper form.

The first ray of the dorsal fin commences exactly midway between the point of the upper jaw and the end of the middle caudal ray; the ventral fins are placed behind the third ray of the dorsal; the tail is deeply forked, the middle ray being not quite half the length of the longest ray of the same fin.

The head, in a specimen five inches long, is not quite one-fourth the length of the whole fish. In a fish four inches long, the head is exactly one-fourth the entire length. In one two inches long, the head measures more than one-fourth the whole length. Each jaw on the anterior part is furnished with a few small slender teeth, about six in number, placed in one row; which are more perceptible on the lower than on the upper jaw; on the roof of the mouth as well as on the tongue, are placed three or more rows of teeth, which can be easily felt by the assistance of the point of a needle. In this respect my observations differ from those of Mr Yarrell, who says, the tongue of the white-bait has an elevated central ridge without teeth; but it is probable that that author did not examine a dried specimen, for until in that state, it is almost impossible to perceive the teeth, in consequence of their extreme minuteness. This is a most important character, and at once removes it from the shad, which has the tongue and roof of the mouth destitute of teeth.

The white-bait, four inches long, differs from the herring, sprat, and pilchard of the same length, in the following characters:

The herring has the dorsal fin half-way between the point of the upper jaw and end of the long caudal rays; with the head nearly one-fifth the entire length. The white-bait has the dorsal fin much nearer the tip of the tail, than to the point of the upper jaw, with the head one-fourth the length of the whole fish; the body is more compressed, of a much lighter colour, and the belly much rougher under the pectorals, than is observed in the herring.

The sprat has the origin of the ventral fins situated

* The white-bait has also been observed by Dr Parnell in abundance in the Solway Frith.

to 1756 inclusive, amounted to nearly thirty thousand hogsheads each year; every hogshead has amounted, upon an average, to the price of one pound thirteen shillings and threepence. Thus the money paid for pilchards exported, has annually amounted to near fifty thousand pounds."

Whence these infinite numbers are derived, still remains obscure; but it will increase our wonder to be told, that so small a fish as the stickleback, which is seldom above two inches long, and that one would think could easily find support in any water, is yet obliged to colonize, and leave its native fens in search of new habitations. Once every seventh or eighth year, amazing shoals of these appear in the river Welland, near Spalding, and come up the stream, forming one great column. There are supposed to be multitudes collected in some of the fens, till overcharged with numbers, they are periodically obliged to migrate. An idea may be had of their numbers, when we are informed, that a man, employed by a farmer to take them, for the purpose of manuring his grounds, has got, for a considerable time, four shillings a day by selling them at a halfpenny a bushel!

Thus we see the amazing propagation of fishes along our own coasts and rivers; but their numbers bear no proportion to the vast quantities found among the islands of the Indian ocean. The inhabitants of these countries are not under the necessity even of providing instruments for fishing: it is but going down to the shore, and there the fish are found in great numbers in the plashes that still continue to have water in them. In some of these places the quantity is so great that they are left in shoals on those swamps, dried up by the sun, and their putrefaction contributes to render the country unhealthful.

This power of increasing in these animals, exceeds our ideas, as it would in a very short time outstrip all calculation. A single herring, if suffered to multiply unmolested and undiminished for twenty years, would show a progeny greater in bulk than ten such globes as that we live upon. But happily the balance of Nature is exactly preserved; and their consumption is equal to their fecundity. For this reason we are to consider the porpoise, the shark, or the cod-fish, not in the light of plunderers and rivals, but of benefactors to mankind. Without their assistance, the sea would soon become overcharged with the burden of its own productions; and that element, which

---

anterior to a vertical line dropped from the first dorsal ray, with forty-eight vertebræ; the white-bait has fifty-six vertebræ, with the origin of the ventral fins placed behind the third ray of the dorsal. In the pilchard the dorsal fin is placed exactly in the centre of gravity, so that when the fish is held up by the anterior rays, the body preserves an equilibrium, whereas if the white-bait, herring, or sprat, be taken up by the same part, the head will be observed to dip considerably.

The stomach of the white-bait I have found frequently filled with minute crustacea.

Sprat or *Garvie Herring*, (*Clupea sprattus.*) This little fish, although well known to every one by the name of Sprat or Garvie herring, is not admitted by all to be a distinct species, being considered as the young of the pilchard or the herring. This mistake is not to be wondered at, since authors either omit the most important characters, or place reliance on characters which do not exist.

Sprats are found in the Frith of Forth, throughout the whole of the year, and, like many small animals, appear to be very susceptible of cold. During the warm summer months, they are seen sporting about in large shoals, in every part of the Frith, occupying a considerable extent of water, and causing a ripple on the surface with their fins, while they become the principal food of many marine birds, which assail them in the water, or prey on them from above. As the cold weather advances, these little fish are no longer seen in the lower part of the estuary, but are found to ascend the Frith to a considerable distance, and to select that part of the river where the fresh and salt waters mingle together; for it is a well known law in chemistry, that when two fluids of different densities come in contact, the temperature of the mixture is elevated for a time in proportion to the difference in density of the two fluids. Owing to mutual penetration and condensation, such a mixture is constantly taking place in the rivers that run into the sea, and the temperature of the mixed water is accordingly elevated. In the year 1830, the sprat was remarkably abundant all over the British coast, but more particularly on the coasts of Kent and Essex, where they were taken in immense quantity, so that they were sold at sixpence a bushel as manure for the land.

The sprat is generally considered as a delicious well-flavoured and wholesome fish, and is eaten in considerable quantity in this country, both in the fresh and salted conditions, but is very seldom brought to the Edinburgh market. They spawn early in the month of March, and feed on small crustaceous animals.

The most common size of a sprat is from four to five inches in length, but it is observed occasionally to exceed six inches and a half, when it is named in the neighbourhood of Alloa the King of Garvies.

The colour of the back is a deep glossy blue, the sides, belly, and gill-covers of a pure silvery white, passing into green and blue reflections, when viewed in different lights; the dorsal and caudal fins dusky, minutely spotted with black; the pectoral and ventral fins white, slightly tinged with orange. On the crown of the head is a dark spot placed between the eyes, which is very perceptibly seen when young, but as the fish increases in size the spot gradually becomes obliterated. The eye is large, the diameter being not less than one-fourth of the whole head; the upper and lower margins are tinged with black. Each operculum has a slight notch placed on its upper and posterior edge. The teeth in the jaws are small, slender, and few in number; they are situated on the most anterior parts, and are more obvious on the lower than on the upper jaw; the tongue as well as the roof of the mouth is also armed with fine teeth, their points being slightly bent inwards. The under jaw is the longest. The belly is strongly serrated as far as the anal aperture. The convexity of the dorsal and abdominal lines is much greater than is observed either in the white-bait or the herring.

The sprat differs from the herring, white-bait, pilchard, and shad, in two most striking characters; in having only forty-eight vertebræ, and in having the origin of the ventral fins placed before a vertical line dropped from the commencement of the first dorsal ray.

at present distributes health and plenty to the shore, would but load it with putrefaction.

In the propagation of all fish, some degree of warmth seems absolutely necessary, not only to their preservation, but to the advancement of their posterity. Their spawn is always deposited in those places where the sun beams may reach them, either at the bottom of shallow shores, or floating on the surface in deeper waters. A small degree of heat answers all the purposes of incubation, and the animal issues from the egg in its state of perfect formation, never to undergo any succeeding change.

Yet, still I have some doubts whether most fish come from the egg completely formed. We know that in all the frog tribe, and many of the lizard kind, they are produced from the egg in an imperfect form. The tadpole, or young frog, with its enormous head and slender tail, are well known; a species of the lizard also, which is excluded from the shell without legs, only acquires them by degrees, and not till after some time does it put off its serpent form. It is probable that some kinds of fish in like manner suffer a change; and though it be too inconsiderable to strike the fisherman or the inattentive spectator, yet it makes a very material difference to the naturalist, and would, perhaps, disarrange his most favourite systems. A slight alteration in the fins or bones that cover the gills would overturn the whole fabric of the most applauded ichthyologist; and yet, as I observed, it is most probable that these minute alterations often take place.

As a proof of this, during the month of July, there appear near Greenwich, innumerable shoals of small fishes, which are known to the Londoners by the name of White bait. It is universally agreed that they are the young of some fish; they are never seen but at this time of the year, and never found to have any roe, a circumstance that proves their not being come to maturity. The quantity is amazing; and the fish that produces them in such numbers must be in plenty, though it is not yet known what that fish is, as they correspond with no other species whatever. They most resemble the smelt in form; and yet they want a fin, which that animal is never without. They cannot be the bleak, as they are never found in other rivers where the bleak breed in great abundance. It is most probable, therefore, that they are the young of some animal not yet come to their perfect form, and therefore reducible to no present system.

The time that spinous fishes continue in the pea is in proportion to the size of the kind. It is a rule that chiefly holds through nature, that the larger the animals are, the longer they continue before exclusion. This I say holds generally through all nature, though it is not easy to assign a cause for so well known a truth. It may probably be, that as all large bodies take a longer time to grow hot than small ones, so the larger the egg, the longer influence of vital warmth it requires to reach through all its recesses, and to unfold the dormant springs that wait to be put into motion.

The manner in which the eggs of fishes are impregnated is wholly unknown. All that obviously offers is, that in ponds the sexes are often seen together among the long grass at the edge of the water; that there they seem to struggle; and that during this time they are in a state of suffering; they grow thin; they lose their appetite, and their flesh becomes flabby; the scales of some grow rough, and they lose their lustre. On the contrary, when the time of coupling is over, their appetite returns; they re-assume their natural agility, and their scales become brilliant and beautiful.

Although the usual way with spinous fishes is to produce by spawn; yet there are some, such as the eel and the blenny, that are known to bring forth their young alive. Bowlker, who has written a treatise upon fishing, seems to determine the question relative to the viviparous production of eels, upon the authority of one or two credible witnesses. An eel, opened in the presence of several persons of credit, was found to have an infinite number of little creatures, closely wrapped up together in a lump, about the size of a nutmeg, which being put into a basin of water, soon separated, and swam about: yet still, whether these may not have been worms generated in the animal's body, remains a doubt; for there are scarcely any fishes that are not infested with worms in that manner.[1]

With respect to the growth of fishes, it is observed, that among carps, particularly the first year, they grow to about the size of the leaf of a willow-tree; at two years, they are about four inches long. They grow but one inch more the third season, which is five inches. Those of four years old are about six inches; and seven after the fifth. From that to eight years old they are found to be large in proportion to the goodness of the pond, from eight to twelve inches. With regard to sea-fish, the fishermen assure us, that a fish must be six years old before it is fit to be served up to table. They instance it in the growth of a mackarel. They assure us that those of a year old are as large as one's finger; that those of two years, are about twice that length; at three and four years, they are that small kind of mackarel that have neither milts nor roes;

[1] The eel, it is known, is viviparous.

and between five and six, they are those full-grown fish that are served up to our tables. In the same manner, with regard to flat fishes, they tell us, that the turbot and barbel at one year are about the size of a crown-piece; the second year, as large as the palm of one's hand; and at the fifth and sixth year, they are large enough to be served up to table. Thus it appears, that fish are a considerable time in coming to their full growth, and that they are a long time destroyed before it comes to their turn to be destroyers.[1]

All fish live upon each other in some state of their existence. Those with the largest mouths attack and devour the larger kinds; those whose mouths are less, lie in wait for the smaller fry; and even these chiefly subsist upon spawn. Of those which live in the ocean, of the spinous kinds, the dorado is the most voracious. This is chiefly found in the tropical climates; and is at once the most active and the most beautiful of the finny region. It is about six feet long; the back all over enamelled with spots of a bluish green and silver; the tail and fins of a gold colour; and all have a brilliancy of tint, that nothing but nature's pencil can attain to; the eyes are placed on each side of the head, large and beautiful, surrounded with circles of shining gold. In the seas where they are found, these fish are always in motion, and play round ships in full sail with ease and security: for ever either pursuing or pursued, they are seen continually in a state of warfare; either defending themselves against the shark, or darting after the smaller fishes. Of all others, the Flying-fish most abounds in these seas; and as it is a small animal, seldom growing above the size of a herring, it is chiefly sought by the dorado. Nature has furnished each respectively with the powers of pursuit and evasion. The dorado being above six feet long, yet not thicker than a salmon, and furnished with a full compliment of fins, cuts its way through the water with amazing rapidity: on the other hand, the flying-fish is furnished with two pair of fins longer than the body, and these also moved by a stronger set of muscles than any other. This equality of power seems to furnish one of the most entertaining spectacles those seas can exhibit. The efforts to seize on the one side, and the arts of escaping on the other, are perfectly amusing. The dorado is seen, upon this occasion, darting after its prey, which will not leave the water, while it has the advantage of swimming, in the beginning of the chase. But, like a hunted hare, being tired at last, it then has recourse to another expedient for safety by flight. The long fins, which began to grow useless in the water, are now exerted in a different manner, and different direction, to that in which they were employed in swimming: by this means, the timid little animal rises from the water, and flutters over its surface for two or three hundred yards, till the muscles employed in moving the wings are enfeebled by that particular manner of exertion. By this time, however, they have acquired a fresh power of renewing their efforts in the water, and the animal is capable of proceeding with some velocity by swimming: still, however, the active enemy keeps it in view, and drives it again from the deep; till, at length, the poor little creature is seen to dart to shorter distances, to flutter with greater effort, and to drop down at last into the mouth of its fierce pursuer. But not the dorado alone, all animated nature seems combined against this little fish, which seems possessed of double powers, only to be subject to greater dangers. For though it should escape from its enemies of the deep, yet the tropic bird and the albatross are for ever upon the wing to seize it. Thus pursued in either element, it sometimes seeks refuge from a new enemy; and it is not unfrequent for whole shoals of them to fall on shipboard, where they furnish man with an object of useless curiosity.

The warfare in fresh water is not carried on with such destructive activity; nor are the inhabitants of that element so numerous. It would seem that there is something more favourable to the fecundity of fishes in the ocean than in an element less impregnated with salt. It has been the opinion of some philosophers that all fish are natives of that great reservoir; and that only colonies have been sent up rivers, either through accident, or the necessity of procuring subsistence. They have been led to this opinion by the superior fecundity of sea-fish, which breed twenty to one; as well as by their superiority in strength and size, over those of the same kind found in lakes and rivers. This is a matter too remotely speculative to be worth pursuing; but certain it is that, in fresh water, fishes seem to abate much of their courage and rapacity; pursue each other with less violence, and seem to be less powerfully actuated by all their appetites. The greediness with which sea-fish devour the bait is prodigious, if compared with the manner they take it in fresh water. The lines of such fishermen as go off to sea are coarse, thick, and clumsy, compared to what are used by those who fish at land. Their baits are seldom more than a piece of a fish, or the flesh of some quadruped, stuck on the hook in a bungling manner; and scarcely any art is employed to conceal the deception. But it is otherwise in fresh water:

[1] Traite des Peches, par Monsieur Duhamel. Sect. 3. p. 100.

the lines must often be drawn to a hair-like fineness; they must be tinctured of the peculiar colour of the stream; the bait must be formed with the nicest art, and even, if possible, to exceed the perfection of nature: yet still the fishes approach it with diffidence, and often swim round it with disdain. The cod, on the banks of Newfoundland, the instant the hook, which is only baited with the guts of the animal last taken, is dropped into the water, darts to it at once, and the fishermen have but to pull up as fast as they throw down. But it is otherwise with those who fish in fresh waters, they must wait whole hours in fruitless expectation; and *the patience of a fisherman* is proverbial among us.[1]

[1] *Fish usually taken by anglers in Great Britain.*—The *Barbel*, so called from its four barbs, two of which are at the corners of its mouth, and the others at the end of its snout, is a heavy, dull fish, and gives very inferior

sport to the angler, in proportion to his size and strength. They begin to shed their spawn about the middle of April, and come in season about a month or six weeks after. In their usual haunts, among weeds, &c., they are fond of rooting with their nose like the pig. In summer, they frequent the most powerful and rapid currents, and settle among logs of wood, piles, and weeds, where they remain for a long time apparently immovable; during the winter time, they return to deep bottoms. The most killing baits for the barbel are the spawn of trout, salmon, or indeed of any other fish, especially if it be fresh, respecting which, the barbel is very cunning; the paste that imitates it must, therefore, be well made, and of fresh flavour. It is also an advisable plan to bait the water over night, by spawn or a quantity of cut worms. The barbel will also bite well at the cobworm, gentles, and cheese, soaked in honey. The rod and line, with which you fish for barbel, must both be extremely long, with a running plummet attached to the latter, as they swim very close to the bottom. By a gentle inclination of the rod, you may easily ascertain when there is a bite; immediately upon which the fish should be struck, and seldom escapes, unless he break the line.

The *Bleak*, or *Blay*, is a common river fish, so called from its bleak or white appearance, that spawns in March; and is fond of many of the baits for trout. It is usually caught with a small artificial fly of a brown colour; and the hook should be suited in size to the fly. The bleak seldom exceeds six inches in length; its flesh is highly valued by epicures, and beads are made of its scales.

Bream (see it figured at page 297) shed their spawn about midsummer, and although they are occasionally met with in slow running rivers, are reckoned a pond fish, where they will thrive in the greatest perfection; and have been known to weigh from eight to ten lbs. In fishing for them, the angler should be very silent, and take all possible care to keep concealed from the fish, which are angled for near the bottom. His tackle also must be strong. This fish, according to Dr Shaw, is a native of many parts of Europe, inhabiting the still lakes and rivers, and sometimes found even in the Caspian sea.

This comparative neglect of food, which is found in all the tribes of fresh-water fishes, renders them less turbulent and less destructive among each other. Of all these the pike

Bull head, or *Miller's thumb*, is a small ugly fish, which hides itself in brooks and rivers under a gravelly bottom. They spawn in April, and their average length is from four to five inches. When their gill fins are cut off they serve as good baits for pike and trout, and, like the cray fish, when boiled, their flesh turns red.

Carp (see it described at page 305) is a fish that by its frequency of spawning, and quickness of growth, is greatly used to stock ponds, where it thrives better, and lives longer than in rivers. Gesner speaks of one who lived to 100 years old; there is much doubt about its general age, but it is supposed to be a very long lived fish. They spawn three or four times a year, but the earliest time is about the commencement of May. They are observed to live uncommonly long out of water, and in Holland are frequently kept alive for three weeks, or a month, in a cool place, by being hung with wet moss in a net, and fed with bread, steeped in milk. In angling for carp, it is necessary to make use of strong tackle, with a fine gut next the hook, and a float formed of the quill of a goose. They bite almost close to the bottom, and are rarely caught if angled for in a boat. From its subtlety, it has been sometimes called the water fox. The river carp is accustomed to haunt, in the winter, the most quiet and broad parts of the stream. In summer they live in deep holes, reaches, and nooks, under the roots of trees, and among great banks of weeds, until they are in a rotten condition. The pond carp loves a rich and fat soil, and will seldom or never thrive in cold, hungry waters. The carp ponds of Germany yield a considerable income to the gentry.

The *Chub*, (see it figured at page 307) or *Chevin*, is, like the perch, a very bold biter, and will rise eagerly at a natural or artificial fly. They spawn in June, or at the latter end of May, at which time they are easily caught by a fly, a beetle with its legs and wings cut off, or still more successfully by a large snail. When they are fished for at mid-water, or at bottom, a float should be made use of; when at top, it is customary to dip for them, or to use a fly, as if a trout were the angler's object. Strong tackle is also requisite, as they are a heavy fish, and usually require a landing net to pull them out. Their average length is from ten to fourteen inches.

Dace, *Dart*, or *Dare*, are a very active and cautious fish, and rise to a fly, either real or artificial. It is necessary, in angling for them, to remain in concealment as much as possible. They spawn in February and March, and their flesh is but inferior in point of flavour. They frequent gravelly, clayey, and sandy bottoms, leaves of the water lily, and deep holes, if well shaded. In sultry weather they are frequently caught in the shallows; and during that period, are best taken with grasshoppers or gentles. In fishing at bottom for roach and dace, who are similar in their haunts and disposition, bread soaked in water, and kneaded to a good consistency, and then made up together with bran into round balls, and thrown into the place where it is proposed to angle, will be found very serviceable, but must always be thrown up the stream. There is a mode of intoxicating dace, and by this means rendering them an easy prey; but this is no part of the real angler's sport. The Thames is well known to abound in dace, and the graining of the Mersey is thought to be a variety of the same species.

The *Eel* (see an account of eels at page 286) is rarely angled for, but it is usually caught by the process of sniggling or bobbing, with night lines, &c. Being fond of quiet in the day time, all who expect much sport in eel fishing must devote their evenings and even whole nights to the pursuit. The method for sniggling for eels

is the most active and voracious; and our poets, whose business it is to observe the surface of nature, have called it the tyrant of the watery plain. In fact, in proportion to its strength and celerity, the pike does some mischief; but what are its effects compared to those of the cachalot or the shark! they resemble the petty depredations of a robber, put in com-

is as follows :—Take a common needle, attached in the middle by fine waxed twine, a packthread line, or a strong small hook fixed to this kind of line; place a large lobworm, by the head end, on your needle or hook, and draw him on to his middle; affix another needle to the end of a long stick, and guide your bait with it into any of the known haunts of the fish, between mill boards, or into clefts of banks or holes, holding the line in your hand; now give the eel time to gorge the bait, and then by a sharp twitch fix the needle across his throat, or the hook into his body; tire him well, and your triumph is certain. Although this is not strictly a method of angling, the lovers of that sport will find it so successful a mode of diversifying their pursuits, where eels are common, that the present appeared the most convenient place to insert it. Bobbing is a rough species of angling. The best method is to provide yourself with a considerable number of good-sized worms, and string them from head to tail, by a needle, on fine strong twine, viz. to the amount of a pound, or a pound and a half in weight. Wind them round a card into a dozen or fifteen links, and secure the two ends of each link by threads. Now tie a strong cord to the bundle of strung worms, about a foot from which put on a bored plummet, and angle with a line from two to three feet long, attached to a stout tapering pole. Eels, and perhaps pike, are found in no part of Great Britain in such numbers or variety as in the marshy parts of the counties of Cambridge and Lincoln. The silver eel is the finest, and is very common in Scotland. The manner in which this fish is propagated, has long been a matter of dispute. They have neither spawn nor melt, as known organs of generation. Walton gravely argues for their being bred of corruption, "as some kind of bees and wasps are;" others strongly contend for their being viviparous. It is a subject, indeed, upon which naturalists have no certain information. The lamprey, (see it noticed at page 280) "a lambendo petras, from licking the rocks," says the quaint author of the Worthies of England, is a species of eel, variously esteemed. In Worcestershire and Gloucestershire, the Severn lamprey is regarded as a luxury; and, by the city of Gloucester, a pie made of this fish is annually presented to the queen. In the north of Great Britain it is much disliked. Eels bait in a shower, and in windy, gloomy weather, at the lob and garden worm, designed for other fish, particularly trout. Unlike other fish, they are never out of season. They are a very greedy fish, and if you wish to angle for them in the ordinary way, they will take a lamprey, wasp, grubs, minnows, &c., but particularly the first.

The *Pinnock*, or *Hirling*, is a species of sea trout which usually attains the length of from nine to fourteen inches, and is principally known in Scotland; the whitling, another species, is from sixteen to twenty-four inches long. They will both rise equally at an artificial fly, but require generally a more showy one than the common trout.

The *Grayling*, or *Umber*, (noticed at page 303) spawns in May, and is in the best condition in November. They will greedily take all the baits that a trout does, and frequent the same streams. They are said to have the fragrant smell of the plant Thymallus. Their average length is from sixteen to eighteen inches; and they must be angled for with very fine tackle, as they are a remarkably timid fish. When hooked, they must also be cautiously worked, as the hold in their mouth easily gives way; but they will speedily return to the bait. It is fine eating, unknown to Scotland or Ireland.

The *Gudgeon* (figured at page 295) is a fish in some request, both for its flavour and the sport it affords to the inexperienced angler. It is very simple, and is allured with almost any kind of bait. It spawns two or three times during the year; is generally from five to six inches long, and fond of gentle streams with a gravelly bottom. In angling for gudgeon, the bottom should be previously stirred up, as this rouses them from a state of inactivity, and collects them in shoals together. Some anglers use two or three hooks in gudgeon fishing. A float is always used, but the fish should not be struck on the first motion of it; as they are accustomed to nibble the bait before they swallow it. It frequently happens, that in angling for gudgeons, perch are caught.

The *Loach*, or *Groundling*, sheds its spawn in April, and remains in the gravel; where they are usually caught with a small red worm. They are principally found in the north of Great Britain, and in the streams of the mountainous parts. They are about three inches in length; and their flesh is pleasant and wholesome.

The *Minnow*, or *Minim*, one of the smallest river fish, seldom exceeds two inches in length. They spawn generally about once in two or three years, and swim together in shoals, in shallow waters, where they are very free, and bold in biting. They serve also as excellent baits for pike, trout, chub, perch, and many other fish, which prey upon and devour them greedily.

The *Mullet* takes almost the same baits as the trout, and will very eagerly rise to an artificial fly; they are considered free baiters, and come and go with the tide. If artificial flies are made use of, their size should be larger than those generally used to insnare the trout. They are found in their greatest perfection, in the river Arun, Sussex; but are seldom or never seen in Scotland.

The *Par*, or *Samlet*, (see it figured and described at page 302) is a fish that is known by different names in different parts of Great Britain. On the river Wye it is usually called a skirling; in Yorkshire, a brandling; in Northumberland, a rack-rider; and in some parts of England, a fingering, from the resemblance of its spotted streaks to the human fingers. Par, or Samlet, is its Scottish name, and in that part of Britain it is best known. Some have affirmed, that it is the blended spawn of the trout and salmon. This opinion is strengthened by the circumstances of their usually frequenting the same haunts with the salmon and sea trout, and their being forked in their tail like the former.

The *Perch* (see it noticed at page 298) is a very bold biting fish, and affords excellent amusement to the angler. He is distinguished by the beauty of his colours, and by a large erection on his back, strongly armed with stiff and sharp bristles, which he can raise or depress at pleasure. Defended by this natural excrescence, he bids defiance to the attacks of the ravenous and enormous pike, and will even dare to attack one of his own species. Perch spawn about the beginning of March, and measure from eight to fourteen inches. In fishing for perch with a minnow, or brandling, the hook should be run through the back fin of the bait, which must hang about six inches from the ground. A large cork float should be attached to the line, which should be leaded about nine inches from the hook. It must be observed, that they invariably refuse a fly.

The *Pike*, *Luce*, or *Jack*, (see it figured and described at page 303) is a fish of enormous size, and the greatest voracity; indeed, so notorious is he for the latter quality,

petition with the ravages of a conqueror! However, the pike will attack every fish less than itself; and it is sometimes seen choked, by attempting to swallow such as are too large a morsel. It is immaterial of what species the animal it pursues appears to be, whether of another or its own, all are indiscriminately devoured; so that every fish owes

as to have gained the appellation of the fresh water shark. They are also great breeders. Their usual time of shedding their spawn is about March, in extremely shallow waters. The finest pike are those which feed in clear rivers; those of fens or meres, being of very inferior quality. They grow to a vast size in these last mentioned places, where they feed principally on frogs, and such like nutriment. They are reckoned to be the most remarkable for longevity of all fresh water fish; are solitary and melancholy in their habits, generally swimming by themselves, and remaining alone in their haunts, until compelled by hunger to roam in quest of food. There are three modes of catching pike: by the ledger, the trolling, or walking bait, and the trimmer.

The *Pope*, or *Ruff*, is a fish very similar in its nature and appearance to the perch, and is frequently caught when fishing for the latter. They spawn in March and April, and are taken with a brandling, gentles, or caddis. They are extremely voracious in their disposition, and will devour a minnow, which is almost as big as themselves. In their favourite haunts of gentle deep streams, overhung by trees, they swim in shoals together; and you may fish for them either at the top or the bottom of the water, as they are known to bait in almost any weather, and in any situation. Their average length is from six to seven inches.

Roach are frequently taken with flies under water. They will bite at all the baits which are prepared for chub or dace, and are considered a simple and foolish fish. They spawn in May, and turn red when boiled. The compactness of their flesh gave rise to the proverb, "sound as a roach." The roach haunts shallow and gentle streams, and the mouths of small streams which run into larger ones. In angling for roach, the tackle must be strong, and the float large and well leaded.

The *Rud*, or *Finscale*, is a very scarce fish, found only in the river Charwell, in Oxfordshire, and a few of the lakes of Lincolnshire and Yorkshire. It sheds its spawn in April, will take all kinds of worms, and will rise at an artificial fly. Its colour is a kind of yellowish brown, and its average length from nine to fifteen inches.

Salmon (see page 301) are accustomed to quit the fresh waters, and retire into the sea at the approach of winter, which, at the commencement of April, they usually leave for rivers; but the Wye and Usk in Monmouthshire, and the Exe in Devonshire, have them in season during the six wintry months. The finest species are caught in the Exe, Thames, and Tamar, but not so abundantly as in many other places. Salmon prefer more chilly streams, and are consequently found in greater numbers northward, in the rivers of Scotland, particularly in the Tweed, the Tyne, the Clyde, and the Tay. In the latter, they occasionally occur at the immense weight of seventy pounds; and in the Tweed, and Clyde, at about fifty or sixty pounds weight. They are also found in all the great streams of Europe north of 51°, and in the United States of America north of 41°. Some recent accounts of the north-west coast of America, describe them also as abounding there. In the American rivers, they seldom exceed from fifteen to twenty pounds weight. They appear some time in the rivers before they are in a healthy state; and the best season for the angler to commence his operation, is in the close of the month of May, or the early part of June. The usual time for the salmon to deposit their spawn, is from the first of September to the latter end of October, when they grow very sickly both in appearance and flavour. Previous to this, they generally retire to brooks which branch out irregularly from the main river, or remain in shallows, where they sometimes are scarcely covered with water. During their residence in fresh water, it is a well authenticated circumstance, that they always lie with their heads pointing up the river; and never swim down the stream, unless during the period of their emigration to the sea, or when their position is molested. The length of the rod for catching salmon should be from about seventeen to twenty feet, which, however, can be regulated according to the breadth and general size of the river in which the angler pursues his operations. The reel, which on these occasions, forms the most material appendage to the rod, is made of brass; it should be constructed with the utmost nicety, and capable of the swiftest circumvolutions. The line, which is fastened to the reel, may be composed either of strong silk or twisted horse hair, gradually diminishing at the top, and having a loop at the end of the wheel, and another at the cast lines, to fasten them to each other. Let this last line be very carefully twisted with the fingers, and shorter than the rod, so that none of the knots may come within the top ring; sixteen to twenty horse hairs may be used in the upper links, but they must be diminished toward the hook, where they are best made of three small round twisted silk worm guts, or a few strong horse hairs. Of worms, lob-worms, earth-bobs, &c., and of fish, minnow have been used with great success. The artificial flies should be generally of large dimensions, and of a gaudy and glittering colour. The materials that compose them are hairs, furs, and wools, of every variety that can be collected, mingled with the tail-feathers of cocks and game, and secured together by plated wire, or gold and silver thread, marking silk, shoemakers' wax, bees' wax, &c. Their wings may be made of the feathers of domestic fowls, or any others of a showy colour. Imitate principally the natural flies; but you may safely indulge your fancy, rather than depart without a bite; for many anglers succeed with the most monstrous and capricious baits of this kind. A raw cockle, or muscle, taken out of the shell, prawns, and minnows, have also been recommended as salmon baits. The mode of angling with these is to drop the line, which must be totally unincumbered with shot, into some shallow which approximates to the edge of a hole of considerable depth, and in this situation to suffer it to be carried in by the current. The noviciate in angling will, at first, experience considerable difficulty in throwing his line to any great extent. For this we can give no recipe, but a most inflexible determination to proceed, and the most consummate patience in disappointment. It should always be thrown across the river, and on the off side from the spot where you expect the fish to rise. When you imagine that the salmon has been struck, be cautious in giving him time sufficient to enable him to poach his bait, that is, to swallow it fairly and securely. After this, fix the hook firmly in him, by a gentle twitch. On the first sensation of this pain, the salmon will plunge and spring with great violence, and use every endeavour of strength and cunning to effect his escape. He will then, perhaps, run away with a considerable length of line, which is to be kept in a gently relaxed situation, so that it may always yield with facility to his obstinate resistance: nor can you give him too much line, if you do but clear it of weeds and encumbrances. If he now become sullen and quiet in the water, rouse him gently, by flinging in a few stones; and when he once more commences resistance, do not be too eager in checking his career, but let him gradually exhaust himself of his

its safety to its minuteness, its celerity, or its courage: nor does the pike confine itself to feed on fish and frogs; it will draw down the water-rat and the young ducks, as they are swimming about. Gesner tells us of a mule that stooped to drink in the water, when a famished pike, that was near, seized it by the nose, nor was it disengaged till the beast flung it on shore. So great is their rapacity, that they will contend with the otter for his prey, and even endeavour to force it from him. For this reason it is dreaded by all other fish: and the small ones show the same uneasiness and detestation at the presence of their tyrant, as the little birds do at the sight of a hawk or an owl. When the pike lies asleep near the surface, as is frequently the case, the lesser fish are often observed to swim around it in vast numbers, with a mixture of caution and terror.

The other tribes of fresh-water fish are much inferior to this animal in courage and rapacity: they chiefly subsist upon worms and insects, pursuing them at the bottom, or jumping after them to the surface of the water. In winter also, their appetite seems entirely to forsake them; at least they continue in so torpid a state, that few baits will tempt them to their destruction. At that season, they forsake the shallow waters, and seek those deep holes to be found in every river, where they continue for days together, without ever appearing to move. The cold seems to affect them; for at that time they lie close to the bottom, where the water is most warm, and seldom venture out, except the day be peculiarly fine, and the shallows at the edges of the stream become tepified by the powerful rays of the sun. Indeed I have been assured, that some fishes may be rendered so torpid by the cold, in the northern rivers, as to be frozen up in the great masses of ice, in which they continue for several months together, seemingly without life or sensation, the prisoners of congelation, and waiting the approach of a warmer sun to restore them at once to life and

---

strength; follow him down the stream, or allow him to cross it; while, at every, opportunity, you keep winding up your line until you approach him in this wearied state, and take him softly by the gills out of the water. The salmon peal may be caught in the same manner; he is smaller than the salmon, and seldom exceeds fourteen or fifteen inches in length.

Tench, (see page 306 for a figure of the Tench) like the carp, are generally considered pond fish, although they have been frequently caught in the river Stour. They shed their spawn about the commencement of July, and are in season from September to the latter end of May. They will bite very freely during the sultry months. Their haunts are similar to those of the carp; except that they frequent the foulest and muddiest bottoms, where they may shelter themselves among an infinite quantity of reeds; hence you must angle for them very near the bottom, and allow them sufficient time to gorge the bait.

Trout (see page 302) are considered as one of the finest river fish that this country can produce. Its colours are beautifully varied at different seasons of the year, and according to the rivers it frequents. They abound in the generality of our streams, rivers, and lakes, and are usually angled for with an artificial fly. Their weight also differs from half a pound to three; some few have been caught which weighed upwards of four pounds. Trout are extremely voracious; and, by their activity and eagerness, afford famous diversion to the angler. Previous to their spawning, they are observed to force a passage through weirs and flood-gates against the stream; and how they are enabled to overcome some of these impediments, is a subject of much conjecture. Their general time of shedding the spawn is about October or November; in some rivers, however, it is much sooner, in others later. They are also met with in eddies, where they remain concealed from observation behind a stone, or log, or a bank that projects into the stream; during the latter part of the summer, they are frequently caught in a mill-tail, and sometimes under the hollow of a bank, or the roots of a tree. In angling for trout, there are many things worthy of particular observation: 1st. That the day on which the sport is undertaken, be a little windy, or partially overcast, and the south wind is superior to all others, if it do not too much disturb your tackle. 2d. The sportsman should remain as far as possible from the stream, fish it downwards, the line never touching the water, as the agitation proceeding from the fall might disturb the fish, and preclude all possibility of capturing them. 3d. Clear streams are famous for sport, and in fishing in them, a small fly with slender wings must be attached to the hook. When the water is thick, and the sight more imperfect from this disadvantage, a larger species of bait must of necessity be used. 4th. The line should, on an average, be about twice as long as the rod, unless in cases of emergency, when the number and variety of trees exclude the probability of a successful throw, if at any distance. 5th. Let the fly be made to suit the season. After a shower, when the water becomes of a brown appearance, the most killing bait is the orange fly; in a clear day, the light coloured fly; and on a gloomy day, in overshadowed streams, a dark fly. Very large trout have been killed in Ullswater, in Cumberland, and still larger in Loch Awe in Argyleshire. Specimens of this great fish are to be found in Loch Awe, weighing from ten to twenty pounds. (See it figured and described at page 302.) It is said to be by far the most powerful of our fresh-water fishes, exceeding the salmon in actual strength, though not in activity. The most general size caught by trolling, ranges from three to fifteen pounds; beyond that weight they are of uncommon occurrence. If hooked upon tackle of moderate strength, they afford excellent sport; but the general method of fishing for them is almost as well adapted for catching sharks as trout; the angler being apparently more anxious to have it in his power to state that he had caught a fish of such a size, than to enjoy the pleasure of the sport itself. However, to the credit of both parties, it may be stated, that the very strongest tackle is sometimes snapped in two by its first tremendous springs. The ordinary method of fishing for this king of trouts is with a powerful rod, from a boat rowing at the rate of from three to four miles an hour; the lure, a common trout, from three to ten inches in length, baited upon six or eight salmon hooks, tied back to back upon strong gimp, assisted by two swivels, and the wheel-line strong whip cord. Yet all this, in the first impetuous efforts of the fish to regain its liberty, is frequently carried away for ever into the crystal depths of Loch Awe!

liberty. Thus that cheerful luminary not only distributes health and vegetation to the productions of the earth, but is ardently sought even by the gelid inhabitants of the water.

As fish are enemies one to another, so each species is infested with worms of different kinds peculiar to itself. The great fish abound with them; and the little ones are not entirely free. These troublesome vermin lodge themselves either in the jaws and the intestines internally, or near the fins without. When fish are healthy and fat they are not much annoyed by them; but in winter, when they are lean or sickly, they then suffer very much.

Nor does the reputed longevity of this class secure them from their peculiar disorders. They are not only affected by too much cold, but there are frequently certain dispositions of the element in which they reside unfavourable to their health and propagation. Some ponds they will not breed in, however artfully disposed for supplying them with fresh recruits of water, as well as provisions. In some seasons they are found to feel epidemic disorders, and are seen dead by the water side, without any apparent cause: yet still they are animals of all others the most vivacious, and they often live and subsist upon such substances as are poisonous to the more perfect classes of animated nature.

It is not easy to determine whether the poisonous qualities which many of them are found to possess, either when they wound our bodies externally with their spines, or when they are unwarily eaten at our tables, arises from this cause. That numbers of fishes inflict poisonous wounds, in the opinion of many, cannot be doubted. The concurrent testimony of mankind they think sufficient to contradict any reasonings upon this head, taken from anatomical inspection. The great pain that is felt from the sting given by the back fin of the weaver, bears no proportion to the smallness of the instrument that inflicts the wound. How the poison is preserved, or how it is conveyed by the animal, it is not in our power to perceive; but its actual existence has been often attested by painful experience. In this instance we must decline conjecture, satisfied with history.

The fact of their being poisonous when eaten, is equally notorious; and the cause equally inscrutable. My poor worthy friend, Dr Grainger, who resided for many years at St Christopher's, assured me, that of the fish caught, of the same kind, at one end of the island, some were the best and most wholesome in the world; while others taken at a different end were always dangerous, and most commonly fatal. We have a paper in the Philosophical Transactions, giving an account of the poisonous qualities of those found at New Providence, one of the Bahama islands. The author assures us, that the greatest part of the fish of that dreary coast are all of a deadly nature: their smallest effects being to bring on a terrible pain in the joints, which, if terminating favourably, leaves the patient without any appetite for several days after. It is not those of the most deformed figure, or the most frightful to look at, that are alone to be dreaded; all kinds, at different times, are alike dangerous; and the same species which has this day served for nourishment, is the next, if tried, found to be fatal!

This noxious quality has given rise to much speculation, and many conjectures. Some have supposed it to arise from the fishes on these shores eating of the manchineel apple, a deadly vegetable poison, that sometimes grows pendent over the sea; but the quantity of those trees growing in this manner, bears no proportion to the extensive infection of the fish. Labat has ascribed it to their eating the galley-fish, which is itself most potently poisonous: but this only removes our wonder a little farther back; for it may be asked, with as just a cause for curiosity, how comes the galley-fish itself to procure its noxious qualities? Others have ascribed the poison of these fishes to their feeding upon copperas-beds: but I do not know of any copper-mines found in America. In short, as we cannot describe the alembic by which the rattlesnake distils its malignity, nor the process by which the scorpion, that lives among roses, converts their sweets to venom, so we cannot discover the manner by which fishes become thus dangerous; and it is well for us of Europe that we can thus wonder in security. It is certain that with us, if fishes, such as carp or tench, acquire any disagreeable flavour from the lakes in which they have been bred, this can be removed, by their being kept some time in finer and better water: there they soon clear away all those disagreeable qualities their flesh had contracted, and become as delicate as if they had been always fed in the most cleanly manner. But this expedient is with us rather the precaution of luxury than the effect of fear: we have nothing to dread from the noxious qualities of our fish; for all the animals our waters furnish are wholesome.

Happy England! where the sea furnishes an abundant and luxurious repast, and the fresh waters an innocent and harmless pastime; where the angler, in cheerful solitude, strolls by the edge of the stream, and fears neither the coiled snake, nor the lurking crocodile; where he can retire at night, with his few trouts (to borrow the pretty description of old Walton) to some friendly cottage, where the

landlady is good, and the daughter innocent and beautiful; where the room is cleanly, with lavender in the sheets, and twenty ballads stuck about the wall! There he can enjoy the company of a talkative brother sportsman, have his trouts dressed for supper, tell tales, sing old tunes, or make a catch! There he can talk of the wonders of nature with learned admiration, or find some harmless sport to content him, and pass away a little time, without offence to God, or injury to man!

A

HISTORY OF FISHES.

BOOK IV.

OF CRUSTACEOUS AND TESTACEOUS FISHES.

CHAP. I.

THE DIVISION OF SHELL FISH.

In describing the inhabitants of the water, a class of animals occur, that mankind, from the place of their residence, have been content to call fish; but that naturalists, from their formation, have justly agreed to be unworthy of the name. Indeed the affinity many of this kind bear to the insect tribe, may very well plead for the historian who ranks them rather as insects. However, the common language of a country must not be slightly invaded; the names of things may remain, if the philosopher be careful to give precision to our ideas of them.

There are two classes of animals, therefore, inhabiting the water, which commonly receive the name of fishes, entirely different from those we have been describing, and also very distinct from each other. These are divided by naturalists into Crustaceous and Testaceous Animals; both, totally unlike fishes to appearance, seem to invert the order of nature; and as those have their bones on the inside, and their muscles hung upon them for the purposes of life and motion, these, on the contrary, have all their bony parts on the outside, and all their muscles within. Not to talk mysteriously—all who have seen a lobster or an oyster, perceive that the shell in these bears a strong analogy to the bones of other animals; and that, by these shells, the animal is sustained and defended.

Crustaceous fish, such as the crab and the lobster, have a shell not quite of a stony hardness, but rather resembling a firm crust, and in some measure capable of yielding.—Testaceous fishes, such as the oyster or cockle, are furnished with a shell of a stony hardness; very brittle, and incapable of yielding. Of the crustaceous kinds are the Lobster, the Crab, and the Tortoise: of the testaceous, that numerous tribe of Oysters, Mussels, Cockles, and Sea-Snails, which offer with infinite variety.

The crustaceous tribe[1] seems to hold the middle rank between fishes, properly so called, and those snail-like animals that receive the name of testaceous fishes. Their muscles are strong and firm, as in the former; their shell is self-produced, as among the latter. They have motion, and hunt for food with great avidity, like the former. They are incapable of swimming, but creep along the bottom, like the latter: in short, they form the link that unites these two classes, that seem so very opposite in their natures.

Of testaceous fishes we will speak hereafter. As to animals of the crustaceous kind, they are very numerous, their figure offers a hundred varieties: but as to their nature, they are obviously divided into two very distinct kinds, differing in their habits and their conformation.—The chief of one kind is the Lobster; the chief of the other, the Tortoise. Under the Lobster we rank the Prawn, the Cray-fish, the Shrimp, the Sea-Crab, the Land-Crab, and all their varieties. Under the Sea-Tortoise, the Turtle, the Hawksbill-Turtle, the Land-Tortoise, and their numerous varieties.

CHAP. II.

CRUSTACEOUS ANIMALS OF THE LOBSTER KIND.

However different in figure the lobster and the crab may seem, their manners and con-

[1] All the animals of this class are covered with inte-

formation are nearly the same. With all the voracious appetites of fishes, they are condemned to lead an insect life at the bottom of the water; and though pressed by continual hunger, they are often obliged to wait till accident brings them their prey. Though without any warmth in their bodies, or even without red blood circulating through their veins, they are animals wonderfully voracious. Whatever they seize upon that has life, is sure to perish, though never so well defended: they even devour each other; and to increase our surprise still more, they may, in some measure, be said to eat themselves; as they change their shell and their stomach every year, and their old stomach is generally the first morsel that serves to glut the new.

The *lobster* is an animal of so extraordinary a form, that those who first see it are apt to mistake the head for the tail; but it is soon

discovered that the animal moves with its claws foremost; and that the part which plays within itself by joints, like a coat of armour, is the tail. The two great claws are the lobster's instruments of provision and defence; these, by opening like a pair of nippers, have great strength, and take a firm hold; they are usually notched like a saw, which still more increases their tenacity. Beside these powerful instruments, which may be considered as arms, the lobster has eight legs, four on each side, and these, with the tail, serve to give the animal its progressive and sidling motion. Between the two claws is the animal's head, very small, and furnished with eyes that seem like two black horny specks on each side; and these it has a power of advancing out of the socket, and drawing in, at pleasure. The mouth, like that of insects, opens the long way of the body, not crossways, as with man, and the higher race of animals. It is furnished with two teeth for the comminution of its food; but, as these are not sufficient, it has three more in the stomach; one on each side, and the other below. Between the two teeth there is a fleshy substance, in the shape of a tongue. The intestines consist of one long bowel, which reaches from the mouth to the vent; but what this animal differs in from all others, is, that the spinal marrow is in the breast-bone. It is furnished with two long feelers or horns, that issue on each side of the head, that seem to correct the dimness of its sight, and apprize the animal of its danger, or of its prey. The tail, or that jointed instrument at the other end, is the grand instrument of motion; and with this it can raise itself in the water. Under this we usually see lodged the spawn in great abundance; every pea adhering to the next by a very fine filament, which is scarcely perceivable. Every lobster is an hermaphrodite and is supposed to be self-impregnated![1] The ovary, or place where the spawn is first produced, is backwards toward the tail, where a red substance is always found, and which is nothing but a cluster of peas, that are yet too small for exclusion. From this receptacle there go two canals, that open on each side at the jointures of the shell, at the belly; and through these passages the peas

guments of a crustaceous substance, more calcareous than that which envelopes the *myriapods*, the *arachnida*, and the *insects*. Most of them feed on bodies in a state of putrefaction, and in all the sexes are distinct.

[1] The animals of this tribe are by no means hermaphrodites, but are found distinctly male and female. The eggs are deposited under the tail of the females, which for that purpose is often much broader than that of the males. Amongst the numerous examples given by Dr Paley, of the wonderful manner in which Nature contrives to overcome difficulties, which would at first appear insurmountable, there is perhaps none more striking than the mode in which the lobster is released from his case when the increasing size of his body requires more room. In most animals the skin grows with their growth. In some animals, instead of a soft skin, there is a shell, which admits by its form of gradual enlargement. Thus the shell of the tortoise, which consists of several pieces, is gradually enlarged at the joinings of those pieces which are called "sutures." Shells with two sides, like those of the mussel, grow bigger by addition at the edge. Spiral shells, as those of the snail, receive this addition at their mouth. The simplicity of their form admits of this; but the lobster's shell being applied to the limbs of his body, as well as to the body itself, does not admit of either of the modes of enlargement which is observed in other shells. It is so hard that it cannot expand or stretch, and it is so complicated in its form that it does not admit of being enlarged by adding to its edge. How, then, was the growth of the lobster to be provided for? We have seen that room could not be made for him in his old shell: was he then to be annually fitted with a new one? If so, another difficulty arises: how was he to get out of his present confinement? How was he to open his hard coat, or draw his legs out of his boots which are become too tight for him? The works of the Deity are known by expedients, and the provisions of his power extend to the most desperate cases. The case of the lobster is thus provided for: At certain seasons his shell grows soft. The animal swells his body; the seams open, and the claws burst at the joints. When the shell is thus become loose upon the body, the animal makes a second effort, and by a trembling motion, a sort of spasm, casts off his case. In this state of nakedness the poor defenceless fish retires to a hole in the rocks. The released body makes a sudden growth. In about eight and forty hours a fresh concretion of humour takes place all over the surface of his body; it quickly hardens; and thus a new shell is formed, fitted in every part to the increased size of the body and limbs of the animal. See the subject fully handled by Mr Couch, in the following Note.

descend to be excluded, and placed under the tail, where the animal preserves them from danger for some time, until they come to maturity; when, being furnished with limbs and motion, they drop off into the water.

When the young lobsters leave the parent, they immediately seek for refuge in the smallest clefts of rocks, and in such like crevices at the bottom of the sea, where the entrance is but small, and the opening can be easily defended. There, without seeming to take any food, they grow larger in a few weeks' time, from the mere accidental substances which the water washes to their retreats. By this time, also, they acquire a hard firm shell, which furnishes them with both offensive and defensive armour. They then begin to issue from their fortresses, and boldly creep along the bottom, in hopes of meeting with more diminutive plunder. The spawn of fish, the smaller animals of their own kind, but chiefly the worms that keep at the bottom of the sea, supply them with plenty. They keep in this manner close among the rocks, busily employed in scratching up the sand with their claws for worms, or surprising such heedless animals as fall within their grasp: thus they have little to apprehend, except from each other; for in them, as among fishes, the large are the most formidable of all other enemies to the small.

But this life of abundance and security is soon to have a most dangerous interruption; for the body of the lobster still continuing to increase, while its shell remains unalterably the same, the animal becomes too large for its habitation, and, imprisoned within the crust that it has naturally gathered round it, there comes on a necessity of getting free. The young of this kind, therefore, that grow faster, as I am assured by the fishermen, change their shell oftener than the old, who come to their full growth, and who remain in the same shell often for two years together. In general however, all these animals change their shell once a-year; and this is not only a most painful operation, but also subjects them to every danger.[1] Moulting season is generally about the beginning of summer, at which time their food is in plenty, and their strength and vigour in the highest perfection. But soon all their activity ceases; they are seen forsaking the

[1] *Process of Exuviation in Shrimps, Lobsters, and Crabs.*—Dr Milne Edwards, in his Histoire Naturelle des Crustaces, has given an account of what may be considered the present state of our knowledge, of the circumstances under which the process of exuviation is effected, and the methods by which it is accomplished in the long-tailed stalk-eyed crustaceans; but as much of what that eminent naturalist advances is derived from other authorities, and I have reason to conclude, contrary to the general opinion, that the circumstances attending this process of nature, are different in even nearly allied species, there still remains space for inquiry.

Réaumur is our only original authority for the minute circumstances attending the process of exuviation, which he observed in the river crayfish (Potamobius fluviatilis, Leach,) but not having an opportunity of consulting that author's work, I copy his narrative from Dr M. Edwards's quotation: A few days previous to the commencement of the operations, the creature abstains from all solid nourishment, and the carapace and abdominal segments will be found to offer less than the usual resistance to the pressure of the finger. Shortly afterwards the crayfish appears restless, and rubs its legs against each other; it then throws itself on its back, agitates its whole body and then distends it, by which the membrane joining the carapace to the abdomen is burst, and this great dorsal plate is raised. Some degree of rest follows these first struggles; but after a short time the animal again puts all its organs in motion, the carapace is seen to rise gradually from the legs beneath, and in less than half an hour, the animal has extricated itself from this portion of its slough. By retracting its head, the antennæ, eyes, and legs are withdrawn as from a case; and the extrication of the last, being the most difficult and complicated operation, is attended with so much pain, that the effort sometimes occasions the loss of one or more of the organs. The hinder parts are withdrawn with less difficulty; the head is conducted below the carapace, and the tail being thrown off by a forward motion attended with a brisk and distensive action, the creature is seen divested of all its encumbrances, and the case is left unbroken, as if no struggle had ever taken place within it.

I have no doubt that the process here described in the cray-fish corresponds to what takes place in the common prawn (Palæmon serratus, Leach,) although I have never been able to observe it in operation:—the following is a description of the case from which the animal has recently extricated itself: The whole is thin, elastic and transparent; the carapace with its serrated process whole, the antennæ perfect to their minute extremities: the palpi and jaws drawn within the cavity of the thorax, and partially separated from the sternal plate; the latter with the legs still forming a loose attachment to each other, and without fracture, but drawn somewhat posteriorly into the thoracic cavity. The case and pedestal of one eye were within the thorax, but the other could not be found;—the legs perfect, and attached to the sternal plate. The caudal plates were united at their joints, but in no part was there any intervening membrane, this portion of the body not appearing to be thrown off with the more solid covering: a circumstance which will account for the fact, that the eyes do not long remain attached to the adjacent parts after the slough is left by its inhabitant.

The habits of the lobster (Astacus Europeus, Leach,) at this periodical crisis, and the circumstances attending it, present a very considerable difference from those of the species already mentioned. So far from abstaining from food, it is not uncommon for it to be taken in crab pots, which it has been enticed to enter by the allurement of the usual bait; and instances have been related to me, where, when the fishermen commenced to handle his capture, the animal has slipped away, leaving an empty husk as the only reward of his labour. It was by a circumstance somewhat similar that the opportunity is afforded me of giving a minute description of a very perfect case, left by the creature when it made its escape:—for escape it did, through an aperture too narrow to have allowed it to pass if its new covering had possessed a very moderate degree of firmness—to the no small annoyance of the fisherman, who had calculated on the possession of a prize somewhat above the ordinary magnitude. I cannot find that any extraordinary actions or contortions have been observed in the lobster, when

open parts of the deep, and seeking some retired situation among the rocks, or some outlet where they may remain in safety from the attacks of their various enemies. For some days before their change, the animal discontinues its usual voraciousness; it is no longer seen laboriously harrowing up the sand at the bottom, or fighting with others of its

engaged in delivering itself from its trammels, or that the time is prolonged, as is the case with the cray-fish; circumstances which are easily accounted for by an examination of the crust; and it is certain that when delivered it possesses great activity in effecting its escape, and that neither the prawn nor the lobster devour, as has been supposed, any portion of the old shell.

In the specimen referred to, the case of the antennæ and palpi was perfect to their minutest extremities; the stalk also, and transparent covering of the eyes, were uninjured, but the former was attached on its inferior portion only, the superior half hanging loose, so that it would soon have fallen away in the agitation of the sea. The segments and joints of the posterior portion of the body, with the caudal plates, were all joined together, but without any intervening membrane; and the inferior parts from beneath the snout, including the jaws and footjaws, chelædlegs, with the sternal plate, œsophagus and internal coat of the stomach, formed one connected portion, with no further separation than arises from the absence of every portion of membrane. The whole of these inferior portions was drawn very considerably within the carapace; and it was the latter section of the surface only that showed a mark of the manner in which the animal had delivered itself from its case; and this it did in a way not to be mistaken. Through the middle of this space, ran a line as straight as if it had been cut with a knife, and evidently formed by a natural process of separation: for it even proceeded through the centre of the snout, to the terminal pointed process, at the root of which it turned off on the right side; so that the least effort of the animal was sufficient to afford it a passage.

The observation here made on a very perfect specimen that came into my possession by great accident, has been further confirmed by a careful examination, both of the living lobster, in which an obscure line is perceptible, where the natural separation takes place: and also of a specimen of small size, in which the sloughing or natural process of division had only begun. In the latter case a deep channel had been formed on the external part, nearly half through the carapace; while the internal portion still remained firm; but I have little doubt that if the creature had lived but a few days longer, the separation would have been complete, and the animal would have escaped from its prison.

The growth of the young of the long-tailed Crustaceans, is well known to be exceedingly rapid; and there seems reason to believe that the process of exuviation is repeated at least two or three times in the course of the first year of their age. In the course of a summer, among many prawns one or two may always be found in a state that indicates the having lately passed through this process; but about October or November they all seem to undergo it at once, the breeding season finishes, and no further change in the shell takes place until the approach of the spring. It is not improbable that the general opinion is correct, which limits the exuviation of the adult animals to once in the year; but from the marks of old injuries, and the incrustation of parasitic animals, I have come to the conclusion that in advanced age the lobster does not throw off its case with any regularity, and perhaps not at all.

When about to throw off its exuviæ the crab commonly retires to some secret place, in the near neighbourhood of rocks that will afford it shelter when unable to escape from danger, or defend itself from enemies. Its craving appetite seems also at this time to be suspended; but the particular subject of my observation

differed from others, in wandering into a crab-pot at this period, in search of food; and being known by the fishermen to be what is called *peel*, that is, about to throw off its crust, it was transferred to the safe custody of the store-pot, on Saturday, July 30th, where, on the morning of August 1, it was found just then delivered from its covering. As quickly as possible, and without injury, the living crab and its empty representative were brought to me: and the following is a description of the exuviæ.

The longest diameter of the carapace was 6¾ inches; compass of the largest chela, and length of the flap or tail, severally 3¾ inches: the individual a female, or what is termed by fishermen a Bon Crab. The carapace was sound, except on its under surface, where in its ordinary state a curved line passes backward from the jaws to the hinder part of the body. When caught on the 30th this portion was observed by the fishermen to be loosened; and now the portion included between this waved line and the sternal plate, was entirely separate and fallen inward. The sheaths of the antennæ and palpi perfect; one eye gone, the other remaining, with the transparent covering perfect, the stalk loosely attached; the tail and all its appendages perfect; the sternal plate beginning to break across in the middle, leaving to each portion a pair of legs on each side; but this not being a complete or natural separation, may have been produced by the weight of the limbs alone, or the efforts of the animal. The chelæ and legs perfect in all their attachments, the membranes unbroken; and the flat bones which occupy the middle of the muscles and serve them for tendons or points of attachment for motion, were uninjured and fastened to each joint, their distant extremities hanging loosely in the cavity of the case of the limb. The coverings of the branchiæ were perfect to their minutest extremities; and besides the internal coat of the stomach, the whole internal skeleton of the animal was thrown off without fracture or displacement:—including the two motive bones or levers that pass through the middle of the body from the jaws, to be attached to the internal dorsal aspect of the carapace: where formerly attached, however, to the carapace they hung loose. The curious bony articulations of the grinding apparatus of the stomach, which renders the digestion of these Crustaceans analogous to the rumination of quadrupeds, together with the double crustaceous body (perhaps gland) at the pyloric orifice, and the whole of the bony crusts or chambers that receive the muscles which move the legs, were disengaged with displacement.

The living representative of this wonderful skeleton measured 7½ inches in its longest diameter, the compass of the largest chela, and length of the flap or tail, 4 inches; the weight 24½ ounces, being 5½ ounces less than an ordinary crab of the same dimensions, weighed with it for comparison. It was plump, having much the appearance of a lump of dough enclosed in a membrane; and it was also equally soft, with scarcely more power of motion: appearing sensitive only when pressed on the under surface of the carapace. The colour above was red, beneath a pale yellow, the flap purplish; the bristles on the legs fully formed, but soft, which is the more worthy of notice, as I have seen the Procellana platycheles, in which villosity forms a conspicuous character, entirely naked when just escaped from the crust. On cutting open the legs and chelæ, the bony plates to which the muscles are attached, and which serve for tendons, were found as soft as wet parchment, and towards the extreme joints, could not be distinguished with certainty. On breaking off the largest chela at the

kind, or hunting its prey; it lies torpid and motionless, as if in anxious expectation of the approaching change. Just before casting its shell, it throws itself upon its back, strikes its claws against each other, and every limb seems to tremble; its feelers are agitated, and the whole body is in violent motion; it then swells itself in an unusual manner, and at last the shell is seen beginning to divide at its junctures; particularly, it opens at the junctures of the belly, where, like a pair of jumps, it was before but seemingly united. It also seems turned inside out, and its stomach comes away with its shell.—After this, by the same operation, it disengages itself of the claws, which burst at the joints; the animal, with a tremulous motion, casting them off as a man would kick off a boot that was too big for him.

Thus, in a short time, this wonderful creature finds itself at liberty, but in so weak and enfeebled a state, that it continues for several hours motionless. Indeed, so violent and painful is the operation, that many of them die under it; and those which survive are in such a weakly state for some time, that they neither take food nor venture from their retreats. Immediately after this change, they have not only the softness but the timidity of a worm. Every animal of the deep is then a powerful enemy, which they can neither escape nor oppose; and this, in fact, is the time when the dog-fish, the cod, and the ray, devour them by hundreds. But this state of defenceless imbecility continues for a very short time: the animal, in less than two days, is seen to have the skin that covered its body grown almost as hard as before; its appetite is seen to increase; and, strange to behold! the first object that tempts its gluttony, is its own stomach, which it so lately was disengaged from. This it devours with great eagerness; and some time after eats even its former shell. In about forty-eight hours, in proportion to the animal's health and strength, the new shell is perfectly formed, and as hard as that which was but just thrown aside.

To contribute to the speedy growth of the shell, it is supposed by some, that the lobster is supplied with a very extraordinary concretion within its body, that is converted into the shelly substance. It is a chalky substance, found in the lower part of the stomach of all lobsters, improperly called crabs' eyes, and

---

joint where the animal is itself accustomed to separate it when injured, the usual membrane formed towards the body, and no discharge took place; but a watery fluid proceeded copiously from the surface towards the limb, which was thus soon left empty, speedily becoming capable of being blown up with air like a bladder. On proceeding to dissect the body a similar circumstance took place, the fluid running off in so large a quantity, that I regretted when too late, that I had not taken the precaution to have measured it. In a few minutes, the body had so sunk into one mass that I was unable to distinguish the separate parts. At the lower and inner part of each joint of the chelæ and legs, an opening remained, in the form of a slit; through which the flat central bony plate, found in the empty crust, had been withdrawn; which opening of course must be closed when the shell is finally consolidated.

It appears from close inspection, that the exuviæ of a lobster consists of the same parts as those of a crab; the whole internal skeleton and external surface of the branchiæ, with the osseous tendons of the muscles, having been rejected. But they are more distinctly ascertained in the latter species, from their greater firmness of texture; and I may add also in reference to myself, that a desire to preserve the specimen perfect, had in the former case prevented a very minute examination of the internal structure.

Having procured a crab that was beginning to show signs of a commencement of the process of exuviation, I found the limbs shrunk to three-fourths of what the shell could well contain; the soft contents of the points of the chelæ being diminished much more than the muscular structure. A greater diminution than this, however, takes place before the process of deliverance is accomplished; but all the vigilance that I have exerted has not enabled me to see the actual escape from the crust; which is usually left in some void place, often in a sandy basin, and, as several fishermen have informed me, always on its back; as the living specimen I have described is represented also to have been found in the store-pot.

The newly extricated crab has at first strength enough to crawl off to a place of safety, commonly beneath the shelter of a neighbouring crevice, of such limited dimensions at its entrance, that it seems surprising it should ever be able to return from it, in its new state of growth. The first instinct of nature after securing a place of retreat, is to absorb, I suppose by swallowing it, as much fluid as will distend its organs and their common covering, now as flexible as velvet, to the full extent of their capacity; by which means the deposition of crustaceous particles is made according to the dimensions of its newly acquired bulk: which in the instance now described, that had arrived at the ordinary size of a female, and allowing for the thickness of the first crust, exceeded the former by at least an inch in its longest diameter, and in all its dimensions in the same proportion. In the early stages of growth, the increase of bulk at exuviation is, of course, much more considerable, in relative proportion. Some of these smaller specimens may be found passing through this natural process in every month of the year; but in some adult individuals, the same crust must continue for a long time, since I have seen one with oysters measuring two inches and a half in length, on the carapace; and in another, a mussel (mytilus) about an inch in length, attached by its byssus to a joint near the body.

Whether, as has been said, the rejected case forms a meal for its old inhabitant, on its first return to habits of activity, may well be questioned; though I have known an instance where one crab has devoured another, leaving nothing but the points of the legs, and a small portion of the carapace;—but in the analogous instance of a prawn, that had just thrown off its exuviæ, I have detected the source of the firmness of the new covering, in the presence of small shell-fish in its stomach. Under a lens, a minute trochus, perhaps the T. zizyphinus, and some specimens of an oval bivalve, were distinguishable. This is perhaps the only period of their lives when their food is of this kind, but its nature cannot often be ascertained, by the comminution it undergoes from the manner in which it is devoured, when the jaws have attained their firmness.—*From two communications by Mr Couch in the Magazine of Zoology and Botany.*

sold under that title in the shops. About the time the lobster quits its shell, the teeth in its stomach break these stones to pieces, and the fluids contained therein dissolve them. This fluid, which still remains in the new stomach, is thought to be replete with a petrifying quality, proper for forming a new shell: however, the concreting power that first formed these, shows a sufficient power in the animal to produce also the shell; and it is going but a short way in the causes of things when we attempt to explain one wonder by another.

When the lobster is completely equipped in its new shell, it then appears how much it has grown in the space of a few days; the dimensions of the old shell being compared with those of the new, it will be found that the creature is increased above a third in its size; and, like a boy that has outgrown his clothes, it seems wonderful how the deserted shell was able to contain so great an animal as entirely fills up the new.

The creature thus furnished, not only with a complete covering, but also a greater share of strength and courage, ventures more boldly among the animals of the bottom; and not a week passes, that, in its combats, it does not suffer some mutilation. A joint, or even a whole claw, is sometimes snapped off in these encounters. At certain seasons of the year these animals never meet each other without an engagement. In these, to come off with the loss of a leg, or even a claw, is considered as no great calamity; the victor carries off the spoil to feast upon at leisure, while the other retires from the defeat to wait for a thorough repair. This repair it is not long in procuring. From the place where the joint of the claw was cut away, is seen in a most surprising manner to burgeon out the beginning of a new claw. This, if observed at first, is small and tender, but grows, in the space of three weeks, to be almost as large and as powerful as the old one. I say almost as large, for it never arrives to the full size; and this is the reason we generally find the claws of lobsters of unequal magnitude.[1]

After what has been thus described, let us pause a little, to reflect on the wonders this extraordinary creature offers to our imagination! An animal without bones on the inside, yet furnished with a stomach capable of digesting the hardest substances, the shells of muscels, of oysters, and even its own; an animal gaining a new stomach and a new shell at stated intervals! furnished with the instruments of generation double in both sexes; and yet with an apparent incapacity of uniting! without red blood circulating through the body, and yet apparently vigorous and active! but, most strange of all, an animal endowed with a vital principle that furnishes out such limbs as have been cut away; and keeps continually combating it, though in constant repair to renew its engagements! These are but a small part of the wonders of the deep, where nature sports without a spectator!

Of this extraordinary yet well-known animal there are many varieties, with some differences in the claws, but little in the habits or conformation.[2] It is found above three feet long; and if we may admit the shrimp and the prawn into the class, though unfurnished with claws, it is seen not above an inch. These all live in the water, and can bear its absence for but a few hours. The shell is black when taken out of the water, but turns red by boiling. The most common way of taking the lobster is in a basket, or pot, as the fishermen call it, made of wicker-work, in which they put the bait, and then throw it to the bottom of the sea, in six or ten fathom water. The lobsters creep into this for the sake of the bait, but are not able to get out again. The river cray-fish[3] differs little from

[1] In the water, these animals are able to run nimbly upon their legs or small claws; and, if alarmed, they can spring, tail foremost, to a surprising distance almost as swiftly as a bird can fly.

[2] The *Norway Lobster*.—It has generally eight legs, besides two claspers, with six unequal feelers; two eyes, commonly distant, placed on fast stakes, and movable; the tail is articulated and unarmed. The body is long, with the thorax aculeated forwards; and prismatic arms, with the angles spiny. This species is nearly equal in size to the common lobster, and is principally found in the northern ocean. It also inhabits Great Britain.

The *Prawn*.—Prawns have a long serrated snout, bending upwards; three pair of very long filiform feelers; claws small, furnished with two fangs; smooth thorax; five joints to the tail; middle caudal fin subulated, two outmost flat and rounded. It is frequent in several shores among loose stones; sometimes found at sea, and taken on the surface over thirty fathoms depth of water: cinereous when fresh, and of a fine red when boiled.

The *Shrimp*.—Shrimps possess long slender feelers, and between them two projective laminæ; the claws have a single-hooked movable fang; they have three pair of legs; seven joints in the tail; the middle caudal fin subulated, the four others round and fringed; a spine on the exterior side of each of the outmost. These animals inhabit the shores of Britain in vast quantities, and are the most delicious of the genus.

The *Squilla*.—This has a snout like a prawn, but deeper and thinner; the feelers longer in proportion to the bulk; the sub-caudal fins rather larger. This animal is, at full growth, not above the bulk of the shrimp. The squilla inhabits the coast of Kent, and is sold in London under the name of the white shrimp, as it assumes that colour when boiled.

[3] *Cray* or *Craw fish*.—This species of lobster has a projecting snout, slightly serrated on the sides; a smooth thorax; the back smooth, with two small spines on each side; the claws large, beset with small tubercles; the two first pair of legs clawed, the two next subulated; the tail consists of five joints; and the caudal fins are rounded. The flesh of the craw-fish is cooling, moistening, and adapted to nourish such as labour under con-

the lobster, but that the one will live only in fresh water, and the other will thrive only in the sea.

The *crab* is an animal found equally in fresh and salt water; as well upon land as in the ocean. In shape it differs very much from

the lobster, but entirely resembles it in habits and conformation. The tail in this animal is not so apparent as in the former, being that broad flap that seems to cover a part of the belly, and when lifted discovers the peas or spawn, situated there in great abundance. It resembles the lobster in the number of its claws, which are two; and its legs, which are eight, four on either side. Like the lobster, it is a bold voracious animal; and such an enmity do crabs bear each other, that those who carry them for sale to market, often tie their claws with strings to prevent their fighting and maiming themselves by the way. In short, it resembles the lobster in every thing but the amazing bulk of its body compared to the size of its head, and the length of its intestines, which have many convolutions.

As the crab, however, is found upon land as well as in water, the peculiarity of its situation produces a difference in its habitudes, which it is proper to describe. The Land Crab is found in some of the warmer regions of Europe, and in great abundance in all the tropical climates in Africa and America. They are of various kinds, and endued with

---

sumptions. Though they are variously dressed, yet no parts of them are eatable except their claws and tails. Soups are frequently made of them.

There are great quantities of these fish in the river Obra, on the borders of Silesia; but the people find them scarcely eatable, because of a bitter aromatic flavour, very disagreeable in food. Craw-fish also abound in the river Don, in Muscovy, where they are laid in heaps to putrefy, after which the stones called crab's eyes are picked out. These animals are very greedy of flesh, and flock in great numbers about carcases thrown in the water where they are, and never leave them while any remains: they also feed on dead frogs when they come in their way. In Switzerland there are some craw-fish which are red when they are alive, and others bluish. Some kinds of them also will never become red, even by boiling, but continue blackish.

Craw-fish are found in many of our rivers lodged in holes which they form in the clayey banks; and their presence is generally esteemed an evidence of the goodness of the water. They are frequently taken by means of sticks, split at the end, with a bait inserted in the cleft, and stuck in the mud at the distance of a few feet from each other. These sticks, after remaining some time, are taken up, generally with an animal adhering to each. They are gently drawn out of the mud, and a basket is put under them, to receive the animals which always drop off when brought to the surface of the water.

---

[2] Who would expect an animal so low in the scale of creation as a *crab*, to be furnished with ten or twelve pair of jaws to its mouth? Yet such is the fact; and all these variously constructed pieces are provided with appropriate muscles, and move in a manner which can scarcely be explained, though it may be very readily comprehended when once observed in living nature. But after all the complexity of the jaws, where would an inexperienced person look for their teeth? surely not in the stomach? Nevertheless, such is their situation; and these are not mere appendages, that are called teeth by courtesy, but stout regular grinding teeth, with a light brown surface. They are not only within the stomach, but fixed to a cartilage nearest to its lower extremity, so that the food, unlike that of other creatures, is submitted to the action of the teeth as it is passing *from* the stomach, instead of being chewed before it is swallowed. In some species the teeth are five in number; but throughout this class of animals the same general principle of construction may be observed. Crabs and their kindred have no brain, because they are not required to reason upon what they observe; they have a nervous system excellently suited to their mode of life, and its knots or ganglia send out nerves to the organs of sense, digestion, motion, &c. The senses of these beings are very acute, especially their sight, hearing, and smell. Most of my readers have heard of crab's eyes, or have seen these organs in the animal on the end of two little projecting knobs, above and on each side of the mouth; few of them, however, have seen the crab's ear; yet it is very easily found, and is a little triangular bump placed near the base of the feelers. This bump has a membrane stretched over it, and communicates with a small cavity, which is the internal ear. The *organ* of smell is not so easily demonstrated as that of hearing, though the evidence of their possessing the sense to an acute degree is readily attainable.

The greater proportion of the genera feed on animal matter, especially after decomposition has begun; a large number are exclusively confined to the deep waters, and approach the shoals and lands only during the spawning season. Many live in the sea, but daily pass many hours upon the rocky shores for the pleasure of basking in the sun; others live in marshy or moist ground, at a considerable distance from the water, and feed principally on vegetable food, especially the sugar cane, of which they are extremely destructive. Others again reside habitually on the hills or mountains, and visit the sea only once a year, for the purpose of depositing their eggs in the sand. All those which reside in burrows made in moist ground, and those coming daily on the rocks to bask in the sun, participate in about an equal degree in the qualities of vigilance and swiftness. Many a breathless race have I run in vain, attempting to intercept them, and prevent their escaping into the sea. Many an hour of cautious and solicitous endeavour to steal upon them unobserved, has been frustrated by their long-sighted watchfulness; and several times, when, by extreme care and cunning approaches, I have actually succeeded in getting between a fine specimen and the sea, and had full hope of driving them farther inland, have all my anticipations been ruined by the wonderful swiftness of their flight, or the surprising facility with which they would dart off in the very opposite direction, at the very moment I felt almost sure of my prize.

The fleet-running crab (*Cypoda pugilator*), mentioned as living in burrows dug in a moist soil, and preying chiefly on the sugar cane, is justly regarded as one of the

various properties; some being healthful, delicious, and nourishing food; others, poisonous or malignant to the last degree; some are not above half an inch broad, others are found a foot over; some are of a dirty brown, and others beautifully mottled. That animal called the Violet Crab of the Caribbee islands, is the most noted, both for its shape, the deli-

---

most noxious pests that can infest a plantation. Their burrows extend to a great depth, and run in various directions; they are also, like those of our fiddlers, nearly full of muddy water; so that, when these marauders once plump into their dens, they must be considered as entirely beyond pursuit. They are so numerous, and they multiply in such numbers, as in some seasons to destroy a large proportion of a sugar crop, and sometimes their ravages, combined with those of the rats and other plunderers, are absolutely ruinous to the sea-side planters. I was shown, by the superintendent of a place thus infested, a great quantity of cane utterly killed by these creatures, which cut it off in a peculiar manner, in order to suck the juice; and he assured me that, during that season, the crop would be two-thirds less than its average, solely owing to the inroads of the crabs and rats, which, if possible, are still more numerous. It was to me an irresistible source of amusement to observe the air of spite and vexation with which he spoke of the crabs; the rats he could shoot, poison, or drive off for a time with dogs. But the crabs would not eat his poison while sugar cane was growing; the dogs could only chase them into their holes; and if, in helpless irritation, he sometimes fired his gun at a cluster of them, the shot only rattled over their shells like hail against a window. It is truly desirable that some summary mode of lessening their number could be devised, and it is probable that this will be best effected by poison, as it may be possible to obtain a bait sufficiently attractive to ensnare them. Species of this genus are found in various parts of our country, more especially towards the south. About Cape May, our friends may have excellent opportunities of testing the truth of what is said of their swiftness and vigilance.

The *land crab*, which is common to many of the West India islands, is more generally known as the *Jamaica crab*, because it has been most frequently described from observation in that island. Wherever found, they have all the habit of living, during great part of the year, in the highlands, where they pass the daytime concealed in huts, cavities, and under stones, and come out at night for their food. They are remarkable for collecting in vast bodies, and marching annually to the sea-side, in order to deposit their eggs in the sand; and this accomplished, they return to their former abodes, if undisturbed. They commence their march in the night, and move in the most direct line towards the destined point. So obstinately do they pursue this route, that they will not turn out of it for any obstacle that can possibly be surmounted. During the daytime, they skulk and lie hid as closely as possible, but thousands upon thousands of them are taken for the use of the table by whites and blacks, as on their seaward march they are very fat and of fine flavour. On the homeward journey, those that have escaped capture are weak, exhausted, and unfit for use. Before dismissing the crabs, I must mention one which was a source of much annoyance to me at first, and of considerable interest afterwards, from the observation of its habits. At that time I resided in a house situated about two hundred yards from the sea, fronting the setting sun, having in clear weather the lofty mountains of Porto Rico in view, distant about eighty miles. Like most of the houses in the island, ours had seen better days, as was evident from various breaks in the floors, angles rotted off the doors, sunken sills, and other indications of decay. Our sleeping room, which was on the lower floor, was especially in this condition; but as the weather was delightfully warm, a few cracks and openings, though rather large, did not threaten much inconvenience. Our bed was provided with that indispensable accompaniment, a mosquito bar or curtain, to which we were indebted for escape from various annoyances. Scarcely had we extinguished the light, and composed ourselves to rest, than we heard, in various parts of the room, the most startling noises. It appeared as if numerous hard and heavy bodies were trailed along the floor; they then sounded as if climbing up the chairs and other furniture, and frequently something like a large stone would tumble down from such elevations with a loud noise, followed by a peculiar chirping noise. What an effect this produced upon entirely inexperienced strangers, may well be imagined by those who have been suddenly waked up in the dark, by some unaccountable noise in the room. Finally, these invaders began to ascend the bed; but happily the musquito bar was securely tucked under the bed all around, and they were denied access, though their efforts and tumbles to the floor produced no very comfortable reflections. Towards daylight they began to retire, and in the morning no trace of any such visitants could be perceived. On mentioning our troubles, we were told that this nocturnal disturber was only Bernard the Hermit, called generally the soldier crab, perhaps from the peculiar habit he has of protecting his body by thrusting it into an empty shell, which he afterwards carries about, until he outgrows it, when it is relinquished for a larger. Not choosing to pass another night quite so noisily, due care was taken to exclude Monsieur Bernard, whose knockings were thenceforward confined to the outside of the house. I baited a large wire rat-trap with some corn meal, and placed it outside of the back door, and in the morning found it literally half filled with these crabs, from the largest sized shell that could enter the trap, down to such as were not larger than a hickory nut. Here was a fine collection made at once, affording a very considerable variety in the size and age of the specimens, and the different shells into which they had introduced themselves.

The *soldier*, or *hermit* crab, when withdrawn from his adopted shell, presents about the head and claws a considerable family resemblance to the lobster. The claws, however, are very short and broad, and the body covered with hard shell only in that part which is liable to be exposed or protruded. The posterior or abdominal part of the body is covered only by a tough skin, and tapers towards a small extremity, furnished with a sort of hook-like apparatus, enabling it to hold on to its factitious dwelling. Along the surface of its abdomen, as well as on the back, there are small projections, apparently intended for the same purpose. When once fairly in possession of a shell, it would be quite a difficult matter to pull the crab out, though a very little heat applied to the shell will quickly induce him to leave it. The shells they select are taken solely with reference to their suitableness, and hence you may catch a considerable number of the same species, each of which is in a different species or genus of shell. The shells commonly used by them, when of larger size, are those of the whilk, which are much used as an article of food by the islanders, or the smaller conch (strombus) shells. The very young hermit crabs are found in almost every variety of small shell found on the shores of the Antilles. I have frequently been amused by ladies eagerly engaged in making collections of these beautiful little shells, and not dreaming of their being tenanted by a living animal, suddenly startled, on displaying their acquisitions, by observing

cacy of its flesh and the singularity of its manners.

The Violet Crab somewhat resembles two hands cut through the middle and joined together; for each side looks like four fingers, and the two nippers or claws resemble the thumbs. All the rest of the body is covered with a shell as large as a man's hand, and bunched in the middle, on the fore part of which there are two long eyes of the size of a grain of barley, as transparent as crystal, and as hard as horn. A little below these is the mouth, covered with a sort of barbs, under which there are two broad sharp teeth as white as snow. They are not placed, as in other animals, crossways, but in the opposite direction, not much unlike the blades of a pair of scissars. With these teeth they can easily cut leaves, fruits, and rotten wood, which is their usual food. But their principal instrument for cutting and seizing their food is their nippers, which catch such a hold, that the animal loses the limb sooner than its grasp, and is often seen scampering off, having left its claw still holding fast upon the enemy. The faithful claw seems to perform its duty, and keeps for above a minute fastened upon the finger while the crab is making off. In fact, it loses no great matter by leaving a leg or an arm, for they soon grow again, and the animal is found as perfect as before.[1]

This, however, is the least surprising part of this creature's history; and what I am going to relate, were it not as well known and as confidently confirmed as any other circumstance in natural history, it might well stagger our belief. These animals live not only in a kind of orderly society in their retreats in the mountains, but regularly once a year march down to the sea-side in a body of some millions at a time. As they multiply in great numbers, they choose the months of April or May to begin their expedition; and then sally out by thousands from the stumps of hollow trees, from the clefts of the rocks, and from the holes which they dig for themselves under the surface of the earth. At that time the whole ground is covered with this band of adventurers; there is no setting down one's foot without treading upon them.[2] The sea is their place of destination, and to that they direct their march with right-lined precision. No geometrician could send them to their destined station by a shorter course; they neither turn to the right or left, whatever obstacles intervene; and even if they meet with a house, they will attempt to scale the walls to keep the unbroken tenor of their way. But though this be the general order of their rout, they upon other occasions are compelled to conform to the face of the country; and if it be intersected by rivers, they are then seen to wind along the course of the stream. The procession sets forward from the mountains with the regularity of an army, under the guidance of an experienced commander. They are commonly divided into three battalions; of which the first consists of the strongest and boldest males, that, like pioneers, march forward to clear the route, and face the greatest dangers. These are often obliged to halt for want of rain, and go into the most convenient encampment till the weather changes. The main body of the army is composed of females, which never leave the mountains till the rain is set in for some time, and then descend in regular battalia, being formed into columns of fifty paces broad and three miles deep, and so close that they almost cover the ground. Three or four days after this the rear-guard follows; a straggling undisciplined tribe consisting of males and females, but neither so robust nor so numerous as the former. The night is their chief time of proceeding; but if it rains by day, they do not fail to profit by the occasion; and they

---

them to be actively endeavouring to escape; or on introducing the hand into the reticule to produce a particular fine specimen, to receive a smart pinch from the claws of the little hermit. The aquatic soldiers may be seen towing along shells of most disproportionate size; but their relatives, who travel over the hills by moonlight, know that all unnecessary encumbrance of weight should be avoided. They are as pugnacious and spiteful as any of the crustaceous class; and when taken, or when they fall and jar themselves considerably, utter a chirping noise, which is evidently an angry expression. They are ever ready to bite with their claws, and the pinch of the larger individuals is quite painful. It is said that when they are changing their shells for the sake of obtaining more commodious coverings, they frequently fight for possession, which may be true where two that have forsaken their old shells meet, or happen to make choice of the same vacant one.—*Rambles of a Naturalist, by John D. Godman, M. D. United States.*

[1] The skeleton of the crab is external. Each side is provided with four legs and a hand. The latter is divided at the extremity into two parts, resembling the notched jaws of a pair of pincers. One of these parts is movable and the other is not. The feet are furnished with bristles. The senses of the crab are not deficient in acuteness. The sense of smell is not wanting, though it is not yet known where that organ is seated. The powers of vision are lively, and are the result of a complex structure, while the organ of hearing, placed near the base of the antennæ, is doubtless in every respect adapted to its necessities. It is generally difficult to surprise land-crabs; their acuteness of sight or hearing, or perhaps both, being soon alarmed. The antennæ are the organs of touch. The crab has no tongue, but possesses the organ of taste. It is a voracious feeder, and not very delicate in its choice. The mouth is furnished with eight pieces or pairs of jaws; and grinding teeth are attached to a cartilaginous appendage in the stomach, where the process of mastication is completed. Hence the crab is said to be a ruminating animal. The liver is very large, and is considered by epicures as a delicious morsel. The blood is either colourless or has a slight blue tinge.

[2] Labat. Voyage aux Isle Françoises, vol. ii. p. 221.

continue to move forward in their slow uniform manner. When the sun shines and is hot upon the surface of the ground, they then make a universal halt, and wait till the cool of the evening. When they are terrified, they march back in a confused disorderly manner, holding up their nippers, with which they sometimes tear off a piece of the skin, and then leave the weapon where they inflicted the wound. They even try to intimidate their enemies; for they often clatter their nippers together, as if it were to threaten those that come to disturb them. But though they must strive to be formidable to man, they are much more so to each other; for they are possessed of one most unsocial property, which is, that if any of them by accident is maimed in such a manner as to be incapable of proceeding, the rest fall upon and devour it on the spot, and then pursue their journey.

When after a fatiguing march, and escaping a thousand dangers, (for they are sometimes three months in getting to the shore,) they have arrived at their destined port, they prepare to cast their spawn. The peas are as yet within their bodies, and not excluded, as is usual in animals of this kind, under the tail; for the creature waits for the benefit of the sea-water to help the delivery. For this purpose, the crab has no sooner reached the shore, than it eagerly goes to the edge of the water, and lets the waves wash over its body two or three times. This seems only a preparation for bringing their spawn to maturity; for without farther delay they withdraw to seek a lodging upon land: in the mean time the spawn grows larger, is excluded out of the body, and sticks to the barbs under the flap, or more properly the tail. This bunch is seen as big as a hen's egg, and exactly resembling the roes of herrings. In this state of pregnancy, they once more seek the shore for the last time, and shaking off their spawn into the water, leave accident to bring it to maturity. At this time whole shoals of hungry fish are at the shore, in expectation of this annual supply; the sea to a great distance seems black with them; and about two-thirds of the crabs' eggs are immediately devoured by those rapacious invaders. The eggs that escape are hatched under the sand; and soon after millions at a time of these little crabs are seen quitting the shore, and slowly travelling up to the mountains.

The old ones, however, are not so active to return; they have become so feeble and lean, that they can hardly creep along, and the flesh at that time changes its colour. The most of them, therefore, are obliged to continue in the flat parts of the country till they recover, making holes in the earth, which they cover at the mouth with leaves and dirt, so that no air may enter. There they throw off their old shells, which they leave as it were quite whole, the place where they opened on the belly being unseen. At that time they are quite naked, and almost without motion for six days together, when they become so fat as to be delicious food. They have then under their stomachs four large white stones, which gradually decrease in proportion as the shell hardens, and when they come to perfection are not to be found. It is at that time that the animal is seen slowly making its way back; and all this is most commonly performed in the space of six weeks.

This animal, when possessed of its retreats in the mountains, is impregnable; for only subsisting upon vegetables, it seldom ventures out; and its habitation being in the most inaccessible places, it remains for a great part of the season in perfect security. It is only when impelled by the desire of bringing forth its young, and when compelled to descend into the flat country, that it is taken. At that time the natives wait for its descent in eager expectation, and destroy thousands: but disregarding the bodies, they only seek for that small spawn which lies on each side of the stomach within the shell; of about the thickness of a man's thumb. They are much more valuable upon their return, after they have cast their shell; for being covered with a skin resembling soft parchment, almost every part except their stomach may be eaten. They are taken in their holes by feeling for them in the ground with an instrument: they are sought after by night, when on their journey, with flambeaux. The instant the animal perceives itself attacked, it throws itself on its back, and with its claws pinches most terribly whatever it happens to fasten on. But the dexterous crab-catcher takes them by the hinder legs in such a manner, that its nippers cannot touch him, and thus he throws it into his bag. Sometimes also they are caught when they take refuge at the bottom of holes, in rocks by the sea-side, by clapping a stick at the mouth of the hole, which prevents their getting out; and then soon after the tide coming, enters the hole, and the animal is found, upon its retiring, drowned in its retreat. [1]

[1] There are various modes of taking crabs—some extremely simple, and others on a larger and more complex scale for commercial purposes. In the West Indies the monkeys adopt an ingenious expedient for catching crabs. They insert their tails in the holes where the crabs take refuge, and the crab fastening upon it, the monkey withdraws his tail with a jerk, and then conveys his prey on shore. By what expedient the crab is induced to release its hold we are not informed, but this must be no easy matter, as it grasps whatever it seizes in its claws with remarkable tenacity. Several species of birds, which occasionally live on shell-fish, obtain the meat out of the shell by dropping the shell from a considerable height;

These crabs are of considerable advantage to the natives; and the slaves very often feed entirely upon them. In Jamaica, where they are found in great plenty, they are considered as one of the greatest delicacies of the place. Yet still, the eating of them is attended with some danger; for even of this kind many are found poisonous, being fed, as it is thought, upon the manchineel apple; and whenever they are found under that noxious plant, they are always rejected with caution. It is thus with almost all the productions of those luxurious climates; however tempting they may be to the appetite, they but too often are found destructive; and scarce a delicacy among them that does not carry its own alloy.

The descent of these creatures for such important purposes, deserves our admiration; but there is an animal of the lobster kind that annually descends from its mountains in like manner, and for purposes still more important and various. Its descent is not only to produce

---

and the monkeys are probably not less ingenious in their devices. Brickell gives an interesting account, in his *History of North Carolina* of the wonderful cunning manifested by the racoon in that country. It is fond of crabs, and, when in quest of them, will take its station by a swamp, and hang its tail over into the water, which the crabs mistake for food, and lay hold of it; as soon as the racoon feels them pinch, he pulls up his tail with a sudden jerk, and they generally quit their hold upon being removed from the water. The racoon instantly seizes the crabs in his mouth, removes them to a distance from the water, and greedily devours his prey. He is very careful how he takes them up, which he always does from behind, holding them transversely, in order to prevent them catching his mouth with their nippers. The children of fishermen are often employed in crab-catching, as crabs are found on a rocky beach at low water, hidden in crevices and under stones. A stick, with a hook at the end of it, is inserted in their retreat, and the crab, instantly grasping it, is drawn out. But only a small number, and those not of the finest sort, are taken in this manner, as the largest and strongest crabs betake themselves to the sea on the ebbing of the tide. On a shore which is rugged, and abounding in cavities which afford it a hiding place, the crab is also taken on a small scale by another method. At the spot where they are most numerous, the fisherman places a bait at the end of a small cord, at the other end of which a stone is tied. When the tide flows the crab seizes the bait, which it drags to some hole, and the stone, which it draws after it, closes the entrance. As a stone may be dragged in the water, which cannot be moved by the same power exerted in a less advantageous manner, the animal finds itself a prisoner. The stone must be large enough to close the entrance of the cavity in which the crab conceals itself, and not too heavy to obstruct its movements. But none of these methods are sufficient to provide for an extensive demand.

Crab-fishing, as generally pursued along the British coasts, is conducted by two men who go out in one boat. In addition to their boat they require creels, cruives, or crab-pots, and lines. These creels (in the south of England generally termed crab-pots) are made of dry osier, and resemble basket-work. They are constructed on the same principle as a wire mouse-trap, but the aperture instead of being on the side is at the top. Within the creel the bait, consisting of pieces of thorn-back or skate, is fastened at the bottom, and the creel is then dropped in some favourable situation, three stones of sufficient weight being fastened in the inside to sink it. The creels are sometimes sunk to the depth of twenty fathoms, the fishermen being guided in this respect by the state of the weather or the nature of the ground. In fine weather they are dropped in from three to five fathoms deep; but the crabs are chiefly to be found where the bottom is rocky. A line is fastened to the creel, and at the upper end of the line a cork is attached which floats on the surface. By this means the place where the creel is sunk is known to the fishermen, who usually set from forty to fifty creels at one time. The bait is suspended about the middle of the creel, and can easily be seen by the crabs, which, entering at the aperture, find, like a mouse in a wire-trap, that escape is impossible. The difficulty of egress is increased by the entrance being overhead. Lobsters, prawns, and shrimps are frequently found captured in the same creel with crabs. When the fishermen have sunk the whole of their creels, they have still some time left to proceed farther out to sea for other fish before it is necessary to visit them. Crab-fishing is therefore a valuable addition to their means of livelihood, for it does not preclude the pursuit of other fish at the same season. The demand for this species of shell-fish is usually good, and in the nearest large town on many parts of the coast it is often fully equal to the supply. Thither the fisherman's wife or some of his family may convey the quantity taken; and, if the market be already abundantly provided, they can by means of the well-boxes, although already caught, be kept back for a time until prices rise again. These are all advantages peculiar to this fishery. When a few hours have elapsed, the fishermen visit their creels, one of them rowing and the other keeping a look-out for the floats, and taking out of the creels whatever has been captured. There may perhaps be a dozen different owners of boats thus engaged, and it is therefore necessary to have recourse to some means by which they may each secure the fruits of their individual industry without the risk of dispute. This is accomplished by distinguishing their respective floats by some peculiar mark—by a notch in the side—a mark in the shape of a diamond cut on the top—an angle cut off, &c. &c. The necessity of mutual protection points out to them the value of combination and union, and the marks adopted by the fishermen to distinguish their floats are consequently the result of some common understanding amongst them; or otherwise, of an instinctive regard to the means by which not only one but all are enabled to pursue their calling in confidence and security.

Crabs are brought to market both in a boiled and in a raw state. If the market be distant they are placed in a well-box, which is attached to the outside of the fishing-vessel, and in this manner they are brought to Billingsgate from parts so distant as Norway. The crab is so tenacious of life that it does not lose its vital powers until two or three days after leaving its native element. May, June, and July are the months in which it is generally out of season: but even in these months many may be obtained which are in a perfectly good state for the table. The male is of greater value than the female, and has larger claws. The sexes are distinguished as the cock and the hen. Before boiling, a good crab is known by the roughness of its shell, particularly on the claws. When boiled, the mode of ascertaining its goodness is by holding the claws tight, and shaking the body, which will rattle, or seem as if water were in the inside, if it be not in perfection. The time they are usually boiled is from a quarter of an hour to a couple of hours in sea-water, or in water in which salt has been infused. Sometimes they are put into cold water, which is afterwards heated to the boiling point.

an offspring, but to provide itself a covering; not only to secure a family, but to furnish a house. The animal I mean is the Soldier Crab, which has some similitude to the lobster, if divested of its shell. It is usually about four inches long, has no shell behind, but is covered down to the tail with a rough skin, terminating in a point. It is, however, armed with strong hard nippers before, like the lobster; and one of them is as thick as a man's thumb, and pinches most powerfully. It is, as I said, without a shell to any part except its nippers; but what nature has denied this animal, it takes care to supply by art; and taking possession of the deserted shell of some other animal, it resides in it, till, by growing too large for its habitation, it is under a necessity of change. It is a native of the West India islands; and, like the former, it is seen every year descending from the mountains to the sea-shore, to deposit its spawn, and to provide itself with a new shell. This is a most bustling time with it, having so many things to do; and in fact, very busy it appears. It is very probable that its first care is to provide for its offspring, before it attends to its own wants; and it is thought, from the number of little shells which it is seen examining, that it deposits its spawn in them, which thus is placed in perfect security till the time of exclusion.

However this be, the soldier is in the end by no means unmindful of itself. It is still seen in its old shell, which it appears to have considerably outgrown; for a part of the naked body is seen at the mouth of it, which the habitation is too small to hide. A shell, therefore, is to be found large enough to cover the whole body; and yet not so large as to be unmanageable and unwieldy. To answer both these ends it is no easy matter, nor the attainment of a slight inquiry. The little soldier is seen busily parading the shore along that line of pebbles and shells that is formed by the extremest wave; still, however, dragging its old incommodious habitation at its tail, unwilling to part with one shell, even though a troublesome appendage, till it can find another more convenient. It is seen stopping at one shell, turning it, and passing it by, going on to another, contemplating that for a while, and then slipping its tail from its old habitation, to try on the new. This also is found to be inconvenient; and it quickly returns to its old shell again. In this manner it frequently changes, till at last it finds one light, roomy, and commodious; to this it adheres, though the shell be sometimes so large as to hide the body of the animal, claws and all.[1] Yet it is not only till after many trials, but many combats also, that the soldier is thus completely equipped; for there is often a contest between two of them for some well-looking favourite shell for which they are rivals. They both endeavour to take possession; they strike with their claws, they bite each other, till the weakest is obliged to yield, by giving up the object of dispute. It is then that the victor immediately takes possession, and parades it in his new conquest three or four times backwards and forwards upon the strand before his envious antagonist.

When this animal is taken, it sends forth a feeble cry endeavouring to seize the enemy with its nippers; which if it fastens upon, it will sooner die than quit the grasp. The wound is very painful, and not easily cured. For this reason, and as it is not much esteemed for its flesh, it is generally permitted to return to its old retreat to the mountains in safety. There it continues till the necessity of changing once more, and the desire of producing an offspring expose it to fresh dangers the year ensuing.

[1] Pere du Festre.

CHAP. III.

OF THE TORTOISE AND ITS KINDS.

Having described the lobster and the crab as animals in some measure approaching to the insect tribes, it will appear like injustice to place the Tortoise among the number, that from its strength, its docility, and the warm red blood that is circulating in its veins, deserves to be ranked even above the fishes. But as this animal is covered, like the lobster, with a shell; as it is of an amphibious nature, and brings forth its young from the egg without hatching; we must be content to degrade it among animals that in every respect it infinitely surpasses.

Tortoises are usually divided into those that live upon land, and those that subsist in the water; and use has made a distinction even in the name; the one being called Tortoises, the other Turtles. However, Seba has proved that all tortoises are amphibious; that the land tortoise will live in the water, and that the sea turtle can be fed upon land. A land tortoise was brought to him that was caught in one of the canals of Amsterdam, which he kept for half a year in his house, where it lived very well contented in both elements. When in the water, it remained with its head above the surface; when placed in the sun, it seemed delighted with its beams, and continued immovable while it felt their warmth. The difference, therefore, in these animals, arises

rather from their habits than their conformation; and, upon examination, there will be less variety found between them than between birds that live upon land, and those that swim upon the water.

Yet, though nature seems to have made but few distinctions among these animals, as to their conformation, yet, in their habits, they are very dissimilar; as these result from different qualities of their food, and the different sorts of enemies they have to avoid or encounter. I will therefore exhibit their figure and conformation under one common description, by which their slight differences will be more obvious; and then I will give a separate history of the manners of each, as naturalists and travellers have taught us.

All tortoises, in their external form, pretty much resemble each other; their outward covering being composed of two great shells, the one laid upon the other, and only touching at the edges: however, when we come to look closer we shall find that the upper shell is composed of no less than thirteen pieces, which are laid flat upon the ribs, like the tiles of a house, by which the shell is kept arched and supported. The shells both above and below that, which seem, to an inattentive observer, to make each but one piece, are bound together at the edges by very strong and hard ligaments, yet with some small share of motion. There are two holes at either edge of this vaulted body; one for a very small head, shoulders, and arms, to peep through; the other at the opposite edge, for the feet and the tail. These shells the animal is never disengaged from; and they serve for its defence against every creature but man.[1]

The *tortoise* has but a small head, with no teeth; having only two bony ridges in the place, serrated and hard. These serve to

gather and grind its food; and such is the amazing strength of the jaws, that it is impossible to open them where they once have fastened. Even when the head is cut off, the jaws still keep their hold; and the muscles in death, preserve a tenacious rigidity. Indeed, the animal is possessed of equal strength in all other parts of its body: the legs, though short, are inconceivably strong; and torpid as the tortoise may appear, it has been known to carry five men standing upon its back, with apparent ease and unconcern. Its manner of going forward is by moving its legs one after the other; and the claws with which the toes are furnished, sink into the ground like the nails of an iron-shod wheel, and thus assist its progression.

With respect to its internal parts, not to enter into minute anatomical disquisitions, it may not be improper to observe, that the blood circulates in this animal as in some cartilaginous fishes, and something in the manner of a child in the womb. The greatest quantity of the blood passes directly from the vena cava into the left ventricle of the heart, which communicates with the right ventricle by an opening; while the auricles only receive what the ventricles seem incapable of admitting. Thus the blood is driven by a very short passage through the circulation; and the lungs seem to lend only occasional assistance. From this conformation, the animal can subsist for some time, without using the lungs, or breathing; at least the lungs are not so necessary an instrument for driving on the circulation as with us.

Such is the general structure of this animal, whether found to live by land or water. With regard to the differences of these animals, the land-tortoise, from its habits of making use of its feet in walking, is much more nimble upon land than the sea-turtle: the land-tortoise, if thrown upon its back, by rocking and balancing its body, like a child rocking in a cradle, at last turns itself upon its face again; but the turtle, when once turned, continues without being able to move from the spot. In comparing the feet also of these animals, the nails upon the toes of one that has long been used to scratch for subsistence upon land, are blunt and worn; while those that have only been employed in swimming, are sharp and long, and have more the similitude of fins. The brain of the land-tortoise is but small; and yet it is three times as large as that of the turtle.—There is a difference also in the shape of their eggs, and in the passage by which they are excluded; for, in the land-tortoise, the passage is so narrow, that the egg conforms to the shape of the aperture, and though round when in the body, yet becomes much more oblong than those of fowls upon being excluded; otherwise they would never be able to pass through the bony canal by which they are protruded; on the contrary, the passage is wider in the turtle, and therefore its eggs are round. These are the most striking distinctions; but that which is most known is their size; the land-tortoise

[1] There are various species of land tortoise, such as the Indian tortoise—the Radiated tortoise—the Tabular tortoise—the Geometrical tortoise—the Starred tortoise—the Leopard tortoise—the Kinyxis tortoise, &c.—and the Emys tortoise, which latter term is employed to designate the species that live habitually in fresh water.

often not exceeding three feet long, by two feet broad; the sea-turtle being sometimes from five to seven feet long. The size, however, is but a fallacious distinction: since land-tortoises, in some parts of India, grow to a very great magnitude; though probably not, as the ancients affirm, big enough for a single shell to serve for the covering of a house.

But if the different kinds of tortoises are not sufficiently distinguished by their figure, they are very obviously distinguishable by their methods of living. The land-tortoise lives in holes dug in the mountains, or near marshy lakes; the sea-turtle in cavities of rocks, and extensive pastures at the bottom of the sea. The tortoise makes use of its feet to walk with, and burrow in the ground; the turtle chiefly uses its feet in swimming or creeping at the bottom.

The land-tortoise is generally found, as was observed above, from one foot to five feet long, from the end of the snout to the end of the tail; and from five inches to a foot and a half across the back. It has a small head, somewhat resembling that of a serpent; an eye without the upper lid; the under eye-lid serving to cover and keep that organ in safety. It has a strong scaly tail, like the lizard. Its head the animal can put out and hide at pleasure, under the great penthouse of its shell; there it can remain secure from all attacks; there, defended on every side, it can fatigue the patience of the most formidable animal of the forest, that makes use only of natural strength to destroy it. As the tortoise lives wholly upon vegetable food, it never seeks the encounter; yet, if any of the smaller animals attempt to invade its repose, they are sure to suffer. The tortoise, impregnably defended, is furnished with such a strength of jaw, that, though armed only with bony plates instead of teeth, wherever it fastens it infallibly keeps its hold, until it has taken out the piece.

Though peaceable in itself, it is formed for war in another respect, for it seems almost endued with immortality. Nothing can kill it; the depriving it of one of its members, is but a slight injury: it will live, though deprived of the brain; it will live, though of its head. Redi informs us, that in making some experiments upon vital motion, he, in the beginning of the month of November, took a land-tortoise, made a large opening in its skull, and drew out all the brain, washed the cavity, so as not to leave the smallest part remaining, and then leaving the hole open, set the animal at liberty. Notwithstanding this, the tortoise marched away without seeming to have received the smallest injury; only it shut the eves. and never opened them afterwards. Soon after the hole in the skull was seen to close; and in three days, there was a complete skin covering the wound. In this manner the animal lived without a brain, for six months; walking about unconcernedly, and moving its limbs as before. But the Italian philosopher, not satisfied with this experiment, carried it still farther; for he cut off the head, and the animal lived twenty-three days after its separation from the body. The head also continued to rattle the jaws, like a pair of castanets, for above a quarter of an hour.

Nor are these animals less long-lived than difficult in destroying. Tortoises are commonly known to exceed eighty years old; and there was one kept in the Archbishop of Canterbury's garden, at Lambeth, that was remembered above a hundred and twenty. It was at last killed by the severity of a frost, from which it had not sufficiently defended itself in its winter retreat, which was a heap of sand, at the bottom of the garden.[1]

[1] "From a document belonging to the archives of the cathedral, called the Bishop's Barn, it is well ascertained that the tortoise at Peterborough must have been about 220 years old. Bishop Marsh's predecessor in the see of Peterborough had remembered it above sixty years, and could recognize no visible change. He was the seventh bishop who had worn the mitre during its sojourn there. If I mistake not, its sustenance and abode were provided for in this document. Its shell was perforated, in order to attach it to a tree, &c., to limit its ravages among the strawberry borders. The animal had its antipathies and predilections. It would eat endive, green peas, and even the leek; while it positively rejected asparagus, parsely, and spinage. In the early part of the season, its favourite pabulum were the flowers of the dandelion, of which it would devour *twenty* at a meal; and lettuce, of the latter a good sized one at a time; but if placed between lettuce and the flowers of the dandelion, it would forsake the former for the latter. It was also partial to the pulp of an orange, which it sucked greedily. About the latter end of June, (discerning the times and the seasons,) it looked out for fruit, when its former choice was forsaken. It ate currants, raspberries, pears, apples, peaches, nectarines, &c., the riper, the better, but would not taste cherries. Of fruits, however, the strawberry and gooseberry were the most esteemed: it made great havoc among the strawberry borders, and would take a pint of gooseberries at intervals. The gardener told me it knew him well, the hand that generally fed it, and would watch him attentively at the gooseberry bush, where it was sure to take its station while he plucked the fruit. I could not get it to take the root of the dandelion, nor indeed any root I offered it, as that of the carrot, turnip, &c. All animal food was discarded, nor would it take any liquid; at least neither milk nor water; and when a leaf was moist, it would shake it to expel the adhering wet. This animal moved with apparent ease, though pressed by a weight of eighteen stones; itself weighed 13½ lbs. In cloudy weather it would scoop out a cavity, generally in a southern exposure, where it reposed, torpid and inactive, until the genial influence of the sun roused it from its slumber. When in this state the eyes were closed, and the head and neck a little contracted, though not drawn within the shell. Its sense of smelling was so acute, that it was roused from its lethargy if any person approached,

The usual food of the land tortoise seems not so nourishing as to supply this extraordinary principle of vitality. It lives upon vegetables in its retreats in the mountains or the plain; and seldom makes its prey of snails or worms, but when other food is not found in grateful plenty. It is fond also of fruits; and when the forest affords them, is generally found not far from where they grow. As it can move but slowly, it is not very delicate in the choice of its food; so that it usually fills itself with whatever offers. Those that are kept in a domestic state will eat any thing; leaves, fruits, corn, bran, or grass.

From the smallness of its brain, and the slowness of its motion, it obviously appears to be a torpid heavy animal, requiring rest and sleep; and, in fact, it retires to some cavern to sleep for the winter. I already observed that its blood circulated through the heart by a short passage; and that it did not, as anatomists express it, go through the great circulation. With us, and quadrupeds, the blood goes from the veins to the heart; and from the heart it is sent to be spread over the lungs; from the lungs it returns to the heart again; and from thence it goes to the arteries to be distributed through the whole body. But its passage in the tortoise is much shorter; for, from the veins it goes to the heart; then leaving the lungs entirely out of its course, it takes a short cut, if I may so say, into the beginning of the arteries, which send it round the animal frame. From hence we see the lungs are left out of the circulation; and, consequently, the animal is capable of continuing to live without continuing to breathe. In this it resembles the bat, the serpent, the mole, and the lizard; like them it takes up its dark residence for the winter; and, at that time, when its food is no longer in plenty, it happily becomes insensible to the want. Nor is it unmindful to prepare its retreat, and make it as convenient as possible; it is sometimes buried two or three feet in the ground, with its hole furnished with moss, grass, and other substances, as well to keep the retreat warm, as to serve for food, in case it should prematurely awake from its state of stupefaction. But it must not be supposed, that, while it is thus at rest, it totally discontinues to breathe; on the contrary, an animal of this kind, if put into a close vessel, without air, will soon be stifled; though not so readily as in a state of vigour and activity.

From this dormant state the tortoise is awakened by the genial return of spring; and is thought not to be much wasted by its long confinement. To animals that live a hundred and fifty years, a sleep of six months is but as the nap of a night. All the actions of these long-lived creatures seem formed upon a scale answering the length of their existence; their slumbers are for a season; their motions are slow, and require time in every action; even the act of procreation, which among other animals is performed in a very few minutes, is with them the business of days. About a month after their enlargement from a torpid state, they prepare to transmit their posterity; and both continue joined for near a month together. The eggs of the female are contained in the ovary, above the bladder, which is extremely large; and these are, before their exclusion, round and naked, with some spots of red; after they are laid, however, they assume another form, being smaller and longer than those of a hen. This alteration in the figure of the eggs most probably proceeds from the narrowness of the bony passage through which they are excluded. Swammerdam, who compared the size of the eggs taken out of this animal's body with the diameter of the passage through which they were excluded, was of opinion that the bones themselves separated from each other, and closed again; but, in my opinion, it is more probable to suppose, that the eggs, and not the bones, alter their form. Certain it is, that they are round in the body, and that they are oval upon being protruded.

The eggs of all the tortoise kind, like those of birds, are furnished with a yolk and a white; but the shell is different, being somewhat like those soft eggs that hens exclude before their time; however, this shell is much thicker and stronger, and is a longer time in coming to maturity in the womb. The land-tortoise lays but a few in number, if compared to the sea-turtle, who deposits from a hundred and fifty to two hundred in a season.

The amount of the land-tortoise's eggs I have not been able to learn;[1] but, from the scarceness of the animal, I am apt to think they cannot be numerous. When it prepares

even at a distance of twelve feet. About the beginning of October, or latter end of September, it began to immure itself, and had for that purpose for many years selected a particular angle of the garden; it entered in an inclined plane, excavating the earth in the manner of the mole; the depth to which it penetrated varied with the character of the approaching season, being from one to two feet, according as the winter was mild or severe. It may be added, that for nearly a month prior to this entry into its dormitory, it refused all sustenance whatever. The animal emerged about the end of April, and remained for at least a fortnight before it ventured on taking any species of food. Its skin was not perceptibly cold: its respiration, entirely effected through the nostrils, was languid. I visited the animal, for the last time, on the 9th June, 1813, during a thunder storm: it then lay under the shelter of a cauliflower, and apparently torpid."—*Murray's Experimental Researches.*

[1] Land tortoises are supposed to lay five or six eggs, but on this point we have no very positive information.

to lay, the female scratches a slight depression in the earth, generally in a warm situation, where the beams of the sun have their full effect: there depositing her eggs, and covering them with grass and leaves, she forsakes them, to be hatched by the heat of the season. The young tortoises are generally excluded in about twenty-six days; but, as the heat of the weather assists, or its coldness retards incubation, sometimes it happens that there is a difference of two or three days. The little animals no sooner leave the egg than they seek for their provision, entirely self-taught; and their shell, with which they are covered from the beginning, expands and grows larger with age. As it is composed of a variety of pieces, they are all capable of extension at their sutures, and the shell admits of increase in every direction. It is otherwise with those animals, like the lobster, whose shell is composed all of one piece, that admits of no increase; which, when the tenant is too big for the habitation, must burst the shell, and get another. But the covering of the tortoise grows larger in proportion as the internal parts expand; in some measure resembling the growth of the human skull, which is composed of a number of bones, increasing in size in proportion to the quantity of the brain. All tortoises, therefore, as they never change their shell, must have it formed in pieces; and though in some that have been described by painters or historians, these marks have not been attended to, yet we can have no doubt that they are general to the whole tribe.

It is common enough to take these animals into gardens, as they are thought to destroy insects and snails in great abundance. We are even told that in hot countries, they are admitted into a domestic state, as they are great destroyers of bugs. How so large and heavy an animal is capable of being expert at such petty prey is not easy to conceive; but I have seen several of them about gentlemen's houses, that, in general, appear torpid, harmless, and even fond of employment. Children have sometimes got upon the back of a tortoise; and such was the creature's strength, that it never seemed overloaded, but moved off with its burden to where it expected to be fed, but would carry them no further. In winter they regularly find out a place to sleep in; but in those warm countries in which the tortoise is found larger, and in greater plenty than in Europe, they live, without retiring, the whole year round.

The Sea Tortoise, or Turtle, as it is now called, is generally found larger than the former. This element is possessed with the property of increasing the magnitude of those animals, which are common to the land and the ocean. The sea pike is larger than that of fresh water; the sea bear is larger than that of the mountains; and the sea turtle exceeds the land tortoise in the same proportion. It is of different magnitudes, according to its different kinds; some turtles being not above fifty pounds weight, and some above eight hundred.

The *Great Mediterranean Turtle* (or Coriaceous Turtle)[1] is the largest of the turtle kind with which we are acquainted. It is found from

five to eight feet long, and from six to nine hundred pounds weight. But, unluckily, its utility bears no proportion to its size; as it is unfit for food, and sometimes poisons those who eat it. The shell also, which is a tough strong integument, resembling a hide, is unfit for all serviceable purposes. One of these animals was taken in the year 1729, at the mouth of the Loire, in nets that were not designed for so large a capture. This turtle, which was of enormous strength, by its own struggles involved itself in the nets in such a manner as to be incapable of doing mischief: yet, even thus shackled, it appeared terrible to the fishermen, who were at first for flying; but finding it impotent, they gathered courage to drag it on shore, where it made a most horrible bellowing; and when they began to knock it on the head with their gaffs, it was to be heard at half a mile's distance. They were still farther intimidated by its nauseous and pestilential breath, which so powerfully affected them, that they were near fainting. This animal wanted but four inches of being eight feet long, and was above two feet over: its shell more resembled leather than the shell of a tortoise; and, unlike all other animals of this kind, it was furnished with teeth in each jaw, one rank behind another, like those of a shark: its feet also, different from the rest of this kind, wanted claws; and the tail was quite disengaged from the shell, and fifteen inches long, more resembling that of a quadruped than a tortoise. This animal was then unknown upon the coasts of France, and was supposed to have been brought into the European seas, in some India ship that might be wrecked upon her return. Since that, however, two or three of these animals have been

[1] Also called the *Leathery Turtle*, from its tough leathery covering.

taken upon the coasts; two in particular upon those of Cornwall, in the year 1756, the largest of which weighed eight hundred pounds; and one upon the isle of Rhe, but two years before, that weighed between seven and eight hundred. One, most probably of this kind also, was caught about thirty years ago near Scarborough, and a good deal of company was invited to feast upon it: a gentleman, who was one of the guests, told the company that it was a Mediterranean turtle, and not wholesome; but a person, who was willing to satisfy his appetite at the risk of his life, ate of it: he was seized with a violent vomiting and purging; but his constitution overpowered the malignity of the poison.

These are a formidable and useless kind, if compared to the turtle caught in the South seas and the Indian ocean. These are of different kinds; not only unlike each other in form, but furnishing man with very different advantages. They are usually distinguished by sailors into four kinds; the Trunk Turtle, the Loggerhead, the Hawksbill, and the Green Turtle.

The Trunk Turtle is commonly larger than the rest, and its back higher and rounder. The flesh of this is rank, and not very wholesome.

The Loggerhead is so called from the largeness of its head, which is much bigger in proportion than that of the other kinds.[1] The flesh of this also is very rank, and not eaten but in case of necessity.

The Hawksbill Turtle (or Imbricated Turtle) is the least of the four, and has a long and small mouth, somewhat resembling the bill of a hawk.[2] The flesh of this also is very indif-

---

[1] *The Loggerhead Turtle.*—The Loggerhead turtle (*testudo caretta*) has some resemblance to the green turtle; but the head is larger, the shell broader, and the colours more intense. There are also two more pieces in the

back plate, and the fore legs are longer and the hind legs shorter in proportion. It is much more active than the green turtle, and ranges over a much greater extent in latitude. It is by no means uncommon in the Mediterranean, not merely on the coasts of Africa, but on those of Italy and Sicily. The flesh is tough and harsh, though eaten by the poor. The shell too, is thin, dull, and of little value, though the Italian workmen sometimes use it in veneering. The principal value of the animal is for its oil, which is abundant, considerably superior to whale-oil, and some suppose it would answer well for the dressing of leather, for which cod-oil, made from the liver, is chiefly used in this country. The eggs of the loggerhead are more palatable than the flesh.

The loggerhead is as formidable and fierce as the green turtle is gentle and inoffensive. Its jaws are very hard and strong, and they come together with much force. They are, however, well adapted to its food, the principal part of which is shelled animals, and it can easily break the hardest shell. It can also strike and scratch with its long fore legs, which have strong claws projecting beyond the webs of the toes. It will snap at a stick or any other object with which it is threatened; and its hold is so firm that it will break a thick stick, or bend a rod of iron. It is exceedingly difficult to get it to quit its hold after once it has been taken; and it is commonly said that the "loggerhead" continues to bite after it has been separated from the body. The hold which, in that case it retains, is not the stiffness of death, for the head of any tortoise lives for some time after it has been cut off.

These animals are formidable in size, too; for it has been said that some weighing 1500 or 1600 pounds have been met with. They also swim with more rapidity than the green turtle, being much more frequently met with "on the high seas." When young, they have so great a resemblance to the green turtle as to lead to a suspicion that the specimens met with on the western coast of France, and described as green turtle, were in fact loggerheads; because green turtle have not been found in the Mediterranean, the shores of which have a much more tropical character than the coast of France. It is probable that all the green turtle described as being found far out at sea, were in truth the species now under consideration. As a grazing animal, the green turtle is not likely to go often or far to places where it can find no bottom, while the loggerhead, a devourer of flesh, can range the ocean at its pleasure. In Europe this turtle is not often found to the north of the Mediterranean; and in America it is seldom found to the north of Florida. As it has not the same charms for the palate of the epicure, its habits, though it has been much longer known, have not been so much studied as those of the other.

[2] *The Hawksbill Turtle.* — The Hawksbill turtle (*Testudo imbricata*) gets its scientific name from the arrangement of the plates, which overlap each other like the tiles on a roof; and it gets its common English name from the partial resemblance of its mouth, seen in profile, to the bill of a hawk. Its head, neck, and legs are longer in proportion to their thickness than those of the other turtles; it is more active, swimming with greater velocity, and righting itself when turned. Its eggs are eatable, but its flesh is not good, and the chief value of it to man are the plates on its back, which are the true tortoise-shell of commerce, and have been highly esteemed from the earliest ages. There are thirteen plates in the central part, surrounded by twenty-five smaller ones. The large central plates are the finest shell; and they are often of considerable thickness. The plates of shell do not form the entire case of the animal. The inner or supporting part is bony, and may be considered as part of the skeleton. The true skin is between the bony substance and the plates of shell. The plates are a production of that skin, and in the living state they are covered by an epidermis, or scarfskin. The common way of obtaining the plates is to heat the entire backpiece of the animal, by fire applied under the hollow on the inside. By that means the gelatine of the skin is dissolved, the skin itself swells, and the plates are easily detached entire. A turtle of about 300 pounds weight will produce about ten or twelve pounds of shell; but in the common way of obtaining the shell, the animal, which is otherwise useless in the arts, is sacrificed. In the eastern isles, where the hawksbill turtle is very abundant, the Malays, who procure large quantities of shell for the Chinese, pursue a different method. They catch the turtle alive, and retain it while they detach the central plates, so dexterously as not to lacerate the

ferent eating; but the shell serves for the most valuable purposes. This is the animal that supplies the tortoise-shell, of which such a variety of beautiful trinkets are made. The substance of which the shells of other turtle are composed is thin and porous; but that of the hawksbill is firm, and when polished, is beautifully marbled. They generally carry about three pounds; but the largest of all, six pounds. The shell consists, as in all the kind, of thirteen leaves or plates, of which eight are flat, and five hollow. They are raised and taken off by means of fire, which is made under the shell after the flesh is taken out. As soon as the heat affects the leaves, they start from the ribs, and are easily raised with the point of a knife. By being scraped and polished on both sides, they become beautifully transparent, or are easily cast into what form the workman thinks proper, by making them soft and pliant in warm water, and then screwing them in a mould, like a medal: however, the shell is most beautiful before it undergoes this last operation.

But of all animals of the tortoise kind, the Green Turtle[1] is the most noted and the most valuable. The delicacy of its flesh, and its nutritive qualities, together with the property of being easily digested, were, for above a century, known only to our seamen, and the inhabitants of the coasts where they were taken. It was not till by slow degrees the distinction came to be made between such as were malignant and such as were wholesome. The controversies and contradictions of our old travellers were numerous upon this head: some asserting, that the turtle was delicious food; and others, that it was actual poison. Dampier, that rough seaman, who has added more to natural history than half of the philosophers that went before him, appears to be the first who informed us of their distinctions; and that, while the rest might be valuable for other purposes, the green turtle alone was chiefly prized for the delicacy of its flesh. He never imagined, however, that this animal would make its way to the luxurious tables of Europe; for he seems chiefly to recommend it as salted up for ship's provision, in case of necessity.

At present the turtle is very well known among us, and is become the favourite food of those that are desirous of eating a great deal without the danger of surfeiting. This is a

---

skin. The animal is said not to show much uneasiness during the operation, and when that is performed it is returned into the sea, where, after a time, the plates are said to be reproduced. That is by no means unlikely, as the reproduction of parts is not uncommon among reptiles, any more than among some of the crustacea, which have at least some analogy with the reptiles.

The hawksbill, or shell turtle, is much more widely diffused than the green turtle. It is found in almost all the tropical seas; being peculiarly abundant in the shallows near Belese, the chief settlement in the mahogany country of Honduras. It is indeed general in the Caribbean sea; and is found browsing on its favourite sea weed, wherever that abounds in latitudes sufficiently warm. It is also plentiful on the shores of tropical Africa, on those of New Holland, and in the Indian ocean. Tortoise-shell is thus so abundant, that though it has been a favourite article of luxury from very early times, the supply is still undiminished.

[1] *The Green Turtle.*—The Green turtle, of which we hear so much as a luxury at the tables of the rich, is a native of the seas in the warm and tropical parts of the world; and instead of being considered as a rarity or a

dainty there, it is so abundant, that the flesh of it is sold cheaper than that of any land animal. The tropical shores of America, both on the Atlantic and the Pacific side, the tropical shores of Africa, and those of New Holland, are the favourite haunts of the turtle. These animals prefer lonely places, and thus they are much more plentiful on desert shores and about little barren islands, than they are on those of fertile countries. The little isles called the Alligator isles, in the West Indian sea; the barren volcanic rocks of the Gallipagos in the Pacific; the island of Ascension, in the Atlantic, and the northern shores of New Holland, which are generally speaking, dreary and barren, abound more with them than any other parts of the world. The green turtle attains an enormous size and weight; some individuals measuring six or seven feet in length from the tip of the nose to the extremity of the tail, by three or four feet broad, and weighing as much as eight hundred pounds. The more common weight, however, is from two to three hundred pounds.

The instinct which leads the female turtle to the shore to lay her eggs, exposes her to the danger of becoming the prey of man. She deposits her eggs on the loose sand, and abandons them at once to the chance, which approaches almost to a certainty in the southern hemisphere, that they will be hatched by the influence of the sun's rays. She digs, by means of her fore-feet, one or more holes about a foot wide and two feet deep, in which she usually deposits more than a hundred eggs. These eggs are round, and are two or three inches in diameter; they are covered with a membrane something like wet parchment. The female generally lays three times in each year, at intervals of about a fortnight or three weeks. They almost always go ashore in the night time. A loose sand being essential to the hatching of the eggs, the turtles frequent only particular shores; but these are often several hundred miles from their feeding places. The eggs are hatched in less than a month after they are laid; and in about eight or ten days the young reptiles crawl to the water. Few however, reach their native element, in proportion to the number produced. They become the prey of seafowl and various quadrupeds of prey. The tiger is an especial enemy to the tortoise; but man is still more actively engaged in their destruction. The collection of tortoise eggs forms one of the most important of the occupations of the Indians of the Orinoco. Humboldt gives an interesting account of this branch of commerce.

property the flesh of the turtle seems peculiarly possessed of; and by the importation of it alive among us, gluttony is freed from one of its greatest restraints. The flesh of the turtle is become a branch of commerce; and therefore ships are provided with conveniences for supplying them with water and provision, to bring them over in health from Jamaica and other West India islands. This, however, is not always effected; for though they are very vivacious, and scarcely require any provision upon the voyage, yet, by the working of the ship, and their beating against the sides of the boat that contains them, they become battered and lean; so that to eat this animal in the highest perfection, instead of bringing the turtle to the epicure he ought to be transported to the turtle.

This animal is called the green turtle, from the colour of its shell, which is rather greener than that of others of this kind. It is generally found about two hundred weight; though some are five hundred, and others not above fifty. Dampier tells us of one that was seen at Port-Royal, in Jamaica, that was six feet broad across the back; he does not tell us its other dimensions; but says that the son of Captain Roach, a boy about ten years old, sailed in the shell, as in a boat, from the shore to his father's ship, which was above a quarter of a mile from land. But this is nothing to the size of some turtles the ancients speak of. Ælian assures us, that the houses in the island of Taprobane are usually covered with a single shell. Diodorus Siculus tells us that a people neighbouring on Ethiopia, called the *Turtle-eaters*, coasted along the shore in boats made of the upper shell of this animal; and that in war, when they had eaten the flesh, the covering served them as a tent. In this account, Pliny, and all the rest of the ancients, agree; and as they had frequent opportunities of knowing the truth, we are not lightly to contradict their testimony.

At present, however, they are not seen of such amazing dimensions. We are told by Laet, that on the isle of Cuba they grow to such a size, as that five men can stand on the back of one of them together; and what is more surprising still, that the animal does not seem overloaded, but will go off with them upon its back, with a slow steady motion, towards the sea.

They are found in the greatest numbers on the island of Ascension; where for several years, they were taken to be salted to feed the slaves, or for a supply of ship's provision. Their value at present seems to be better known.

This animal seldom comes from the sea but to deposit its eggs, and now and then to sport in fresh water. Its chief food is a submarine plant, that covers the bottom of several parts of the sea not far from the shore. There the turtles are seen, when the weather is fair, feeding in great numbers, like flocks of sheep, several fathoms deep, upon the verdant carpet below. At other times they go to the mouths of rivers; and they seem to find gratification in fresh water. After some time thus employed, they seek their former stations: and when done feeding, they generally float with their heads above water, unless they are alarmed by the approach of hunters or birds of prey, in which case they suddenly plunge to the bottom. They often seek their provision among the rocks, feeding upon moss and sea-weed; and it is probable will not disdain to prey upon insects and other small animals, as they are very fond of flesh when taken and fed for the table.

At the time of breeding, they are seen to forsake their former haunts and their food, and to take sometimes a voyage of nine hundred miles to deposit their eggs on some favourite shore. The coasts they always resort to upon these occasions are those that are low, flat, and sandy: for, being heavy animals, they cannot climb a bold shore; nor is any bed so proper as sand to lay their eggs on. They couple in March, and continue united till May; during a great part of which they are seen locked together, and almost incapable of separation. The female seems passive and reluctant; but the male grasps her with his claws in such a manner, that nothing can induce him to quit his hold. It would seem that the grasp, as in frogs, is, in some measure, convulsive, and that the animal is unable to relax its efforts.

When the time for laying approaches, the female is seen towards the setting of the sun drawing near the shore, and looking earnestly about her, as if afraid of being discovered. When she perceives any person on shore, she seeks for another place; but if otherwise, she lands when it is dark, and goes to take a survey of the sand where she designs to lay. Having marked the spot, she goes back without laying, for that night, to the ocean again; but the next night returns to deposit a part of her burden. She begins by working and digging in the sand with her fore-feet till she has made a round hole, a foot broad, and a foot and a half deep, just at the place a little above where the water reaches highest. This done, she lays eighty or ninety eggs at a time, each as big as a hen's egg, and as round as a ball. She continues laying about the space of an hour; during which time, if a cart were driven over her, she would not be induced to stir. The eggs are covered with a tough white skin, like wetted parchment. When she has done laying, she covers the hole so dexterously, that it is no easy matter to find

the place; and those must be accustomed to the search to make the discovery. When the turtle has done laying, she returns to the sea, and leaves her eggs to be hatched by the heat of the sun. At the end of fifteen days she lays about the same number of eggs again; and at the end of another fifteen days she repeats the same; three times in all, using the same precautions every time for safety.

In about twenty-four or twenty-five days after laying, the eggs are hatched by the heat of the sun; and the young turtles being about as big as quails, are seen bursting from the sand, as if earth-born, and running directly to the sea, with instinct only for their guide: but, to their great misfortune, it often happens that, their strength being small, the surges of the sea, for some few days, beat them back upon the shore. Thus exposed, they remain a prey to thousands of birds that then haunt the coast; and these stooping down upon them carry off the greatest part, and sometimes the whole brood, before they have strength sufficient to withstand the waves, or dive to the bottom. Helbigius informs us, that they have still another enemy to fear, which is no other than the parent that produces them, that waits for their arrival at the edge of the deep, and devours as many as she can.[1] This circumstance, however, demands further confirmation; though nothing is more certain than that the crocodile acts in the same unnatural manner.

When the turtles have done laying, they then return to their accustomed places of feeding. Upon their outset to the shore where they breed, they are always fat and healthy; but upon their return, they are weak, lean, and unfit to be eaten. They are seldom, therefore, molested upon their retreat; but the great art is to seize them when arrived, or to intercept their arrival. In these uninhabited islands, to which the green turtle chiefly resorts, the men that go to take them land about night-fall, and without making any noise (for these animals, though without any external opening of the ear, hear very distinctly, there being an auditory conduit that opens into the mouth,) lie close while they see the female turtle coming on shore. They let her proceed to her greatest distance from the sea; and then, when she is most busily employed in scratching a hole in the sand, they sally out and surprise her. Their manner is to turn her upon her back, which utterly incapacitates her from moving; and yet as the creature is very strong, and struggles very hard, two men find it no easy matter to lay her over. When thus secured they go to the next; and in this manner, in less than three hours, they have been known to turn forty or fifty turtles, each of which weighs from a hundred and fifty to two hundred pounds. Labat assures us, that when the animal is in this helpless situation, it is heard to sigh very heavily, and even to shed tears.

At present, from the great appetite that man has discovered for this animal, they are not only thinned in their numbers, but are also grown much more shy. There are several other ways, therefore, contrived for taking them.[2] One is, to seize them when coupled

[1] This account of the turtle's preying upon its young is incorrect.

[2] Audubon, in his *Ornithological Biography*, has a chapter, headed *The Turtlers*, in which he gives an interesting account of the habits of turtles, and the methods of taking them. "The Tortugas," he says, "are a group of islands lying about eighty miles from Key West, and the last of those that seem to defend the peninsula of the Floridas. They consist of five or six extremely low uninhabitable banks formed of shelly sand, and are resorted to principally by that class of men called Wreckers and Turtlers. Between these islands are deep channels, which, although extremely intricate, are well known to those adventurers, as well as to the commanders of the revenue cutters, whose duties call them to that dangerous coast. The great coral reef or wall lies about eight miles from these inhospitable isles, in the direction of the Gulf, and on it many an ignorant or careless navigator has suffered shipwreck. The whole ground around them is densely covered with corals, sea-fans, and other productions of the deep, amid which crawl innumerable testaceous animals, while shoals of curious and beautiful fishes fill the limpid waters above them. Turtles of different species resort to these banks, to deposit their eggs in the burning sand, and clouds of sea-fowl arrive every spring for the same purpose. These are followed by persons called 'Eggers,' who, when their cargoes are completed, sail to distant markets, to exchange their ill-gotten ware for a portion of that gold, on the acquisition of which all men seem bent. . . . . .

"But the Tortugas are not the only breeding places of the turtles; these animals, on the contrary, frequent many other keys, as well as various parts of the coast of the mainland. There are four different species, which are known by the names of the *green* turtle, the *hawksbill* turtle, the *loggerhead* turtle, and the *trunk* turtle. The first is considered the best as an article of food, in which capacity it is well known to most epicures. It approaches the shores, and enters the bays, inlets, and rivers, early in the month of April, after having spent the winter in the deep waters. It deposits its eggs in convenient places, at two different times in May, and once again in June. The first deposit is the largest, and the last the least, the total quantity being at an average about two hundred and forty. The hawksbill turtle, whose shell is so valuable as an article of commerce, being used for various purposes in the arts, is the next with respect to the quality of its flesh. It resorts to the outer keys only, where it deposits its eggs in two sets, first in July, and again in August, although it 'crawls' the beaches of these keys much earlier in the season, as if to look for a safe place. The average number of its eggs is about three hundred. The loggerhead visits the Tortugas in April, and lays from that period until late in June three sets of eggs, each set averaging a hundred and seventy. The trunk turtle, which is sometimes of an enormous size, and which has a pouch like a pelican, reaches the shores latest. The shell and flesh are so soft that one may push his finger into them, almost as

together, at the breeding season, when they are very easily approached, and as easily seen; for these animals, though capable of living for some time under water, yet rise every eight or ten minutes to breathe. As soon as they are thus perceived, two or three people draw near them in a canoe, and slip a noose either round their necks or one of their feet. If they have no line, they lay hold of them by the neck, where they have no shell,

---

into a lump of butter. This species is therefore considered as the least valuable, and indeed is seldom eaten, unless by the Indians, who, ever alert when the turtle season commences, first carry off the eggs, and afterwards catch the turtles themselves. The average number of eggs which it lays in the season, in two sets, may be three hundred and fifty.

"The loggerhead and the trunk turtles are the least cautious in choosing the places in which to deposit their eggs, whereas the two other species select the wildest and most secluded spots. The green turtle resorts either to the shores of the main, between Cape Sable and Cape Florida, or enters Indian, Halifax, and other large rivers or inlets, from which it makes its retreat as speedily as possible, and betakes itself to the open sea. Great numbers, however, are killed by the turtlers and Indians, as well as by various species of carnivorous animals, as cougars, lynxes, bears, and wolves. The hawksbill, which is still more wary, and is always the most difficult to surprise, keeps to the sea islands. All the species employ nearly the same method in depositing their eggs in the sand, and as I have several times observed them in the act, I am enabled to present you with a circumstantial account of it.

"On first nearing the shores, and mostly on fine calm moonlight nights, the turtle raises her head above the water, being still distant thirty or forty yards from the beach, looks around her, and attentively examines the objects on the shore. Should she observe nothing likely to disturb her intended operations, she emits a loud hissing sound, by which such of her many enemies as are unaccustomed to it are startled, and so are apt to remove to another place, although unseen by her. Should she hear any noise, or perceive indications of danger, she instantly sinks and goes off to a considerable distance; but should every thing be quiet, she advances slowly towards the beach, crawls over it, her head raised to the full stretch of her neck; and when she has reached a place fitted for her purpose, she gazes all round in silence. Finding 'all well,' she proceeds to form a hole in the sand, which she effects by removing it from *under* her body with her *hind* flappers, scooping it out with so much dexterity that the sides seldom if ever fall in. The sand is raised alternately with each flapper, as with a large ladle, until it has accumulated behind her, when supporting herself with her head and fore part on the ground fronting her body, she with a spring from each flapper sends the sand around her, scattering it to the distance of several feet. In this manner the hole is dug to the depth of eighteen inches, or sometimes more than two feet. This labour I have seen performed in the short period of nine minutes. The eggs are then dropped one by one, and disposed in regular layers, to the number of a hundred and fifty, or sometimes nearly two hundred. The whole time spent in this part of the operation may be about twenty minutes. She now scrapes the loose sand back over the eggs, and so levels and smooths the surface that few persons on seeing the spot could imagine any thing had been done to it. This accomplished to her mind, she retreats to the water with all possible dispatch, leaving the hatching of the eggs to the heat of the sand. When a turtle, a loggerhead for example, is in the act of dropping her eggs, she will not move although one should go up to her, or even seat himself on her back, for it seems that at this moment she finds it necessary to proceed at all events, and is unable to intermit her labour. The moment it is finished, however, off she starts; nor would it then be possible for one, unless he were as strong as a Hercules, to turn her over and secure her.

"To upset a turtle on the shore, one is obliged to fall on his knees, and, placing his shoulder behind her forearm, gradually raise her up by pushing with great force, and then with a jerk throw her over. Sometimes it requires the united strength of several men to accomplish this; and if the turtle should be of very great size, as often happens on that coast, even hand-spikes are employed. Some turtlers are so daring as to swim up to them while lying asleep on the surface of the water, and turn them over in their own element, when, however, a boat must be at hand to enable them to secure their prize. Few turtles can bite beyond the reach of their forelegs, and few, when once turned over, can without assistance regain their natural position; but notwithstanding this, their flappers are generally secured by ropes, so as to render their escape impossible.

"Persons who search for turtles' eggs are provided with a light stiff cane or gun-rod, with which they go along the shores, probing the sand near the tracks of the animals, which, however, cannot always be seen, on account of the winds and heavy rains that often obliterate them. The nests are discovered not only by men, but also by beasts of prey, and the eggs are collected, or destroyed on the spot in great numbers, as on certain parts of the shores hundreds of turtles are known to deposit their eggs within the space of a mile. They form a new hole each time they lay, and the second is generally dug near the first, as if the animal were quite unconscious of what had befallen it. It will be readily understood that the numerous eggs seen in a turtle on cutting it up could not be all laid the same season. The whole number deposited by an individual in one summer may amount to four hundred, whereas if the animal is caught on or near her nest, as I have witnessed, the remaining eggs, all small, without shells, and as it were threaded like so many large beads, exceed three thousand. In an instance where I found that number, the turtle weighed nearly four hundred pounds. The young, soon after being hatched, and when yet scarcely larger than a dollar, scratch their way through their sandy covering, and immediately betake themselves to the water.

"The food of the green turtle consists chiefly of marine plants, more especially the grasswrack (*Zostera marina*), which they cut near the roots to procure the most tender and succulent parts. Their feeding grounds, as I have elsewhere said, are easily discovered by floating masses of these plants on the flats, or along the shores to which they resort. The hawk-billed species feeds on sea-weeds, crabs, various kinds of shell-fish, and fishes; the loggerhead mostly on the fish of conch-shells of large size, which they are enabled, by means of their powerful beak, to crush to pieces with apparently as much ease as a man cracks a walnut. One which was brought on board the Marion, and placed near the fluke of one of her anchors, made a deep indentation in that hammered piece of iron that quite surprised me. The trunk turtle feeds on mollusca, fish, crustacea, sea urchins, and various marine plants.

"All the species move through the water with surprising speed: but the green and hawk-billed in particular remind you, by their celerity and the ease of their motions, of the progress of a bird in the air. It is therefore no easy matter to strike one with a spear, and yet this is often done by an accomplished turtler. . .

with their hands only; and by this means they usually catch them both together. But sometimes the female escapes, being more shy than the male.

Another way of taking them is by the harpoon, either when they are playing on the surface of the water, or feeding at the bottom; when the harpoon is skilfully darted, it sticks fast in the shell of the back; the wood then disengages from the iron, and the line is long enough for the animal to take its range; for if the harpooner should attempt at once to draw the animal into his boat till it is weakened by its own struggling, it would probably get free. Thus the turtle struggles hard to get loose, but all in vain; for they take care the line fastened to the harpoon shall be strong enough to hold it.

There is yet another way, which, though seemingly awkward, is said to be attended with very great success. A good diver places himself at the head of the boat; and when the turtles are observed, which they sometimes are in great numbers, asleep on the surface, he immediately quits the vessel, at about fifty yards distance, and keeping still under water, directs his passage to where the turtle was seen, and, coming up beneath, seizes it by the tail; the animal awaking struggles to get free; and by this both are kept at the surface until the boat arrives to take them in.

"Turtles such as I have spoken of are caught in various ways on the coasts of the Floridas, or in estuaries and rivers. Some turtlers are in the habit of setting great nets across the entrance of streams, so as to answer the purpose either at the flow or at the ebb of the waters. These nets are formed of very large meshes, into which the turtles partially enter, when, the more they attempt to extricate themselves, the more they get entangled. Others harpoon them in the usual manner; but in my estimation no method is equal to that employed by Mr Egan, the pilot of Indian isle.

"That extraordinary turtler had an iron instrument, which he called a *peg*, and which at each end had a point not unlike what nail-makers call a brad, it being four-cornered but flattish, and of a shape somewhat resembling the beak of an ivory-billed woodpecker, together with a neck and shoulder. Between the two shoulders of this instrument a fine tough line, fifty or more fathoms in length, was fastened, by one end being passed through a hole in the centre of the peg, and the line itself was carefully coiled up and placed in a convenient part of the canoe. One extremity of this peg enters a sheath of iron that loosely attaches it to a long wooden spear, until a turtle has been pierced through the shell by the other extremity. He of the canoe paddles away as silently as possible whenever he spies a turtle basking on the water, until he gets within a distance of ten or twelve yards, when he throws the spear so as to hit the animal about the place which an entomologist would choose, were it a large insect, for pinning it to a piece of cork. As soon as the turtle is struck, the wooden handle separates from the peg, in consequence of the looseness of its attachment The smart of the wound urges on the animal as if distracted, and it appears that the longer the peg remains in its shell, the more firmly fastened it is, so great a pressure is exercised upon it by the shell of the turtle, which being suffered to run like a whale, soon becomes fatigued, and is secured by hauling in the line with great care. In this manner, as the pilot informed me, eight hundred green turtles were caught by one man in twelve months.

"Each turtler has his *crawl*, which is a square wooden building or pen, formed of logs, which are so far separated as to allow the tide to pass freely through and stand erect in the mud. The turtles are placed in this inclosure, fed and kept there until sold. If the animals thus confined have not laid their eggs previous to their seizure, they drop them in the water, so that they are lost.

"When I was in the Floridas, several turtlers assured me, that any turtle taken from the depositing ground, and carried on the deck of a vessel several hundred miles, would, if then let loose, certainly be met with at the same spot, either immediately after, or in the following breeding season. Should this prove true, and it certainly may, how much will be enhanced the belief of the student in the uniformity and solidity of Nature's arrangements, when he finds that the turtle, like a migratory bird, returns to the same locality, with perhaps a delight similar to that experienced by the traveller, who, after visiting distant countries, once more returns to the bosom of his cherished family!"

CHAP. IV.

OF THE SHELL OF TESTACEOUS FISHES.

One is apt to combine very dissimilar objects in the same group, when hurried into the vortex of method. No two animals are more unlike each other than the whale and the limpet, the tortoise and the oyster. Yet, as these animals must find some place in the picture of animated nature, it is best to let them rest in the station which the generality of mankind have assigned them; and as they have been willing to give them all from their abode the name of fishes, it is wisest in us to conform.

But before I enter into a history of shell-fish, it may not be improper to observe, that naturalists, who have treated on this part of history, have entirely attended to outward forms; and, as in many other instances, forsaking the description of the animal itself, have exhausted all their industry in describing the habitation. In consequence of this radical error, we have volumes written upon the subject of shells, and very little said on the history of shell-fish. The life of these industrious creatures, that, for the most part, creep along the bottom, or immovably wait till driven as the waves happen to direct, is almost entirely unknown. The wreathing of the shells, or the spots with which they are tinctured, have been described with a most disgusting prolixity; but their appetites and their combats, their escapes and humble arts of subsistence, have been utterly neglected.

As I have only undertaken to write the history of animated nature, the variety of

shells and their peculiar spots or blemishes, do not come within my design. However, the manner in which shells are formed is a part of natural history connected with my plan, as it presupposes vital force or industry in the animal that forms them.

The shell may be considered as a habitation supplied by nature. It is a hard stony substance, made up somewhat in the manner of a wall. Part of the stony substance the animal derives from outward objects, and the fluids of the animal itself furnish the cement. These united make that firm covering which shell-fish generally reside in till they die.

But, in order to give a more exact idea of the manner in which sea-shells are formed, we must have recourse to an animal that lives upon land, with the formation of whose shell we are best acquainted. This is the garden-snail, that carries its box upon its back, whose history Swammerdam has taken such endless pains to describe. As the manner of the formation of this animal's shell extends to that of all others that have shells, whether they live upon land or in the water, it will be proper to give it a place before we enter upon the history of testaceous fishes.

To begin with the animal in its earliest state, and trace the progress of its shell from the time it first appears—The instant the young snail leaves the egg, it carries its shell or its box on its back. It does not leave the egg till it is arrived at a certain growth, when its little habitation is sufficiently hardened. This beginning of the shell is not much bigger than a pin's head, but grows in a very rapid manner, having at first but two circumvolutions, for the rest are added as the snail grows larger. In proportion as the animal increases in size, the circumvolutions of the shell increase also, until the number of these volutes come to be five, which is never exceeded.

The part where the animal enlarges its shell is at the mouth, to which it adds in proportion as it finds itself stinted in its habitation below. Being about to enlarge its shell, it is seen with its little teeth biting and clearing away the scaly skin that grows at the edges. It is sometimes seen to eat those bits it thus takes off; at other times it only cleans away the margin when covered with films, and then adds another rim to its shell.

For the purposes of making the shell, which is natural to the animal, and without which it could not live three days, its whole body is furnished with glands, from the orifices of which flows out a kind of slimy fluid, like small spider threads, which join together in one common crust or surface, and in time condense and acquire a stony hardness. It is this slimy humour that grows into a membrane, and afterwards a stony skin; nor can it have escaped any who have observed the track of a snail; that glistening substance which it leaves on the floor or the wall, is no other than the materials with which the animal adds to its shell, or repairs it when broken.

Now to exhibit in a more satisfactory manner the method in which the shell is formed —The snail bursts from its egg with its shell upon its back; the shell, though very simple, is the centre round which every succeeding convolution of the shell is formed, by new circles added to the first. As the body of the snail can be extended no where but to the aperture, the mouth of the shell only can, of consequence, receive augmentation. The substance of which the shell is composed is chiefly supplied by the animal itself, and is no more than a slimy fluid which hardens into bone. This fluid passes through an infinite number of little glands, till it arrives at the pores of the skin; but there it is stopped by the shell that covers the part below; and therefore is sent to the mouth of the shell, where it is wanted for enlargement. There the first layer of slime soon hardens; and then another is added, which hardens also, till in time the shell becomes as thick as is requisite for the animal's preservation. Thus every shell may be considered as composed of a number of layers of slime, which have entirely proceeded from the animal's own body.

But though this be the general opinion with regard to the formation of shells, I cannot avoid thinking there are still other substances besides the animal's own slime which go to the composition of its shell, or at least to its external coat, which is ever different from the internal. The substances I mean are the accidental concretions of earthy or saline parts, which adhere to the slimy matter upon its first emission.[1] By adopting this theory, we can more satisfactorily account for the various colours of the shell, which cannot be supposed to take its tincture from the animal's body, as is the usual opinion; for all the internal parts of the shell are but of one white colour; it is only the outermost layer of the shell that is so beautifully varied, so richly tinctured with that variety of colours we behold in the cabinets of the curious. If the external coat be scaled off, as Mr Argenville asserts, all the inner substances will be found but of one simple colouring; and consequently the animal's own juices can give only one colour; whereas we see some shells stained with a hundred.

[1] Our author is mistaken in supposing that any part of the shell is composed of extraneous matter. If such were the case, the same species of shell would often be found to differ in its composition and external appearance, whereas some species are so uniformly alike, that it is difficult to distinguish between two shells.

The usual way of accounting for the different colouring of shells, which seems to me erroneous, is this; in the body of every one of these animals, several streaks are discerned of a different colour from the rest. "This variety," say they, "is an incontestable proof that the juices flowing from these parts will be also of a different hue; and will consequently tinge that part of the shell which their slime composes of a different colour." But this system, as was observed before, is overthrown by the fact, which discovers that only the outer surface of the shell is tinged; whereas by this it would have been coloured throughout; nay, by this system, the internal parts of the shell would be stained with the most vivid colouring, as being least exposed to the external injuries of the element where it is placed. But the truth is, the animal residing in the shell has none of these various colours thus talked of: its slime is a simple pellucid substance; and the only marblings which appear in its body, are the colour of the food, which is seen through its transparent intestines. We must, therefore, account for the various colouring of its shell upon a different principle.

If, as I said, we examine the cabinets of the curious, we shall find shells with various and beautiful colouring; we shall find them generally furnished with a white ground, tinctured with red, yellow, brown, green, and several other shades and lovely mixtures, but never blue. Shells are of almost all colours but blue. The reason seems to be obvious; for blue is the colour which sea-water changes. A piece of silk, or a feather, of this colour, put into an infusion of salt, urine, or nitre, lose their tint entirely. Now may not this give us a hint with respect to the operation of nature in colouring her shells? May we not from hence conclude, that sea-water is efficacious in giving colour, or taking it away? That, to produce colour, the animal not only furnishes its juices, but the sea or the earth that mixture of substance which is to unite with them? Neither the animal slime alone, nor the external earthy or saline substances alone, could produce colours; but both united, produce an effect which neither, separately, was possessed of. Thus shells assume every colour but blue; and that sea-water, instead of producing, would be apt to destroy.

From hence, therefore, it appears, that the animal does not alone tincture its own shell; but that external causes co-operate in contributing to its beauty. It is probable that, from the nature of its food, or from other circumstances unknown to us, the external layers of its slime may be of different consistences; so, as when joined with the particles of earth or salt that are accidentally united with them from without, they assume various and beautiful hues. But the internal layers, which receive no foreign admixture, still preserve the natural colour of the animal, and continue white without any variation.

Thus far we see that the animal is not wholly the agent in giving beauty and colouring to its shell: but it seems otherwise with respect to its convolutions, its prominences, and general form. These entirely depend upon the art of the animal; or rather upon its instincts; which, in the same kinds, are ever invariable. The shell generally bears some rude resemblance to the body upon which it has been moulded. Thus, it is observable in all sea-shells, that if the animal has any tumour, or excrescence on its body, it creates likewise a swelling in that part of the incrustation to which it corresponds. When the animal begins to alter its position, and to make new additions to its apartments, the same protuberance which had raised the shell before in one part, swells it again at some little distance; by which means we see the same inequality, in a spiral line, all round the shell. Sometimes these tumours of the animal are so large, or so pointed, that those which rise over them in the incrustation appear like horns: after this the animal disengages itself from its first cavities; and then, by fresh evacuations, assumes a new set of horns; and so increases the number in proportion to its growth. If, on the other hand, the body happens to be channelled, the shell that covers it will be channelled likewise; if there be any protuberances in the body, which wind in a spiral line about it, the shell will likewise have its tumours and cavities winding round to the end.

In this manner, as the animals are of various forms, the shells exhibit an equal variety. Indeed, the diversity is so great, and the figures and colours so very striking, that several persons, with a kind of harmless indolence, have made the arrangement of them the study and the business of their lives. Those who consult their beauty alone, take care to have them polished, and to have an external crust, or periosteum, as Swammerdam calls it, scoured off from their surfaces by spirit of salt. But there are others that, with more learned affectation, kept them exactly in the state in which they have been found, with their precious crust still round them. The expense men have sometimes been at, in making such collections, is amazing; and some shells, such as the Stairs-shell, or the Admiral-shell, are not more precious for their scarceness, than pearls are for their beauty. Indeed, it is the scarcity, and not the beauty of the object, that determines the value of all natural curiosities. Those shells that offer but

little beauty to the ignorant are often the most precious; and those shells which an unlearned spectator would stop to observe with admiration, one accustomed to the visitation of cabinets would pass over with disdain.—These collections, however, have their use; not only by exhibiting the vast variety of Nature's operations, but also by exciting our curiosity to the consideration of the animals that form them. A mind that can find innocent entertainment in these humble contemplations is well employed; and, as we say of children, is kept from doing mischief. Although there may be nobler occupations than that of considering the convolutions of a shell, yet there may be some who want the ambition to aspire after such arduous pursuits; there may be some unfit for them; there may be some who find their ambition fully gratified by the praise which the collectors of shells bestow upon each other. Indeed, for a day or two, there is no mind that a cabinet of shells cannot furnish with pleasing employment. "What can be more gratifying," as Pliny says,[1] "than to view nature in all her irregularities, and sporting in her variety of shells! Such a difference of colour do they exhibit! such a difference of figure! flat, concave, long, lunated, drawn round in a circle, the orbit cut in two! some are seen with a rising on the back, some smooth, some wrinkled, toothed, streaked, the point variously intorted, the mouth pointing like a dagger, folded back, bent inwards! all these variations, and many more, furnish at once novelty, elegance, and speculation."[2]

[1] Plin. ix. 33.

[2] *Conchology.*—Aristotle had three orders of Testacea,—Univalves, Bivalves and the Turbinated,—but the class itself and these divisions were loosely defined; and the same vagueness is to be found in the writings of those authors who followed his method. Perhaps Dr Walter Charleton, Physician in Ordinary to Charles II. was the first who had a full conviction of the importance of system, but his attempt to arrange the Mollusca is very faulty.* The Limaces he places with apodous insects; and aquatic animals being divided as usual into the sanguineous and exsanguineous, the remaining molluscas are arranged under two classes—viz. the *mollia* or *molluscula* and the *testacea*. The first embraces all the cuttles and the Lepus marinus or Aplysia; the second the shelled tribes, whose primary sections are the same as those of Aristotle's, while his genera, in general without definitions, rest on characters of little or no value. Jean-Daniel Major, Professor of Practical Medicine in the university of Keil, in the duchy of Holstein, was the next to make the attempt, (1675,) which is pronounced by two critics, to whose opinion much deference has been shown, to be "infinitely too complicated and ramifying to admit of any useful application." Sibbald, Grew, Bonanni, Lister, Langius, Hebenstreit, Tournefort, D'Argenville, and Klein are perhaps the principal who followed in their wake, but it is evident that they had all entered on their task without a previous study of what the real object and use of method

* Onomastikon Zoikon. Lond. 1671. 4to.

With respect to the figure of shells, Aristotle has divided them into three kinds: and his method is, of all others, the most conformable to nature. These are, first the *univalve*,

was, what principles were to guide them in framing the various sections, or what the relative bearing of these divisions on one another should be. The division of shells primarily into Multivalve, Bivalve, and Univalve had perhaps superseded the Aristotelian, and many new divisions of secondary rate were of course invented, but they were arbitrary, founded on no common principle, either too lax or too complex to be applicable in practice, cumbersome to the memory, and clumsy in writing. To analyse these methods would be wearisome and unprofitable,—they were next to useless when promulgated, and have now no attraction even in the eyes of the pure conchologist. It is when we rise from their examination that we are in the best mood to appreciate the merits of Linnæus

Linnæus having, with a tact characteristic of his genius for system, divided invertebrated animals into two great classes—*Insecta* and *Vermes*,—was less happy in his reduction of the latter into their secondary groups or orders. The testaceous mollusca occupy one order by themselves, in which there are four sections of equal value—the multivalve, bivalve (*Conchæ*,) the univalves with a regular spire (*Cochleæ*), and the univalves without a regular spire.† In each section there are several genera defined with neat precision,—the characters of the multivalves being derived from the position of the valves —of the bivalves from the number and structure of the hinge-teeth, or, in the absence of these, from a part influencing the opening of the valves,—of the Cochleæ from the unilocular or multilocular shell, but in most from the formation of the aperture; while in the last division the shape of the shell affords the means of discriminating them, excepting in Teredo, which is defined "T. intrusa ligno," in evident contrariety to his principles and his better custom. The naked tribes are placed in the order denominated "Mollusca," where they stand, in "admired disorder," with radiated zoophytes, annelidans, parasitical worms, and the Echinodermata, which latter, however, are better in this strange miscellany, than they were when they stood either amongst simple or multivalved shells.

In estimating the merits of this system it is not fair to look back from our present vantage ground, and magnify its defects by a comparison with modern classifications: we are in candour to place ourselves behind its author, and looking forward, say how far his efforts have been useful or quickening.‡ Standing thus we trust to offend none of his admirers when we admit that there is nothing in its principle of a novel character: the soft mollusca were previously recognized and better assorted by Charleton; and every one of the sections, and, if we mistake not, of the genera also, of the shelled tribes, had been already recognized. It labours under the censure of having too small regard to the animal, a censure in some degree just, for assuredly more was known of these than the definitions of the "Systema," would lead us to suppose; and it had still less regard to the position of the groups in reference to their organical affinities. It often associates species of dissimilar habits; and species are found in almost every genus at variance with the character of this, and where consequently the student ought not to have sought for them. The superiority of it lies in its simplicity; in the regulated subor-

† The expounders of Linnæus' system do not adopt this last division,—why, it is difficult to say. By disregarding it they have injured the naturalness of the method.

‡ The first edition of the 'Systema Naturæ,' was published in 1735, but 1758 is properly the year which gave birth to his conchological system, when the tenth edition was published. It was perfected in 1766.

or *turbinated*, which consists of one piece, like the box of a snail; secondly, the *bivalve*, consisting of two pieces, united by a hinge, like an oyster; and, thirdly, the *multivalve*, consisting of more than two pieces, as the Acorn-shell, which has not less than twelve pieces that go to its composition. All these kinds are found in the sea at different depths, and

dination of all its parts; in the admirable sagacity with which the families or genera are limited; in the assumption of more stable characters for these, and for the clear distinct manner in which they are applied; in the suitableness of its nomenclature; in the invention of trivial names which give a facility in writing hitherto unknown, and was a welcome relief to the memory; in the conciseness of the specific characters and the skill with which those characters were chosen; in the regular indication of the stations which the species occupy on the globe; and in the beauty of the more extended descriptions, and the peculiar felicity of language in which the thoughts suggested by any remarkable structure in the species under review are conveyed to us. That merits of this kind should secure him something more than approbation was natural: there was much excellence in it which prejudice or jealousy only could not see, and which folly alone would have rejected; and while every collector and amateur found it easy to be understood, ready in practice, and neat in nomenclaturing their cabinets, their pursuit assumed the garb of science when they could tell the scorner that they were following the steps, and had the sanction, of a man whose genius has justly won him a place in the first rank of those whom succeeding ages continue to venerate for the good they have done in the promotion of useful knowledge.

While the eyes of almost all were turned to this northern luminary for light to guide them in their pursuit, or as an object by barking at which a few drew notice on their littleness, Jussieu of Paris, the admirer of Linnæus' genius and industry, and his correspondent, was explaining to his select but few disciples the principles of what has been commonly called the "Natural System." Jussieu's profound studies were confined to botany, but he had colleagues and contemporaries who attempted their application to conchology, and whose want of success is to be ascribed mainly to the meagreness of the anatomy of the mollusca then attained, to the fewness of the observations made on the living species, and in part also to the imperfection of the views of the authors. Daubenton, the colleague of Buffon, so early as 1743, insisted on a knowledge of the animal as necessary to form a natural classification of shells; and in 1756, Guttard, who was the personal friend of Jussieu, not only gave his sanction to this opinion, but showed its practicability and excellence by defining, from the peculiarities of the animal and shell combined, a considerable number of the univalves, comprehending among these, in evident agreement with their relations, though contrary to general use, the slugs, the Aplysia, and the Bullæa. But the fullest attempt of this kind was made by Adanson, whose work on Senegal was published some years before Linnæus had given the last revision to his system. Impelled by an indomitable enthusiasm, Adanson visited Senegal, under many disadvantages, to examine and describe the natural productions of a tropical climate; and for this purpose he made very extensive collections in every department of nature, but of his great work the first volume only, containing the outline of his travels and his account of the shells, was ever given to the people. The character of this volume has risen with the progress of the science, and it is more valued by the conchologists of the present day than it was by the contemporaries of its author. He had some personal peculiarities—too visible in his writings—which could not fail to hurt his popularity: an austere temperament, which caused him to treat his fellow-labourers with contemptuous acerbity,—a mind that would neither bend to nor treat with respect the prejudices, as he deemed them, of his age,—an unflinching severity in criticising the writings of others, and a pertinacious tenacity of his own views,—while some barbarisms he attempted to introduce into the nomenclature of conchology repelled the naturalists of a too nice taste, and the very extent of his requirements from those who claimed to be naturalists operated against him, for it was not to be supposed that mere collectors or virtuosos were to enter on so difficult a path, or would be willing to allow themselves to be pushed aside as idlers, and put without the pale of the scientific circle. Shell-fish were, according to him, distinguishable, in the first place, into "Limaçons" and "Conques;" the former were subdivided into univalves and operculated univalves, and the conques into bivalves and multivalves; these primary families were still further divided into smaller groups from the position of the eyes in the Limaçons, and from the figure of the respiratory tubes in the Conques. Now it was a pure arbitrariness in him to fix upon the operculum as a part or organ of primary value, for there is nothing in its use or position to justify the choice, nor did he attempt, by any analysis, to show that it was a regulator of structure and habits; and it was equally arbitrary to divide the bivalves into two sections on the mere existence of a few additional pieces over the hinge, for these pieces were not proved to be an index to the animal's economy. But Adanson's services to conchology are very great,—of those of its labourers who have passed in review we place him next to Lister. He has the merit of having altogether removed from the Testacea the Lepas and Balani, whose structure he saw was modelled after the type of another category; his interesting discovery of the Vermetus was a fine illustration of the shell being of itself useless as a character in natural history; and his knowledge of affinities was made evident by the acuteness which led him to approximate the Teredo to the Pholas. If not the first to point out the importance of the operculum, he was undoubtedly the first who knew its value as an index to natural relationship between genera; perhaps the first who was fully aware that the entireness or canaliculate formation of the aperture of the shell gave an insight into the habits of the snail in regard to food; the first too to point out fully the influence of age and sex in altering the shape of the shell, and more especially of its aperture; the first to describe and delineate the animal tenant of many genera; and although his attention was exclusively directed to external characters, yet we are above all indebted to him for his strong advocacy of the maxim that the anatomy of the animal was the sole sure foundation of a rational arrangement which had in view the mutual affinities of the objects it attempted to classify, and present them not fancifully commixed as they might be placed in a museum, but according to those characters which nature itself had given them of affinity or dissemblance.

The example of Adanson was followed by Geoffroy who, in a history of the shells found in the vicinity of Paris, attempted to arrange them on the external anatomy of their animals; and by Muller, who described in the same manner the mollusca of the north of Europe. The writings of Muller are still deservedly held in high estimation. They contain the descriptions of many novelties, and his descriptions of them, as well as of species previously known, are remarkable for their accuracy; they are thickly strewed with notices of the external anatomy and habits of those he had examined alive; and his style of writing is interesting, rising occasionally to eloquence. As an observer and teller of what he had observed, he claims a place among the first,

are valuable in proportion to their scarceness or beauty.

From the variety of the colours and figures of shells, we may pass to that of their place and situation. Some are found in the sea; some in fresh-water rivers; some alive upon land; and a still greater quantity dead in the bowels of the earth. But wherever shells

---

but he was the discoverer of no fact in their structure or physiology of any consequence—we speak in reference to the mollusca only; and his systematic efforts were limited and partial, although he sometimes drops a hint on the subject, which makes us almost believe that he was capable of better things, had he had courage to have made the attempt. In relation to the mollusca, he clearly saw the impropriety of making the presence or absence of the shell an ordinal character; and he knew, vaguely it may be, the affinity between the bivalvular mollusca and the Tunicata.

The celebrated Pallas was another who at this period had obtained a glimpse of the true relations of the mollusca as a class even clearer than Muller, but he did not pursue the subject, and as his slight incidental notice, though it might have originated inquiry in a predisposed mind, was not otherwise of a nature to produce any effect, so the pains of Geoffroy and Muller were equally unproductive. The authority of Linnæus prevailed every where. The force of his genius having swept away all previous systems, there was no other safety for a naturalist, than to take refuge in the Linnæan ark, which floated on the surface proud amid the ruins, —the systems of his contemporaries also sinking one after another in the waters of forgetfulness. His disciples were distinguished by their enthusiasm in the pursuit of nature, and their love of their master; and the facility with which they found their discoveries were registered, and the easy nature of the discoveries which sufficed to give them a certain reputation, requiring nought but zeal, opportunity, and a knowledge of the 'Systema' not difficult to be acquired, rivetted their attachments. In England nothing was tolerated that was not according to the letter of Linnæus: his works were a code of laws which, like an act of Parliament, was to be interpreted verbally, and the spirit of them was unseen or overlooked. Under his reforming hand, Conchology having passed 'from confusion and incongruity to lucid order and simplicity,' the slightest attempt to alter this order was treated as an attempt to replunge us into the chaos, whence he had brought us, and further improvement or alteration was declared to be futile, since the 'beauties' of the Linnæan 'must perpetuate its pre-eminence.' Were it shewn that, from the very subsidiary station the animal was made to occupy in this system, there was a fear attention should be drawn from the object most worthy of it, we were seriously told that the animal, even could it be procured, which was doubtful, would never present those 'permanent and obvious points of distinction' indispensable in the application of a system meant to be practical. Wherein does the animal differ, it was asked in a tone of triumph, signifying that reply was impossible,—'wherein does the animal differ from an unshapen mass of lifeless matter when coiled up within its shelly habitation? And how are its natural shape and appendages to be examined, but by the knife of an anatomist?' Were it proved, what indeed was most palpable, that species of opposite habits and habitations were huddled together under a common head, it was answered that to derive characters from such particulars was contrary to axiom and unphilosophical; and if it were demonstrative that the class of Testacea, as a whole, was constituted of heterogeneous disparates,—as for example, when Pallas indicated the difference between this class and the Serpulæ,—what then? Nature gloried in variety and oppositions, and was herself systemless, as if it were possible to believe that He who made every thing in wisdom and order had shook His creatures from his hand, with the same wanton unordered profusion that the poet has represented the jocund May, flinging the flowerets from her teeming lap. Such were the futile reasons by which this System was upheld, and so firm was its despotism that, until within these twenty years, there was little or no relaxation on its hold of public opinion; and its evil effects are too evident in the superficialness of the productions which emanated from this school.

Even in France the Linnæan system soon became little less predominant under the leading of Bruguiere, but the regard the French paid to it was of a less slavish character than it had assumed in Britain. Bruguiere, though a Linnæan in principle, carried forward in some degree the system of his master by intercalating several new and obviously necessary genera; and he was otherwise a conchologist of higher attainments than any England could at that period boast of. He cannot be said to have promoted conchology in any very sensible degree, but he made no effort to arrest it, or detain the science at the stage where Linnæus had left it. Nor indeed is it perhaps possible to stop the march of any, however trivial the branch of science, to perfection. Like the operations of Nature in her living productions ever tending to maturity, there are periods of acceleration and delay, and causes may for a season induce a sickly weakness that waits long for a remedy, but come at last this will. Conchology was now in her sickly time,—nevertheless in a state of constant advancement. Ellis, Baster, Bohadtch, Pallas, Muller, Forskal, Solander, and Otho Fabricius, all of whom might have seen Linnæus in the flesh, and were his immediate successors, drew attention to the naked molluscans in particular, whose curious variety was enticing and provocative to further quest; Herissant, Scopoli, Bruguiere, and Olivi, described many species with their animals, and entered too into physiological questions which it was worthy reasonable men to solve; Knorr, Davila, Martini and Chemnitz, Schroter, Born, Pennant, Da Costa, and Martyn, set forth at intervals volumes of figures more numerous in species and more correct than had been hitherto attempted; and the minute or microscopic species, which notwithstanding their littleness have played a most important part in the revolutions of our globe, were well illustrated in the works of Soldani, Plancus, Boys and Walker, and of Fichtel and Moll. Yet this array of names only proves a wider spread of the study, —the students may have been, and we think were, mediocrists,—many of them were simply ichniographists and collectors.* We can remember no discovery by which to distinguish the period, for the developement or improvement of an artificial system, the accumulation of species, and their more accurate discrimination, though points of considerable importance, are not sufficiently so to mark an era. Perhaps the most curious and interesting discovery that was made in it is that of the capability of the snail to reproduce its tentacula, eyes, and head, when these have been cut off,—the phenomena of which singular reintegration were amply elucidated by the experiments of Spallanzani, Bonnet, and others.

* It is most especially necessary to except from this remark John Hunter, but his labours and views were not published, and were not appreciated. 'John Hunter was a great discoverer in his own science; but one who well knew him has told us, that few of his contemporaries perceived the ultimate object of his pursuits; and his strong and solitary genius laboured to perfect his designs without the solace of sympathy, without one cheering approbation.'—D'Israeli's Literary Character, Vol. i. p 146. See Abernethy's Physiological Lectures p. 193, for a list of the Mollusca anatomized and exhibited in Hunter' Museum; also p. 217, 263.

are found, they are universally known to be composed of one and the same substance. They are formed of an animal or calcareous earth, that ferments with vinegar and other acids, and that burns into lime, and will not easily melt into glass. Such is the substance of which they are composed; and of their spoils, many philosophers think that a great

The first to raise us from this enchained slumber was Cuvier. Before this great naturalist entered the field, Poli, a Neapolitan physician, had indeed anatomized with admirable skill the bivalved mollusca of his native shores, and had constructed a new arrangement of them from the characters of the animal alone, but partly from the political position of Europe, partly from the very expensive fashion in which Poli's work was published, and its consequent extremely limited circulation, and in part also from the partial application of his system and its didactic character, the erroneousness of his general views, and the novelty of his nomenclature,—we cannot trace its influence either as diffusive or propulsive of conchology. The result of Cuvier's labours was happily very different. In 1788,-when he was scarcely nineteen years of age, circumstances fixed Cuvier for a time at Caen in Normandy. His sojourn on the borders of the sea induced him, already an enthusiast in natural history, to study marine animals, more especially the mollusca, and the anatomies of them which he now made conducted him to the developement of his great views on the whole of the animal kingdom. With unwearied zeal he collected the materials which were at no distant date to become the basis of a classification which ran through all its details in a harmonious parallelism with the developement of organization, so that the student of it, when in search of the name and place of the object in his hand, was necessitated simultaneously to acquire a knowledge of its principal structural peculiarities, on which, again, as Cuvier beautifully explained, all its habits in relation to food, to habitation, and to locomotion, were made dependant. The Linnæan system of avertebrated animals, even in its primary sections, rested on a single external character. The Insecta were *antennulated*, and the Vermes were *tentaculated* avertebrates. Had the character been constant or even general, it might have had some claim for adoption, but to a want of constancy was added the fundamental defect of its inappreciable influence over the organisms of the body. Cuvier's object being to give us not merely a key to the name, but to make that key open at the same time a knowledge of the structure and relations of the creature, such arbitrary assumption of a character was to him useless. After innumerable dissections had made him familiar with many structures, and after a careful consideration of the respective value of characters, as shown in their constancy and influence on the economy of the species, Cuvier resolved to divide the animal kingdom, not as hitherto into two, but into four principal sub-kingdoms, drawing their lines of separation from differences exhibited in the plan on which their muscular, their nervous, and their circulating systems were formed. "There exist in nature," he says, "*four* principal forms, or general plans, according to which all animals seem to have been modelled, and the ulterior divisions of which, whatever name the naturalists may apply to them, are but comparatively slight modifications, founded on developement or addition of certain parts, which do not change the essence of the plan." Of these forms the mollusca furnish the second, of which the essential character is derived from the peculiar arrangement of the nervous system, consisting of some ganglions scattered as it were irregularly through the body, and from each of which nerves radiate to its various organs. As there is no skeleton, so the muscles are attached to the skin, which forms a soft contractile envelope protected, in many species, by a shell. The greater number possess the senses of taste and sight, but the last is often wanting. "Only one family can boast of the organ of hearing; they have always a complete system of circulation, and organs peculiarly adapted to respiration; those of digestion and secretion are nearly as complicated as the same organs in vertebrated animals." The sub-kingdom, characterized and limited by those important features, is next divided into six classes, the characters of which are mostly derived from the organs of locomotion, or others not less influential. Thus the Cephalopodes bear their feet and arms like a coronet round the summit of the head; the Pteropodes swim in their native seas by fin-like oars; and the Gasteropodes crawl on the belly by means of a flat disk or sole. Reaching now tribes among whom the organs of motion are less developed, and accordingly less influential on their manners, Cuvier resorts to others. Thus the fourth class is named Acephalés, because it is strikingly distinguished by the want of head and amorphous form of its constituents; the Brachiopodes are equally acephalous, but near the mouth they have two fringed fleshy organs which simulate feet; and the Cirropodes have several pairs of subarticulated fringed feet, in addition to a multivalved shell of a peculiar construction. The orders of these classes, when the class admits of further subdivision, rest upon distinct differences in the structure and position of the branchiæ or respiratory organs; and when we reflect a moment on the paramount necessity of these to the animal, and their necessary co-adaptation to its locality and wants, it is scarcely possible to conceive that a happier choice could have been made.*

Early in 1799, Lamarck published his *Prodromus* of a new classification of shells, laying down, more precisely, the generic characters, and establishing many new genera, and still continuing the old division into *univalves*, *bivalves*, and *multivalves*. Up to this time, Lamarck does not seem to have profited much by the labours of his predecessors towards the establishment of a natural conchyliological method, but acknowledges that he has adopted the principles and views of Bruguiére. Late in 1799, Cuvier published a table of the divisions of the class of *mollusca*, at the end of the first volume of his Lessons of Comparative Anatomy. We see, in this, that Cuvier derived light from the *Prodromus* of Lamarck. Indeed, these two great naturalists, by their successive works, seem to have afforded light alternately to each other for a number of years. In 1801, Lamarck published his *Animaux sans Vertèbres*, in which, not confining himself entirely to the shells, he has, like Cuvier, paid atttention also to the animals. From this period until 1822, when he finished publishing the second edition of *Animaux sans Vertèbres*, under the title of *Histoire naturelle des Animaux sans Vertèbres*, many authors, both continental and British, had published memoirs and treatises on conchology, and many interesting facts had been collected, shedding much additional light on the science. Part of the 5th and the whole of the 6th and 7th volumes of the *Histoire naturelle des Animaux sans Vertèbres*, are devoted to the conchyliophorous animals, the proper subjects of conchology. In this excellent work, Lamarck has improved upon the views of his friend Bruguiére in the following particulars:—not confining himself to the consideration of the shell; viewing the shell as forming part of an animal; introducing into conchology a great number of new generic groups; using a very rigorous and exact terminology;

* For the above sketch of the different systems of conchology, we are indebted to an elaborate article on the History of Conchology, in the *Magazine of Zoology and Botany*, Edinburgh. 1838. Vol. II.

part of the surface of the earth is composed at present. It is supposed by them, that chalks, marls, and all such earths as ferment with vinegar, are nothing more than a composition of shells, decayed, and crumbled down to one uniform mass.

Sea-shells are either found in the depths of the ocean, or they are cast empty, and forsaken

---

and treating as the foundation of the principal division among bivalves, the number of the muscular impressions. He has also abandoned the divisions, multivalves, bivalves, and univalves, which had been followed by most of the preceding conchologists, and has increased the number of genera to 261.

Synoptical Table of the Generic Characters of Lamarck's Conchological System; arranged according to the descending scale; with some additional genera, distinguished by an asterisk.

CLASS I.—MOLLUSCA UNIVALVES.

ORDER. I.—HETEROPODA.

Having a head; two eyes; no arms; body free; swims horizontally; destitute of a foot; fins, but irregular.
Phytliroe and *Pterotrachea*, destitute of shells.
Carnaria, *Cymbium*, pl. 31. fig. 1.

ORDER II.—CEPHALOPODA.

DIVISION I.—CEPHALOPODA SEPIARIA.

FAMILY I.—AMMONACEA.

Mantle bag-shaped; head protruding from the bag, with inarticulate arms, having suckers around the mouths; two eyes; mouth with horny mandibles.
The genera are *Sepia*, *Loligo*, *Loligopsis*, and *Octopus*, all destitute of shells.

DIVISION II.—CEPHALOPODA MONOTHALAMA.

Argonauta Argo, pl. 31, fig. 2.

DIVISION III.—CEPHALOPODA POLYTHALAMA.

FAMILY I.—AMMONACEA.

Baculites, *Turrilites*, *Ammonoceras*, *Orbulites*, and *Ammonites*, are fossil.

FAMILY II.—NAUTILACEA.

Nautilus pompilius, pl. 31. fig. 3. *Nummulites*, *Vorticialis*, *Polystomella*, *Siderolites*, and *Discorbis*, are fossil.

FAMILY III.—RADIOLACEA.

Placentula, *Lenticulina*, and *Rotalia*, fossil.

FAMILY IV.—SPHERULACEA.

Melonia, fossil. *Miliola concentrica*.

FAMILY V.—CRISTACEA.

Orbiculina, *Cristellarea*, and *Renulina*, principally fossil.

FAMILY VI.—LITUOLACEA.

Lituola and *Spirolina*, fossil. *Spirula Peronii*, pl. 31. fig. 4.

FAMILY VII.—ORTHOCERATA.

Conilites and *Hippurites*, fossil. *Nodosaria radicula*, pl. 31, fig. 5. *Orthocera raphanus*, fig. 5. *Belemnites*, fossil.

ORDER III.—TRACHELIPODA.

SECTION I.—ZOOPHAGOUS TRACHELIPODA.

Body of the animal spirally convolute posteriorly, separated from the foot; shell spiral enveloping the animal. This order is divided into three sections.

FAMILY I.—INVOLUTA.

Conus betulinus, pl. 31, fig. 6. *Oliva utriculus*, f. 7. *Ancillaria glandiformis*, f. 8. *Terebellum subulatum*, f. 9. *Cypræa Lynx*. f. 10. *Ovula verrucosa*, f. 11.

FAMILY II.—COLUMELLARIA.

Volvaria cylindrica, pl. 31, fig. 12. *Marginella bivaricostata*, f. 13. *Voluta scapha*, f. 14. *Mitra tæneata*, f. 15. *Columbella rustica*, f. 16.

FAMILY III.—PURPURIFERA.

Terebra vittata, pl. 31. fig. 17. *Eburna spirata*, f. 18. *Buccinum lineolatum*, f. 19. *Dolium tesselatum*, f. 20. *Harpa nobilis*, f. 21. *Concholepas Peruvianus*, f. 22. *Monoceros glabratum*, f. 23. *Purpura bicostalis*, f. 24. *Recinula arachnoides*, f. 25. *Cassis areola*, f. 26. *Cassidaria echinophora*, f. 27.

FAMILY IV.—ALATA.

Strombus succinctus, pl. 31. fig. 28. *Pterocera millepeda*, f. 29. *Rostellaria columbina*, f. 30.

FAMILY V.—CANALIFERA.

Triton scorbiculator, pl. 31. fig. 31. *Murex acanthopterus*, f. 32. *Ranella granulata*, f. 33. *Struthiolaria nodulosa*, f. 34. *Fyrula reticulata*, f. 35. *Fusus longicaudata*, f. 36. *Fasciolaria tulipa*, f. 37. *Cancellaria asperella*, f. 38. *Turbinella scolymus*, f. 39. *Pleurotoma Babylonia* f. 40. *Cerithium aluco*, f. 41.

SECTION II.—PHYTOPHAGA.

FAMILY I.—TURBINACEA.

Turitella duplicata, pl. 31. fig. 42. *Phasianella varia*, f. 43. *Planaxis undulata*, f. 44. *Turbo smaragdus*, f. 45. *Monodonta canalifera*, f. 46. *Trochus papillosus*, f. 47. *Rotella vestrarius*, f. 48. *Solarium variegatum*, f. 49.

FAMILY II.—SCALARIDES.

Delphinula laciniata, pl. 31. fig. 50. *Scalaria coronata*, f. 51. *Vermetus lumbricalis*, f. 52.

FAMILY III.—PLICACEA.

Pyramidella maculosa, pl. 31. fig. 53. *Tornatella flammea*, f. 54.

FAMILY IV.—MACROSTOMA.

Haliotis tuberculata, pl. 31. fig. 55. *Stomatia phymotis*, f. 56. *Stomatella auricula*, f. 57. *Sigaretus haliotoideus*, f. 58. *Galericulum lævi jatum*. fig. 111.

FAMILY V.—IANTHINIA.

Ianthina exigua, pl. 31. fig. 59.

FAMILY VI.—NERITACEA.

Natica stercus-muscarum, pl. 31. fig. 60. *Nerita peloronta*, f. 61. **Neritoides littoralis*, f. 112. *Neritina punctulata*, f. 62. *Navicella tesselaria*, f. 63.

FAMILY VII.—PERISTOMIDA.

Ampullaria rugosa, pl. 31. fig. 64. *Paludina vivipara*, f. 65. *Valvata depressa*, f. 66. *Pirena Madagascarensis*, f. 67. *Melanopsis costata*, f. 68. *Melania granifera*, f. 69.

FAMILY IX.—LYMNÆACEA.

Lymnæa auricularia, pl. 31. fig. 70. *Physa hypnorum*, f. 71. *Planorbis corneus*, f. 72.

FAMILY X.—COLIMACEA.

Cyclostoma bistriatus, pl. 31. fig. 73. *Auricula felis*, f. 74. *Succinea amphibia*, f. 75. *Achatina perdix*, f. 76. *Bulimus-radiatus*, f. 77. *Clausilia ventricosa*, f. 78. *Pupa unidentata*, f. 79. *Helicina major*, f. 80. *Anastoma globosa*, f. 81. *Carocolla Madagascarensis*, f. 82. *Helix nemoralis*, f. 83.

ORDER IV.—GASTEROPODA.

Body always straight, never enveloped in a shell which can entirely contain it; foot situated under the abdomen, united to the body nearly its whole length.

of their animals, upon shore. Those which are fished up from the deep, are called by the Latin name *Pelagii*; those that are cast upon shore are called *Littorales*. Many of the pelagii are never seen upon shore; they continue in the depths where they are bred; and we owe their capture only to accident. These, therefore, are the most scarce shells,

FAMILY I.—LIMACINEA.

Vitrina elongata, pl. 31. fig. 84. *Testacella Haliotoidea*, f. 85. *Limax rufus*, f. 86. *Parmacella Olivieri*, f. 87. *Onchidium*. Destitute of a shell. *P. Calyculata*, f. 108.

SECTION II.—HYDROBRANCHIÆ.

FAMILY II.—LAPLYSIACEA.

Dolabella callosa, pl. 31. fig. 88. *Laplysia radiata*, f. 89.

FAMILY III.—BULLACEA.

Bulla amygdala, pl. 31. fig. 90. *Bullæa catena*, f. 91. **Utriculus obtusa*, f. 110. **Akera flexilis*, f. 109. *Acera*. Destitute of a shell.

FAMILY IV.—CALYPTRACEA.

Ancylus fluviatilis, pl. 31. fig. 92. *Crepidula fornicata*, f. 93. *Calyptræa sinense*, f. 94. *Pileopsis Ungarica*, f. 95. *Fisurella Græca*, f. 96. **Sipho striata*, f. 113. *Emarginula fissura*, f. 97. *Parmophorus Australis*, f. 98.

FAMILY V.—SEMPHYLLIDIACEA.

Umbrella Indica, pl. 31. fig. 99. *Pleurobranchus plumula*, f. 100.

FAMILY VI.—PHYLLIDIACEA.

Patella vulgata, pl. 31. fig. 101. *Chiton marginatus*, f. 102. *Chitonellus striatus*, f. 103. *Phyllidia*. Destitute of a shell.

FAMILY VII.—TRITONIACEA.

Doris, *Tethys*, *Scyllæa*, *Titonia*, *Eolis*, and *Glaucus*. Destitute of shells.

ORDER V.—PTEROPODA.

Destitute of foot and arms; two opposite fins; body free. *Pneumodermon*. Shelless. *Cymbulia proboscidea*, pl. 31. fig. 104. *Limacina helicialis*, f. 105. *Cleodora pyramidata*, f. 106. *Clio*. Destitute of a shell. *Hyalæa cuspidata*, f. 107.

CLASS II.—CONCHIFERA. BIVALVES.

Animals soft, inarticulated, without head or eyes, and adhering to a bivalve shell; having external branchiæ, simple circulation, and a unilocular heart.

ORDER. I.—MONOMYARIA.

With one muscular attachment, and one subventral muscular impression.

SECTION I.—NO LIGAMENT.

FAMILY I.—BRACHIOPODA.

Lingula anatina, pl. 32. fig. 1. *Terebratula vitrea*, f. 3. *Orbicula Norwegica*, f. 2.

FAMILY II.—RUDISTA.

Crania striata, pl. 32. fig. 4. *Discina ostreoides*, f. 55. Gen. Birostritus, Calicola, Radiolites, and Sphærulites, fossil.

SECTION II.—LIGAMENT MARGINAL.

FAMILY I.—OSTRACEA.

Anomia Ephipphium, pl. 32. fig. 6. *Placuna sella*, f. 7. *Vulsella spongiarum*, f. 8. *Ostrea cornucopiæ*, f. 9. *Gryphæa secunda*, f. 10.

FAMILY II.—PECTINIDES.

Podopsis truncata, pl. 32. fig. 11. *Spondylus spatuliformis*, f. 12. *Plicatula cristata*, f. 13. *Pecten radula*, f. 14. *Phlagiostoma semilunaris*, f. 15. *Lima fragilis*, f. 16. *Pedum spondyloideum*, f. 17.

SECTION III.—LIGAMENT ELONGATED AND MARGINAL.

FAMILY I.—MALLEACEA.

Meleagrina margaritifera, pl. 32. fig. 18. *Avicula obliqua*, f. 19. *Malleus vulgaris*, f. 20. *Perna isognomum*, f. 21. *Crenatula phasianoptera*, f. 22.

FAMILY II.—MYTILACEA.

Pinna elegans, pl. 32. fig. 23. *Mytilus Afer*, f. 24. *Modiola papuana*, f. 25.

FAMILY III.—TRIDACNITES.

Hippopus maculatus, pl. 32. fig. 26. *Tridacna squamosa*, f. 27.

ORDER II.—DIMYARIA.

Muscular impressions two, separate and lateral.

SECTION I.—IRREGULAR AND ALWAYS INEQUIVALVE.

FAMILY I.—CAMACEA.

Etheria elliptica, pl. 32. fig. 28. *Chama arcinella*, f. 29. *Diceras arietina*, f. 30.

SECTION II.—LAMELLIPEDES.

FAMILY I.—NAYADES.

Inhabit fresh water. *Iridina exotica*, pl. 32. fig. 31. *Anadonta cygnea*, f. 32. *Hyria corrugata*, f. 33. *Unio irroratus*, f. 34.

FAMILY II.—TRIGONACEA.

Castalia ambigua, pl. 32. fig. 35. *Trigonia scabra*, f. 36.

FAMILY III.—ARCACEA.

Nucula tenuis, pl. 32. fig. 37. *Pectunculus pilosus*, f. 38. *Arca tortuosa*, f. 39. *Cucullæa auriculifera*, f. 40.

FAMILY IV.—CARDIACEA.

Isocardia Moltkiana, pl. 32. fig. 41. *Hiatella arctica*, f. 42. *Cypricardia coralliophaga*, f. 43. *Cardita crassicosta*, f. 44. *Cardium elongatum*, f. 45.

FAMILY V.—CONCHACEA.

Venericardia imbricata, pl. 32. fig. 46. **Ortygia sulcata*, f. 47. *Venus verrucosa*, f. 48. *Cytherea erycina*, f. 49. **Exoleta lincta*, f. 50. *Cyprina Islandica*, f. 51. **Lasæa rubra*, f. 52. *Galathea radiata*, f. 53. *Cyrena fuscata*, f. 54. *Cyclas cornea*, f. 55. **Pisidium obliqua*, f. 56.

SECTION III.—TENUIPEDES.

FAMILY I.—NYMPHACEA.

Crassina sulcata, pl. 32. fig. 57. *Capsa Braziliensis*, f. 58. *Donax denticulata*, f. 59. *Lucina carnaria*, f. 60. **Mysia rotundata*, f. 61. *Corbis lamellosa*, f. 62. **Arcopagia crassa*, f. 63. *Tellinides roseus*, f. 64. *Tellina punicea*, f. 65. *Psammotæa variegata*, f. 66. *Psammobia vespertina*, f. 67. *Sanguinolaria Occidens*, f. 68.

FAMILY II.—LITHOPHAGI.

Venerupis irus, pl. 32. fig. 69. *Petricola Pholadiformis*, f. 70. *Saxicava Præcisa*, f. 71.

FAMILY III.—CORBULACEA.

Pandora rostrata, pl. 32. fig. 72. *Corbula sulcata*, f. 73.

FAMILY IV.—MACTRACÆA.

Amphidesma Lucinalis, pl. 32. fig. 74. *Solemya Mediterranea*, f. 75. **Tellimya suborbicularis*, f. 76. *Ungulina transversa*, f. 77. *Erycina striata*, f. 78. *Crassatella Kingicola*, f. 79. **Ligula tenuis*, f. 80. **Mactrina triangula-*

and consequently the most valuable. The litorales are more frequent, and such as are of the same kind with the pelagii are not so beautiful. As they are often empty and forsaken, and as their animal is dead, and, perhaps, putrid in the bottom of the shell, they, by this means, lose the whiteness and the brilliancy of their colouring. They are not, unfrequently

---

ris, f. 81. *Matra Stultorum*, f. 1. *Lutraria compressa*, f. 2.

SECTION IV.—Crassipedes.

Posterior margin gaping.

Family I.—Myaria.

Anatina convexa, pl. 33. fig. 3. *Mya arenaria*, f. 4. **Galeomma Turtoni*, f. 5. **Magdala striata*, f. 6. **Myatella striata*, f. 7. **Crenella elliptica*, f. 8. **Spenia Binghami*, f. 9.

Family II.—Solenides.

Glycimeris Siliqua, pl. 33. fig. 10. *Panopea Aldrovandi*, f. 11. *Solen Vagina*, f. 12.

Family III.—Pholadaria.

Gastrochæna modiolina, pl. 33. fig. 13. *Pholas dactylus*, f. 14.

Family IV.—Tubicola.

Teredo navalis, pl. 33. fig. 15; 16, side valve; 17, one of the bivalves; 18, section of interior part of the tube. *Teredina personata*, f. 19. *Septaria arenaria*, f. 20. *Fistulana clava*, f. 21. Fig. 22. a side valve. *Clavagella aperta*, f. 23. Fig. 24 a face valve. *Aspergillum Javanum*, f. 25.

CLASS III.—CIRRIPEDA.

Animals soft, destitute of head or eyes, covered with an adhering shell.

ORDER. I.—PEDUNCULATA.

Body supported on a tubular peduncle.

Otion Cuvieri, pl. 33. fig. 26. *Cineras vittata*, f. 27. *Pollicipes mitella*, f. 28. **Scalpellum vulgare*, f. 29. *Anatifa vitrea*, f. 30.

ORDER II.—Sessilia.

Body inclosed in a multivalve shell which is seated on rocks or marine bodies; mouth and tentacula in the opening of the shell; operculated.

Pyrgoma crenata, pl. 33. fig. 31. *Creusia verruca*, f. 32. *Acasta Montagui*, f. 33. **Adna Anglica*, f. 34. *Balanus Cranchii*, f. 36. *Coronula testudinaria*, f. 37. *Tubicinilla balænarum*, f. 38.

Division III.—Articulata.

CLASS V.—Annelides.

Elongated, soft, consisting of segments; having red blood.

ORDER I.—Sedentareæ.

Animals placed in a testaceous tube, in which they ever live; branchiæ at one extremity of the body.

Family I.—Serpulacea.

Magilus antiquus, pl. 33. fig 39. *Galeolaria recumbens*, f. 40. *Vermilia triquetra*, f. 41. *Serpula tubularia*, f. 42. *Spirorbis spirillum*, f. 43.

Family II.—Amphitritæa.

Amphitrite ventilabrum, pl. 33. fig. 44. *Terebella conchilega*, f. 45. *Sabellaria crassissima*, f. 46. *Pectinaria Belgica*, f. 47.

Family III.—Maldaniæ.

Dentalium entalis, pl. 33. fig. 48. *Brochus reticulatus*, f. 49. *Cornuoides minor*, f. 50. *Clymene*.

Family IV.—Dorsaliæ.

Siliquaria anguina, pl. 33. fig. 51. *Arnicola*. Destitute of shell.

EXPLANATION OF THE PARTS OF SHELLS.

OF THE OPERCULA OF UNIVALVE SHELLS.

The opening, or aperture of many univalve shells, is covered, when the animal is withdrawn within, by an operculum or lid, intended for the protection of the inhabitant. This is attached to the foot of the animal, and is either of a horny substance, or is testaceous, being as hard as the shell itself. This appendage will be familiar to all who have seen the common periwinkle, which is abundant on most rocky shores. Its texture is of a horny nature.

Operculum of Nerita Undulata, pl. 33. fig. 52. Phasianella Bulimoides, 53. Trochus Pharaonis, 54. Melania Byronensis, 55. Neritia fluviatilis, 56. Panludina achatina, 57. Turbo Pica, 58. Neritoides littoralis, 59. Murex Brandaris, 60. Buccinum undatum, 61. Strombus Auris-Dianæ, 62. Trochus littoralis, 63.

Animal of the *Monodonta Pica* 64. *a*, the tentacula, or feelers; *b*, the trunk; *cc*, the pedicles, with the eyes at their tips; *dd*, the branchiæ or gills; *ee*, mantle; *f*, foot; *g*, the operculum; *h*, the tail, or that extremity of the animal which occupies the volutions at the tip of the shell.

The following are the shells figured, explanatory of the different parts:—Fig. 65, Fusus antiquus; 66, Voluta vespertilio; 67, A lusus naturæ of Helix Pomatia; 68, Spirula Peronii; 69, Cassis ariola; 70, Cypræa exanthema; 71, Clausilia ventricosa; 72, Planorbis Planata; 73, Crepidula aculeata; 74, Fusus discrepans; 75, Dolium galea; 76, Turitella terebra; 76,* Helix Umbilicata; 77, Cytherea Chione; 78, Hinge of Lutraria elliptica; 79, Solen truncatus; 80, Cardium elongatum; 81, Spondylus gæderopus; 82, Anomia squamula; 83, Cardium edule; 84, Venus Cassina; 85, Pecten obsoletus; 86, Pholas candidus; 87, Anatifa striata; 88, Balanus communis; 89, Operculum of Balanus Cranchii; 90, Chiton cinereus.

Apex, is the summit or tip of the spire, pl. 33. fig. 65—*a*.

Base, the opposite extremity to the apex, pl. 33. fig. 65—*b*. In simple univalves, such as the patellæ, it is the margin of the aperture, the tip of the vertex being the apex. Example of the base in a depressed shell, pl. 33. fig. 72—*b*.

Body. The lower volution of the shell in which the aperture is placed, pl. 33 fig. 65—*m*, *m*, *m*.

Front, is the place where the aperture is situated.

Back, the opposite of the front, opposed to that in which the aperture is situated.

Venter, the most bulging part of the front, pl. 33. fig. 65—*c*.

Sides, the extreme edges of the shell, pl. 33. fig. 65—*dd*. Right is the opposite to that in which the aperture is situated.

Aperture, the mouth or opening—*g*.

Beak, the elongated process at the base of many genera of univalves, pl. 33. fig. 65. *i*, f. 75—*c*.

Canal, the inside of the beak, pl. 33. fig. 65. *h*, 75—*b*.

Pillar or *columella*, is that process which runs through the spire, for the support of the volutions, f. 76—*a*, *a*.

Platted columella, is when there are folds at the base of the pillar lip, f. 66—*a*.

Pillar lip, a continuation of the enamelled process which lines the inside of the shell, and is reflected on the base of the pillar: this also is termed the *inner lip*, pl. 33. fig. 65—*k*.

Outer lip, the expansion of the body of the shell or outer edge of the aperture, pl. 33. fig. 65—*l*.

Spire, is the whole volutions of the shell but the lower one, pl. 33. fig. 65—*e*, *e*, *e*. The remaining or lower one is the body, as above noticed.

Crowned or *coronated spire*, f. 66—*b*, *b*, *b*.

Whorl, is one of the volutions, or turnings of the spire,

Depressed spire, is when the spire is partly flattened, or entirely so, as exemplified in the shells of the genus planorbis, pl. 33. fig. 72—*a*.

also found eaten through, either by worms, or by each other; and they are thus rendered less valuable; but what decreases their price still more is, when they are scaled and worn by lying too long empty at the bottom, or exposed upon the shore. Upon the whole, however, sea-shells exceed either land or fossil-shells in beauty; they receive the highest

Involuted spire. Those univalve shells which have their volutions concealed inside of the body of the shell, as in the Nautili and Cypræa, pl. 33. fig. 70.

Reversed or *Heterostrophe spire*, is when the volutions of the spire revolve in a contrary direction to that of a common screw; in which case the aperture is on the right side, in place of the left, which is the case with all dextral shells, pl. 33. fig. 71.

Detached spire, is when the volutions are not adhering together at their base, pl. 33. fig. 67.

Suture of the spire a fine thread-like line, which runs spirally between the volutions, pl. 33. fig. 65—*f, f, f, f, f.*

Sides, are the extreme edges of the shell, when the back or front is held next the observer, *d, d.*

Chambers, are the intervals, between the partitions or septa, of multilocular shells, pl. 33. fig. 68—*bb*, &c., and also occur in simple univalves, f. 73.

Siphuncle is the tube which extends through some of the multilocular univalves, pl. 33. fig. 68—*a.*

Septa, are partitions which divide the chambers in multilocular shells, f. 68—*c*, *c*, &c.

Varices, are transverse ribs which cross the volutions in some species of Murex, Triton, Buccinum, Cassis, &c., f. 69—*aa.*

Ribs, longitudinal and transverse projections, f. 75—*a a*; an example of the former; those in f. 74 illustrate the latter.

Teeth, some projecting laminæ in the aperture of univalves as represented in the aperture of pl. 33. fig. 71.

Umbilicus, a perforation in the base of the body, of Helices, Trochi, &c., pl. 33. fig. 76*—*a.*

PARTS OF BIVALVES.

Equilateral Shells, are those whose sides are alike, that is, both of a uniform size and shape, pl. 33, fig. 85.

Inequilateral Shells, have unequal sides, and of different shapes, as in Donox Lutraria, &c., pl. 33, fig. 77.

Summit, is the most elevated part of the shell, in which the hinge is usually situated, pl. 33, fig. 77—*a.*

Base, the opposite extremity of the above, pl. 33, fig. 77—*b.*

Anterior slope, is that side of the shell in which the ligament is situated, pl. 33, fig. 77—*d.*

Posterior slope. The opposite of the above, and may be distinguished by viewing the shell in front, when the beaks point to the observer, pl. 33, fig. 77—*e.*

Disk, the most prominent part of a valve, if lying with its inside undermost.

Cicatrix, the internal impression by which the animal was affixed to the shell, pl. 33, fig. 77—*gg, f* 80; *d*, f. 81—*e.*

Lunule, the crescent-shaped depressions, in the posterior and anterior slopes, pl. 33, fig. 77—*h.*

Ligament perforation, the circular aperture through which the ligament passes, as exemplified in the Anomiæ, pl. 33, fig. 82—*a.*

Hinge, that part by which the shells are united. It is generally constructed of teeth; those of the one valve fitting into a socket in the opposite one. Some shells have no teeth, but are merely kept together by the ligament, in which case they are called *inarticulate*; when they have many teeth, they are called *multiarticulate.* The *Hinge* is that part which affords the most prominent generic distinction in bivalves.

Teeth of the hinge. The number, relative situation, and construction of these, afford the best specific distinctions in bivalves. A spatuliform central tooth is exhibited, pl. 33, fig. 78.

Primary teeth, are those situated in the centre of the hinge. They are also termed the *cardinal teeth*, pl. 33, fig. 77—*i.*

Lateral teeth, are those divergent from the *umbo;* are usually long, flat, and frequently double, or divided by a groove, pl. 33. fig. 80—*a a.*

Double teeth. When teeth are very deeply cleft they are so termed.

Incurved teeth, are those which are bent round, as in the Spondylus Gæderopus, Solen Siliqua, &c., pl. 33. fig. 79.—*c.*

Recurved teeth, such teeth as are bent backwards are so termed, as in the hinge of the Panopea Aldrovandi, pl. 33. fig. 11; f. 81—*a a.*

Numerous teeth, are generally set in rows, either straight or curved as in pl. 32. fig. 37, 38, 39.

Cavity of the hinge, is a pit or hollow in which the ligament is inserted in the *Ostrea*, &c., as may be seen in pl. 32. fig. 20.

Ligament, is that cartilaginous substance by which the valves are held together, and is situated under the hinge of the shell, pl. 33. fig. 77—*k;* f. 80—*b.* The cavity in which it is inserted, f. 81—*b;* f. 83—*b.*

Beak, the extreme point or summit of bivalves, which, for the most part, is turned aside, or downwards, so that it is seldom the highest part of the bivalve.

Umbo, that part situated immediately under the beak, pl. 33. fig. 84—*a.*

Ears or *Auricles*, are those processes, situated on one or both sides of the beak, as in the scallops, pl. 33. fig. 81—*c c. Superior ear*, 85—*a. Inferior ear*, *b.*

Margin, the extreme edges of the entire shell.

Crenulated margin. When the margin is notched as in the common edible cockle it is so termed, pl. 33. fig. 80—*c c.*

Striæ, are fine thread-like lines, which traverse the exterior surface of shells, as exemplified, pl. 32. fig. 62, 63.

Spines, are exterior acutely pointed protrusions, composed of shelly matter, pl. 33. fig. 81—*d d.*

Right valve, may be distinguished by the anterior slope, pointing to the right hand, when the valve is viewed with the inside uppermost, pl. 32. fig. 46—the under valve, in many species, is flattened, as in the ostrea.

Left valve, the opposite of the above, or where the anterior slope points to the left hand, pl. 32. fig. 46.

Length of the shell—is always understood to be from that part in which the ligament is situated to the opposite extremity. Bivalve shells are called *longitudinal*, when their greatest length is from the hinge to the opposite margin, pl. 33. fig. 80 and 85, from *a* to *b*; and *transverse*, when their breadth exceeds their length —fig. 77 from *c* to *c;* and fig. 79 from *a* to *a.*

Byssus, or *beard.* An accessory filamentary appendage of a silky texture, by which some bivalve shells are affixed to rocks, stones, &c. as may be instanced in the common muscle. *Sides*—the right and left parts of the valves; pl. 33. fig. 77—*c, c.*

Ribs are longitudinal or transverse protuberances, generally running parallel to each other on the external surface of bivalves. *Longitudinal ribs*, pl. 33. fig. 83—*a. Transverse ribs*, f. 84.

Accessory valves are small, unattached valves in the genus Pholas, pl. 33. fig. 86.—*a.*

Valves of Chitons are placed transversely along the back of the animal, usually eight in number, pl. 33. fig. 90—*a, a*, &c. Fig. 91, a central valve; 92, a terminating valve.

Margin in Chitons, is a fleshy border which surrounds the valves, pl. 33. fig. 90—*b.*

PARTS OF CIRRIPEDES.—Multivalves.

Operculum—consists of from two to four small valves, placed in the opening at top of the *Balani*, pl. 33. fig. 88—*a;* f. 89.

Base—the part by which the shells of the genus Balanus, &c. are attached to rocks, pl. 33. fig. 87—*c;* f. 88—*b.*

Ligament—a membranous substance, by which the valves are attached, pl. 33. fig. 87—*d.*

Ridges—are convexities in the Balani, &c., sometimes longitudinal and at others transverse.

polish, and exhibit the most brilliant and various colouring.

Fresh-water shells are neither so numerous, so various, nor so beautiful, as those belonging to the sea. They want that solidity which the others have; their *clavicle*, as it is called, is neither so prominent nor so strong; and not having a saline substance to tinge the surface of the shell, the colours are obscure. In fresh-water there are but two kinds of shells, namely, the bivalved and the turbinated.

Living land-shells are more beautiful, though not so various, as those of fresh water; and some not inferior to sea-shells in beauty. They are, indeed, but of one kind, namely, the turbinated; but in that there are found four or five very beautiful varieties.

Of fossil, or, as they are called, *extraneous* shells, found in the bowels of the earth, there are great numbers, and as great a variety. In this class there are as many kinds as in the sea itself. There are found the turbinated, the bivalve, and the multivalve kinds; and of all these, many, at present, are not to be found even in the ocean. Indeed, the number is so great, and the varieties so many, that it was long the opinion of naturalists, that they were merely the capricious productions of nature, and had never given retreat to animals whose habitations they resembled. They were found, not only of various kinds, but in different states of preservation; some had the shell entire composed, as in its primitive state, of a white calcareous earth, and filled with earth, or even empty; others were found with the shell entire, but filled with a substance which was petrified by time; others, and these in great numbers, were found with the shell entirely mouldered away, but the petrified substance that filled it still exhibiting the figure of the shell; others still, that had been lodged near earth or stone, impressed their print upon these substances, and left the impression, though they themselves were decayed: lastly, some shells were found half mouldered away, their parts scaling off from each other in the same order in which they were originally formed. However, these different stages of the shell, and even their fermenting with acids, were at first insufficient to convince those who had before assigned them a different origin. They were still considered as accidentally and sportively formed, and deposited in the various repositories where they were found, but no way appertaining to any part of animated nature. This put succeeding inquirers upon more minute researches; and they soon began to find, that often, where they dug up petrified shells or teeth, they could discover the petrified remains of some other bony parts of the body. They found that the shells, which were taken from the earth, exhibited the usual defects and mischances which the same kind are known to receive at sea. They showed them not only tinctured with a salt-water crust, but pierced in a peculiar manner by the sea-worms, that make the shells of fishes their favourite food. These demonstrations were sufficient, at last, to convince all but a few philosophers, who died away, and whose erroneous systems died with them.

Every shell, therefore, wherever it is found, is now considered as the spoil of some animal, that once found shelter therein. It matters not by what unaccountable means they may have wandered from the sea; but they exhibit all, and the most certain marks of their origin. From their numbers and situation we are led to conjecture, that the sea reached the places where they are found; and from their varieties we learn how little we know of all the sea contains at present; as the earth furnishes many kinds which our most exact and industrious shell-collectors have not been able to fish up from the deep. It is most probable that thousands of different forms still remain at the bottom unknown; so that we may justly say with the philosopher, *Ea quæ scimus sunt pars minima eorum quæ ignoramus.*

It is well, however, for mankind, that the defect of our knowledge on this subject is, of all parts of learning, that which may be most easily dispensed with. An increase in the number of shells would throw but very few lights upon the history of the animals that inhabit them.[1] For such information we are

Peduncle, or *pedicle*—a sort of stem, or hollow membranaceous tube, on which the Anatifæ are seated, pl. 33. fig. 87—*b*.

Feelers, or *tentacula*—are those arms by which the animals of the Balani and Anatifæ secure their food, pl. 33. fig. 87—*a*.—(See a description of *Fossil* Mollusca at p. 25, Vol. I.)

[1] *Uses and Value of Shells.*—The greater part of the lime used in America for agricultural and architectural purposes, is made of calcined shells: the public streets of Christianstadt and Santa Cruz are paved with the Strombus Gigas; and the town of Conchylion is entirely built of marine shells. The blue and white belts of the Indians of North America, as symbols of peace and amity, in opposition to the war hatchet, and by which the fate of nations is often decided, are made of the Venus Mercenaria; and the gorget of the chieftain's war-dress is formed of the Mytilus Margaritiferus. The military horn of many African tribes is the Murex Tritonis; the rare variety of which, with the volutions reversed, is held sacred, and only used by the high priests. The highest order of dignity among the Friendly Islands, is the permission to wear the Cypræa Aurantium, or orange cowry. And Lister relates that the inhabitants of the province of Nicaragua fasten the Ostrea Virginica to a handle of wood, and use it as a spade to dig up the ground. As matter of traffic, they bear a nominal value and appreciation proportionate to their supposed scarcity or beauty. Rumphius is said to have given nearly a thousand pounds for one of the first discovered specimens of the Venus Dione. The Conus Cedo nulli, so very rarely offered for sale, is valued at three hundred

obliged to those men who contemplated something more than the outside of the objects before them. To Reaumur we are obliged for examining the manners of some with accuracy; but to Swammerdam for more. In fact, this Dutchman has lent an attention to those animals that almost exceeds credibility; he has excelled even the insects he dissected, in patience, industry, and perseverance. It was in vain that this poor man's father dissuaded him from what the world considered as a barren pursuit: it was in vain that an habitual disorder, brought on by his application, interrupted his efforts; it was in vain that mankind treated him with ridicule while living, as they suffered his works to remain long unprinted and neglected when dead: still the Dutch philosopher went on, peeping into unwholesome ditches, wading through fens, dissecting spiders, and enumerating the blood-vessels of a snail: like the bee, whose heart he could not only distinguish, but dissect, he seemed instinctively impelled by his ruling passion, although he found nothing but ingratitude from man, and though his industry was apparently becoming fatal to himself. From him I will take some of the leading features in the history of those animals which breed in shells; previously taking my division from Aristotle, who, as was said above, divides them into three classes: the Turbinated, or those of the Snail-kind; the Bivalved, or those of the Oyster-kind; and the Multivalved, or those of the Acorn-shell kind. Of each I will treat in distinct chapters.

CHAP. V.

OF TURBINATED SHELL-FISH, OR THE SNAIL KIND.

To conceive the manner in which those animals subsist that are hid from us at the bottom of the deep, we must again have recourse to one of a similar nature and formation that we know. The history of the garden-snail[1] has been more copiously considered than that

guineas. The Turbo Scalaris, if large and perfect, is worth a hundred guineas; the Cypræa Aurantium, without a hole beaten through it, is worth fifty; and it has been calculated, that a complete collection of the British Conchology is worth its weight in pure silver. In an economical and political view, they are of no inconsiderable import. Pearls, the diseased excrescences of mussels and oysters, form a portion of the revenues of these and some other kingdoms; and constitute, with jewels, the rich and costly ornaments by which the high and wealthy ranks of polished society are distinguished. The Cypræa Moneta, or money cowry, forms the current coin of many nations of India and Africa; and this covering or coat of an inconsiderable worm, stands at this day as the medium of barter for the liberty of man; a certain weight of them being given in exchange for a slave. The scholar needs not the reminiscence, that the suffrages of the ancient Athenians were delivered in, marked upon a shell; the record of which is still commemorated in the derivation of our terms, *testament* and *attestation*.

[1] *Garden Snails* —The most common in this country of herbivorous Trachelipods, is the Garden-snail; but the species whose history has been most copiously related, is that called in France the *Escargot*, which, though stated to have been originally imported into this country, now abounds in some parts of Surrey, and other southern countries. On the continent, especially in France, this large snail, which is more than double the size of our garden one, is used as an article of food, and though said not to be easy of digestion, is very palatable. They are thought to be in best season in the winter, when they are invested with their temporary calcareous covering, which falls off in the spring.

Early in the spring, snails lay, at different times, a great number of white eggs, varying at each laying from twenty-five to eighty, as large as little peas, enveloped in a membraneous shell, which cracks when dried. They lay these eggs in shady and moist places, in hollows which they excavate with their foot, and afterwards, cover with the same organ. These eggs are hatched sooner or later, according to the temperature, producing little snails, exactly resembling their parent, but so delicate that a sun-stroke destroys them, and animals feed upon them; so that few, comparatively speaking, reach the end of the first year, when they are sufficiently defended by the hardness of their shell.

The animal, at first, lives solely on the pellicle of the egg from which it was produced. This pellicle, consisting of carbonate of lime, united to animal substance, is necessary to produce the calcareous secretion of the mantle, and to consolidate the shell, as yet too soft for exposure. When this envelope is eaten, the little snail finds its nutriment, more or less, in the vegetable soil around it, and from which it continues to derive materials for the growth and consolidation of the shell. It remains thus concealed for more than a month, when it first issues forth into the world, and attacks the vegetable productions around, returning often to an earthly aliment, probably still necessary, for the due growth and hardening of its portable house.

These snails cease feeding when the first chills of autumn are felt; and associating, in considerable numbers, on hillocks, the banks of ditches, or in thickets and hedges, set about their preparations for their winter retreat. They first expel the contents of their intestines, and then concealing themselves under moss, grass, or dead leaves, each forms, by means of its foot, and the viscid mucus which it secretes, a cavity large enough to contain its shell. The mode in which it effects this is remarkable: collecting a considerable quantity of the mucus on the sole of its foot, a portion of earth and dead leaves adheres to it, which it shakes off on one side; a second portion is again thus selected and deposited, and so on till it has reared around itself a kind of wall of sufficient height to form a cavity that will contain its shell; by turning itself round it presses against the sides and renders them smooth and firm. The dome, or covering, is formed in the same way: earth is collected on the foot, which then is turned upwards, and throws it off by exuding fresh mucus; and this is repeated till a perfect roof is formed. Having now completed its winter-house, it draws in its foot, covering it with the mantle, and opens its spiracle to draw in the air. On closing this, it forms with its slime a fine membrane, interposed between the mantle and extraneous substances. Soon afterwards, the mantle secretes a large portion of very white fluid over its whole surface, which instantly sets uniformly,

of the elephant; and its anatomy is as well, if not better, known: however, not to give any one object more room in the general picture of nature than it is entitled to, it will be sufficient to observe that the snail is surprisingly fitted for the life it is formed to lead. It is furnished with the organs of life in a manner almost as complete as the largest animal: with a tongue, brain, salival ducts, glands, nerves, stomach, and intestines; liver, heart, and blood-vessels: besides this, it has a purple bag that furnishes a red matter to different parts of the body, together with strong muscles that hold it to the shell, and which are hardened, like tendons, at their insertion.

But these it possesses in common with other animals. We must now see what it has peculiar to itself. The first striking peculiarity is, that the animal has got its eyes on the points of its largest horns. When the snail is in motion, four horns are distinctly seen: but the two uppermost, and longest, deserve peculiar consideration, both on account of the various motions with which they are endued, as well as their having their eyes fixed at the extreme ends of them. These appear like two blackish points at their ends. When considered as taken out of the body, they are of a bulbous or turnip-like figure; they have but one coat; and the three humours which are common in the eyes of other animals, namely, the vitreous, the aqueous, and the crystalline, are, in these, very indistinctly seen. The eyes the animal can direct to different objects at pleasure, by a regular motion out of the body; and sometimes it hides them by a very swift contraction into the belly. Under the small horns is the animal's mouth; and though it may appear too soft a substance to be furnished with teeth, yet it has not less than eight of them, with which it devours leaves, and other substances, seemingly harder than itself; and with which it sometimes bites off pieces of its own shell.

But what is most surprising in the formation of this animal are the parts that serve for generation. Every snail is at once male and female; and while it impregnates another, is itself impregnated in turn. The vessels supplying the fluid for this purpose, are placed chiefly in the fore part of the neck, and extend themselves over the body; but the male and female organs of generation are always found united, and growing together. There is a large opening on the right side of the neck, which serves for very different purposes. As a vent, it gives a passage to the excrements; as a mouth, it serves for an opening for respiration; and also as an organ of generation, it dilates when the desire of propagation begins. Within this each animal has those parts, or something similar thereto, which continue the kind.

For some days before coition, the snails gather together, and lie quite near to each other, eating very little in the meantime; but they settle their bodies in such a posture, that the neck and head are placed upright. In the meantime, the apertures on the side of the neck being greatly dilated, two organs, resembling intestines, are seen issuing from them, which some have thought to be the instruments of generation. Beside the protrusion of these, each animal is possessed of another peculiarity; for, from the same aperture, they launch forth a kind of dart at each other, which is pretty hard, barbed, and ending in a very sharp point. This is performed when the apertures approach each other; and then

---

and forms a kind of solid operculum about half a line in thickness, which accurately closes the mouth. When this is become hard, the animal separates the mantle from it. After a time, expelling a portion of the air it had inspired, and thus being reduced in bulk, it retreats a little further into the shell, and forms another leaf of mucus, and continues repeating this operation till there are sometimes five or six of these leaves forming cells filled with air between it and the operculum.

The mode in which these animals escape from their winter confinement is singular. The air they had expired on retiring into their shell further and further remains between the different partitions of mucous membrane above mentioned, which forms so many cells hermetically sealed: this they again inspire, and thus acquiring fresh vigour, each separate partition, as they proceed, is broken by the pressure of the foot, projected in part through the mantle; when arrived at the operculum, they burst it by a strong effort, and finally detaching it, then emerge, begin to walk, and to break their long fast.

In all these proceedings, the superintending care and wise provisions of a Father Being are evident. This creature can neither foresee the degree of cold to which it may be exposed in its state of hybernation, nor know by what means it may secure itself from the fatal effects it would produce upon it, if not provided against. But at a destined period,—at the bidding of some secret power, it sets about erecting its winter dwelling, and employing its foot both as a shovel to make its mortar, as a hod to transport it, and a trowel to spread it duly and evenly, at length finishes and covers in its snug and warm retreat; and then, still further to secure itself from the action of the atmosphere, with the slimy secretion with which its Maker has gifted it, fixes partition after partition, and fills each cell formed by it, with air, till it has retreated as far as it can from every closed orifice of its shell—and thus barricades itself against a frozen death. Again, in the spring, when the word is spoken —*Awake!*—it begins immediately to act with energy, it re-inspires the air stored in its cells, bursts all its cerements, returns to its summer-haunts, and again lays waste our gardens.

It is worthy of remark, that the terrestrial animals of this tribe all delight in shady and moist places, and that during hot and dry weather, they seldom make their appearance;—but no sooner comes a shower than they are all in motion. It is probable that their power of motion is impeded by a dry soil, and that the grains of earth and small stones, when quite dry, adhere to their slimy feet.—*Abridged from Kirby's Bridgewater Treatise.*

the one is seen to shoot its weapon, which is received by the other, though it sometimes falls to the ground; some minutes after, the snail which received the weapon, darts one of its own at its antagonist, which is received in like manner. They then softly approach still nearer, and apply their bodies one to the other, as closely as the palms and fingers of hands when grasped together. At that time the horns are seen variously moving in all directions; and this sometimes for three days together. The coupling of these animals is generally thrice repeated, at intervals of fifteen days each; and, at every time, a new dart is mutually emitted.

At the expiration of eighteen days, the snails produce their eggs, at the opening of the neck, and hide them in the earth with the greatest solicitude and industry. These eggs are in great numbers, round, white, and covered with a soft shell: they are also stuck to each other by an imperceptible slime, like a bunch of grapes, of about the size of a small pea.

When the animal leaves the egg, it is seen with a very small shell on its back, which has but one convolution; but in proportion as it grows, the shell increases in the number of its circles. The shell always receives its additions at the mouth, the first centre still remaining; the animal sending forth from its body that slime which hardens into a stony substance, and still is fashioned into similar volutions. The garden-snail seldom exceeds four rounds and a half; but some of the sea-snails arrive even at ten.

The snail, thus fitted with its box, which is light and firm, finds itself defended, in a very ample manner, from all external injury. Whenever it is invaded, it is but retiring into this fortress, and waiting patiently till the danger is over. Nor is it possessed only of a power of retreating into its shell, but of mending it when broken. Sometimes these animals are crushed seemingly to pieces, and, to all appearance, utterly destroyed; yet still they set themselves to work, and, in a few days, mend all their numerous breaches. The same substance by which the shell is originally made goes to the re-establishment of the ruined habitation. But all the junctures are very easily seen, for they have a fresher colour than the rest; and the whole shell, in some measure, resembles an old coat patched with new pieces. They are sometimes seen with eight or ten of these patches; so that the damage must have been apparently irreparable. Still, however, though the animal is possessed of the power of mending its shell, it cannot, when come to its full growth, make a new one. Swammerdam tried the experiment; he stripped a snail of its shell, without hurting any of the blood-vessels, retaining that part of the shell where the muscles were inserted; but it died in three days after it was stripped of its covering: not, however, without making efforts to build up a new shell; for, before its death it pressed out a certain membrane round the whole surface of its body. This membrane was entirely of the shelly nature, and was intended, by the animal, as a supply towards a new one.

As the snail is furnished with all the organs of life and sensation, it is not wonderful to see it very voracious. It chiefly subsists upon leaves of plants and trees; but is very delicate in its choice. When the animal moves to seek its food, it goes forward by means of that broad muscular skin which sometimes is seen projecting round the mouth of the shell; this is expanded before, and then contracted with a kind of undulating motion, like a man attempting to move himself forward by one arm while lying on his belly. But the snail has another advantage, by which it not only smooths and planes its way, but also can ascend in the most perpendicular direction. This is by that slimy substance with which it is so copiously furnished, and which it emits wherever it moves. Upon this slime, as upon a kind of carpet, it proceeds slowly along, without any danger of wounding its tender body against the asperities of the pavement; by means of this it moves upwards to its food upon the trees; and by this descends without danger of falling, and breaking its shell by the shock.

The appetite of these animals is very great; and the damage gardeners in particular sustain from them, makes them employ every method for their destruction. Salt will destroy them, as well as soot; but a tortoise in a garden is said to banish them much more effectually.

At the approach of winter, the snail buries itself in the earth; or retires to some hole, to continue in a torpid state, during the severity of the season. It is sometimes seen alone, but more frequently in company in its retreat; several being usually found together, apparently deprived of life and sensation. For the purposes of continuing in greater warmth and security, the snail forms a cover or lid to the mouth of its shell with its slime, which stops it up entirely, and thus protects it from every external danger. The matter of which the cover is composed, is whitish, somewhat like plaster, pretty hard and solid, yet, at the same time, porous and thin, to admit air, which the animal cannot live without. When the cover is formed too thick, the snail then breaks a little hole in it, which corrects the defect of that closeness, which proceeded from too much caution. In this manner, sheltered in its hole from the weather, defended in its shell by a

cover, it sleeps during the winter; and, for six or seven months, continues without food or motion, until the genial call of spring breaks its slumber, and excites its activity.

The snail, having slept for so long a season, wakes one of the first fine days of April, breaks open its cell, and sallies forth to seek for nourishment. It is not surprising that so long a fast should have thinned it, and rendered it very voracious. At first, therefore, it is not very difficult in the choice of its food; almost any vegetable that is green seems welcome; but the succulent plants of the garden are chiefly grateful; and the various kinds of pulse are, at some seasons, almost wholly destroyed by their numbers. So great is the multiplication of snails in some years, that gardeners imagine they burst from the earth. A wet season is generally favourable to their production; for this animal cannot bear very dry seasons, or dry places, as they cause too great a consumption of its slime, without plenty of which it cannot subsist in health and vigour.

Such are the most striking particulars in the history of this animal; and this may serve as a general picture, to which the manners and habitudes of the other tribes of this class may be compared and referred. These are, the sea-snail, of which naturalists have, from the apparent difference of their shells, mentioned fifteen kinds;[1] the fresh-water-snail, of which there are eight kinds; and the land-snail, of which there are five. These all bear a strong resemblance to the garden-snail, in the formation of their shell, in their hermaphrodite natures, in the slimy substance with which they are covered, in the formation of their intestines, and the disposition of the hole on the right side of the neck, which serves at once for the discharge of the fæces, for the lodging the instruments of generation, and for respiration, when the animal is under a necessity of taking in a new supply.

But, in nature, no two kinds of animals, however like each other in figure or conformation, are of manners entirely the same. Though the common garden-snail bears a very strong resemblance to that of fresh-water, and that of the sea, yet there are differences to be found, and those very considerable ones.

If we compare them with the fresh-water snail, though we shall find a general resemblance, yet there are one or two remarkable distinctions: and, first, the fresh-water snail, and, as I should suppose, all snails that live in water, are peculiarly furnished with a contrivance by Nature, for rising to the surface, or sinking to the bottom. The manner in which this is performed, is by opening and shutting the orifice on the right side of the neck, which is furnished with muscles for that purpose. The snail sometimes gathers this aperture into an oblong tube, and stretches or protends it above the surface of the water, in order to draw in or expel the air, as it finds occasion. This may not only be seen, but heard also by the noise which the snail makes in moving the water. By dilating this it rises; by compressing it the animal sinks to the bottom. This is effected somewhat in the manner in which little images of glass are made to rise or sink in the water, by pressing the air contained at the mouth of the tubes, so that it shall drive the water into their hollow bodies, which, before, were filled only with air, and thus make them heavier than the element in which they swim. In this manner does the fresh water snail dive or swim, by properly managing the air contained in its body.

But what renders these animals far more worthy of notice is, that they are viviparous, and bring forth their young not only alive, but with their shells upon their backs. This seems surprising; yet it is incontestably true: the young come to some degree of perfection in the womb of the parent; there they receive their stony coat; and from thence are excluded, with a complete apparatus for subsistence.

"On the twelfth of March," says Swammerdam, "I began my observations upon this snail, and collected a great number of the kind, which I put into a large basin filled with rain-water, and fed, for a long time, with potter's earth, dissolved in the water about them. On the thirteenth of the same month I opened one of these snails, when I found nine living snails in its womb: the largest of these were placed foremost, as the first candidates for exclusion. I put them into fresh-water, and they lived till the eighteenth of the same month, moving and swimming, like snails full grown: nay, their manner of swimming was much more beautiful." Thus, at whatever time of the year these snails are opened they are found pregnant with eggs, or with living snails; or with both together.

This striking difference between the fresh-water and the garden snail, obtains also in some of the sea kind: among which there are some that are found viviparous, while others lay eggs in the usual manner. Of this kind are one or two of the Buccinums; within which living young have been frequently found upon their dissection. In general, however, the rest of this numerous class bring forth eggs; from whence the animal bursts at a proper state of maturity, completely equipped with a house, which the moistness of the element where it resides does not prevent the in

[1] D'Argenville's Conchyliologie.

habitant from enlarging. How the soft slime of the snail hardens, at the bottom of the sea, into the stony substance of a shell, is not easy to conceive. This slime must at least be possessed of very powerful petrifying powers.

All animals of the snail kind, as was observed before, are hermaphrodites; each containing the instruments of generation double. But some of the sea kinds copulate in a different manner from those of the garden. The one impregnates the other; but, from the position of the parts, is incapable of being impregnated by the same in turn. For this reason it is necessary for a third to be admitted as a partner in this operation: so that, while one impregnates that before it, another does the same office by this; which is itself impregnated by a fourth. In this manner, Mr Adanson has seen vast numbers of sea-snails united together in a chain impregnating each other. The Bulin and the Coret perform the offices of male and female at the same time. The orifices in these are two, both separated from each other: the opening by which the animal performs the office of the male being at the origin of the horns; that by which it is passive, as the female, being farther down upon the neck. It may also be observed, as a general rule, that all animals that have this orifice, or verge, as some call it, on the right side, have their shells turned from the right to the left; on the contrary, those which have it on the left side, have their shells turned from left to right, in a contrary direction to the former.

But this is not the only difference between land and sea-snails. Many of the latter entirely want horns; and none of them have above two. Indeed, if the horns of snails be furnished with eyes, and if, as some are willing to think, the length of the horn, like the tube of a telescope, assists vision, these animals that chiefly reside in the gloomy bottom of the deep, can have no great occasion for them. Eyes would be unnecessary to creatures whose food is usually concealed in the darkest places; and who, possessed of very little motion, are obliged to grope for what they subsist on. To such, I say, eyes would rather be an obstruction than an advantage; and, perhaps, even those that live upon land are without them.

Those that have seen the shells of sea-snails, need not be told that the animal which produces them is larger than those of the same denomination upon land. The sea seems to have the property of enlarging the magnitude of all its inhabitants; and the same proportion that a trout bears to a shark, is often seen to obtain between a shell bred upon the land, and one bred in the ocean. Its convolutions are more numerous. The garden-snail has but five turns at the most; in the sea-snail the convolutions are sometimes seen amounting to ten.

There is a difference also in the position of the mouth in the garden and the water snail. In the former, the mouth is placed crosswise, as in quadrupeds; furnished with jaw-bones, lips, and teeth. In most of the sea-snails, the mouth is placed longitudinally in the head; and in some obliquely, or on one side. Others, of the Trochus kind, have no mouth whatsoever; but are furnished with a trunk, very long in some kinds, and shorter in others.

Snails of the Trochus kind, furnished thus with an instrument of offence, deserve our particular attention. The trunk of the Trochus is fleshy, muscular, supple, and hollow. Its extremity is bordered with a cartilage, and toothed like a saw. The snails that are provided with this may be considered as the predacious tribe among their fellows of the bottom. They are among snails what the tiger, the eagle, or the shark, is among beasts, birds, or fishes. The whole race of shelled animals avoid their approach; for their habitations, however powerfully and strongly built, though never so well fortified, yield to the superior force of these invaders. Though provided with a thick clumsy shell themselves, yet they move with greater swiftness at the bottom than most other shell-fish, and seize their prey with greater facility. No shell so large but they will boldly venture to attack; and, with their piercing auger-like trunk, will quickly bore it through. No efforts the other animal makes can avail: it expands itself, and rises to the surface; but the enemy rises with it: it again sinks to the bottom, but still its destroyer closely adheres. In this manner the carnivorous shell-fish, as some naturalists call it, sticks for several days, nay, weeks, to its prey, until, with its trunk, it has sucked out all the substance, or until it drops off, when the other begins to putrefy.

Thus it would seem, throughout nature, that no animal is so well defended but that others are found capable of breaking in upon its intrenchments. The garden-snail seems tolerably well guarded; but the wall of its shell is paper itself, in comparison with that which fortifies some of the sea-snail kind. Beside this thick shell, many of them are also furnished with a lid, which covers the mouth of the shell, and which opens and shuts at the animal's pleasure. When the creature hunts for food, it opens its box, gropes or swims about; and, when satisfied, drops its lid, and sinks to the bottom: there it might be supposed to remain in perfect security; but the trochus soon finds the way to break into the thickest part of its inclosure, and quickly destroys it with the most fatal industry.

The being liable to the attacks of the trochus

seems to be a calamity to which most of this tribe are subject. Scarce a shell is met with entire and sound to the end of its convolutions; but particularly the thinnest shells are the most subject to be thus invaded. As their shells are easily pierced, the predatory shell-fish, or the sea-worm, chiefly seek them for subsistence; and of those thin paper-like shells, not one in a hundred is found that has not suffered some disaster. As they are lighter than other shell-fish, they swim with greater ease; and this is the chief method of avoiding their heavier thick-shelled pursuers. The food of all snails properly lies at the bottom; when, therefore, the nautilus, or other thin-shelled fish, are seen busily swimming at the surface, it may be that, instead of sporting or sunning themselves, as some are apt to suppose, they are actually labouring to escape their most deadly pursuers.

Of all sea-snails, that which is most frequently seen swimming upon the surface, and whose shell is the thinnest, and most easily pierced, is the nautilus. Whether, upon these occasions, it is employed in escaping its numerous enemies at the bottom, or seeking for food at the surface, I will not venture to decide. It seems most probable, that the former is the cause of its frequently appearing; for, upon opening the stomach, it is found to contain chiefly that food which it finds at the bottom. This animal's industry, therefore, may be owing to its fears; and all those arts of sailing which it has taught mankind, may have been originally the product of necessity. But the nautilus is too famous not to demand a more ample description. Although there be several species of the nautilus, yet they all may be divided into two: the one with a white shell, as thin as paper, which it often is seen to quit, and again to resume; the other with a thicker shell, sometimes of a beautiful mother-of-pearl colour, and that quits its shell but rarely. This shell, outwardly, resembles that of a large snail, but is generally six or eight inches across; within it is divided into forty partitions, that communicate with each other by doors, if I may so call them, through which one could not thrust a goose-quill: almost the whole internal part of the shell is filled by the animal; the body of which, like its habitation, is divided into as many parts as there are chambers in its shell: all the parts of its body communicate with each other, through the doors or openings, by a long blood-vessel, which runs from the head to the tail. thus the body of the animal, if taken out of the shell, may be likened to a number of soft bits of flesh, of which there are forty, threaded upon a string. From this extraordinary conformation, one would not be apt to suppose that the nautilus sometimes quitted its shell, and returned to it again; yet nothing, though seemingly more impossible, is more certain. The manner by which it contrives to disengage every part of its body from so intricate a habitation, by which it makes a substance, to appearance as thick as one's wrist, pass through forty doors, each of which would scarcely admit a goose-quill, is not yet discovered: but the fact is certain; for the animal is often found without its shell; and the shell more frequently destitute of the animal. It is most probable, that it has a power of making the substance of one section of its body remove up into that which is next; and thus, by multiplied removals, it gets free.[1]

But this, though very strange, is not the peculiarity for which the nautilus has been the most distinguished. Its "spreading the thin oar," and "catching the flying gale," to use the poet's description of it, has chiefly excited human curiosity. These animals, particularly those of the white light kind, are chiefly found in the Mediterranean; and scarcely any who have sailed on that sea, but must often have seen them. When the sea is calm, they are observed floating on the surface; some spreading their little sail; some rowing with their feet, as if for life and death; and others still, floating upon their mouths, like a ship with the keel upward. If taken while thus employed, and examined, the extraordinary mechanism of their limbs for sailing will appear more manifest. The nautilus is furnished with eight feet, which issue near the mouth, and may as properly be called barbs: these are connected to each other by a thin skin, like that between the toes of a duck, but much thinner and more transparent. Of these eight feet thus connected, six are short, and these are held up as sails to catch the wind in sailing; the two others are longer, and are kept in the water,

[1] Goldsmith has confounded two shells very different in their characters. The one is an Argonauta, and the other a Nautilus. The paper argonaut is extremely thin, spiral, involute, membraneous, and unilocular, or consisting of a single apartment or cell. It has a narrow keel, bordered on each side by a row of conical sharp tubercles; its sides are nearly flat, with numerous angular waved ridges; its colour is white, with the keel often brown. The shell is very thin and brittle; from which circumstance it has obtained the name of paper nautilus. This shell is *the nautilus* of the ancients, mentioned in the writings of Pliny and others. It is supposed, that, in the early ages of society, the art of navigation owed its origin to the expert management of this instinctive sailor.

Learn of the little Nautilus to sail,
Spread the thin oar, and catch the driving gale.—*Pope.*

It swims on the surface of the sea, on the back of its shell, which exactly resembles the hull of a ship; it raises two feet like masts, and extends a membrane between, which serves as a sail; the other two feet are employed as oars. This fish is usually found in the Mediterranean.

serving like paddles to steer their course by. When the weather is quite calm, and the animal is pursued from below, it is then seen expanding only a part of its sail, and rowing with the rest: whenever it is interrupted, or fears danger from above, it instantly furls the sails, catches in all its oars, turns its shell mouth downward, and instantly sinks to the bottom. Sometimes also it is seen pumping the water from its leaking hulk; and, when unfit for sailing, deserts its shell entirely. The forsaken hulk is seen floating along, till it dashes, by a kind of shipwreck, upon the rocks or the shore.

From the above description, I think we may consider this animal rather as attempting to save itself from the attacks of its destroyers, than as rowing in pursuit of food. Certain it is, that no creature of the deep has more numerous or more powerful enemies. Its shell is scarcely ever found in perfect preservation; but is generally seen to bear some marks of hostile invasion. Its little arts, therefore, upon the surface of the water may have been given it for protection; and it may be thus endued with comparative swiftness, to avoid the crab, the sea-scorpion, the trochus, and all the slower predacious reptiles that lurk for it at the bottom of the water.

From this general view of snails, they appear to be a much more active animated tribe, than from their figure one would at first conceive. They seem to an inattentive spectator, as mere inert masses of soft flesh, rather loaded than covered with a shell, scarcely capable of motion, and insensible to all the objects around them. When viewed more closely, they are found to be furnished with the organs of life and sensation in tolerable perfection; they are defended with armour that is at once both light and strong; they are as active as their necessities require; and are possessed of appetites more poignant than those of animals that seem much more perfectly formed. In short, they are a fruitful industrious tribe; furnished, like all other animals, with the powers of escape and invasion; they have their pursuits and their enmities; and, of all creatures of the deep, they have most to fear from each other.

CHAP. VI.

OF BIVALVED SHELL-FISH, OR SHELLS OF THE OYSTER KIND.

It may seem whimsical to make a distinction between the animal perfections of turbinated and bivalved shell-fish; or to grant a degree of superiority to the snail above the oyster. Yet this distinction strongly and apparently obtains in nature; and we shall find

[1] *The Oyster, the Mussel, and the Cockle.*—The Mollusca which inhabit bivalved shells, such as the Oyster, the Mussel, and the Cockle, are all *acephalous*; that is, destitute of a head. The two valves of the shell are united at the back by a hinge-joint, often very artificially constructed, having teeth that lock into each other; and the mechanism of this articulation varies much in different species. The hinge is secured by a substance of great strength.

During the life of the animal, the usual and natural state of its shell is that of being kept open for a little distance, so as to allow of the ingress and egress of the water necessary for its nourishment and respiration; but, as a security against danger, it was necessary to furnish the animal with the means of rapidly closing the shell, and retaining the valves in a closed state. These actions being only occasional, yet requiring considerable force, are effected by a muscular power, for which purpose sometimes one, sometimes two, or even a greater number of strong muscles are placed between the valves, their fibres passing directly across from the inner surface of the one to that of the other, and firmly attached to both. They are named, from their office of bringing the valves towards each other, the *adductor muscles*.

The simple actions of opening and closing the valves, are capable of being converted into a means of retreating from danger, or of removing to a more commodious situation, in the case of those bivalves which are not actually attached to rocks or other fixed bodies. Diquemare long ago observed, that even the oyster has some power of locomotion, by suddenly closing its shell, and thereby expelling the contained water with a degree of force, which, by the reaction of the fluid in the opposite direction, gives a sensible impulse to the heavy mass. He notices the singular fact, that oysters which are attached to rocks occasionally left dry by the retreat of the tide, always retain within their shells a quantity of water sufficient for respiration, and that they keep the valves closed till the return of the tide; whereas, those oysters which are taken from greater depths, where the water never leaves them, and are afterwards removed to situations where they are exposed to these vicissitudes, of which they have had no previous experience, improvidently open their shells after the sea has left them; and, by allowing the water to escape, soon perish.

Many bivalved mollusca are provided with an instrument shaped like a leg and foot, which they employ extensively for progressive motion. In the *cardium*, or cockle, this organ is composed of a mass of muscular fibres, interwoven together in a very complex manner, and which may be compared to the muscular structure of the human tongue; the effect in both is the same, namely, the conferring a power of motion in all possible ways; thus it may be readily protruded, retracted, or inflected at every point. The *solen*, or razor-shell fish, has a foot of a cylindrical shape, tapering at the end, and much more resembling in its form a tongue than a foot. In some bivalves the dilatation of the foot is effected by a curious hydraulic mechanism: the interior of the organ is formed of a spongy texture, capable of receiving a considerable quantity of water, which the animal has the power of injecting into it, and of thus increasing its dimensions.

The foot of the *Mytilus edulis*, or common mussel, can be advanced to the distance of two inches from the shell, and applied to any fixed body within that range. By attaching the point to such body, and retracting the foot, this animal drags its shell towards it, and by repeating the operation successively on other points of the fixed object, continues slowly to advance.

the bivalved tribe of animals in every respect inferior to those we have been describing. Inferior in all their sensations; inferior in their powers of motion; but particularly inferior in their system of animal generation. The snail tribe, as we saw, are hermaphrodite, but require the assistance of each other for fecundation; all the bivalve tribe are hermaphrodite in like manner, but they require no assistance from each other towards impregnation; and a single mussel or oyster, if there were on other in the world, would quickly replenish the ocean. As the land-snail, from its being best known, took the lead in the former class, so the fresh-water mussel, for the same reason, may take the lead in this. The life and manners of such as belong to the sea will be best displayed in the comparison.

The mussel, as is well known, whether belonging to fresh or salt water, consists of two equal shells, joined at the back by a strong muscular ligament, that answers all the purposes of a hinge. By the elastic contraction of these, the animal can open its shell at pleasure, about a quarter of an inch from each other. The fish is fixed to either shell by four tendons, by means of which it shuts them close, and keeps its body firm from being crushed by any shock against the walls of its own habitation. It is furnished, like all other animals of this kind, with vital organs, though these are situated in a very extraordinary manner. It has a mouth furnished with two fleshy lips; its intestine begins at the bottom of the mouth, passes through the brain, and makes a number of circumvolutions through the liver; on leaving this organ, it goes on straight into the heart, which it penetrates, and ends in the anus: near which the lungs are placed, and through which it breathes,

---

This instrument is of great use to such shell-fish as conceal themselves in the mud or sand, which its structure is then peculiarly adapted for scooping out. The cockle continually employs its foot for this purpose; first elongating it, directing its point downwards, and insinuating it deep into the sand, and next, turning up the end, and forming it into a hook, by which, from the resistance of the sand, it is fixed in its position, and then the muscles which usually retract it are thrown into action, and the whole shell is alternately raised and depressed, moving on the foot as on a fulcrum. The effect of these exertions is to drag the shell downwards. When the animal is moderately active, these movements are repeated two or three times in a minute. The apparent progress is at first but small; the shell, which was raised on its edge at the middle of the stroke, falling back on its side at the end of it; but when the shell is buried so far as to be supported on its edge, it advances more rapidly, sinking visibly at every stroke, till nothing but the extremity of the tube can be perceived above the sand.

By a process exactly the inverse of this, that is, by doubling up the foot, and pushing with it downwards against the sand below, the shell may be again made to rise by the same kind of efforts which before protruded the foot. By this process of burrowing, the animal is enabled quickly to retreat when danger presses, and when this is past, it can, with equal facility, emerge from its hiding-place.

The *Cardium* can also advance at the bottom of the sea along the surface of the soft earth, pressing backwards with its foot, as a boatman impels his boat onwards by pushing with his pole against the ground in a contrary direction. It is, likewise, by a similar expedient, that the *Solen* forces its way through the sand, expanding the end of its foot into the form of a club. The *Tellina* is remarkable for the quickness and agility with which it can spring to considerable distances, by first folding the foot into a small compass, and then suddenly extending it, while the shell is at the same time closed with a loud snap.

The *Pinna*, or marine mussel, when inhabiting the shores of tempestuous seas, is furnished, in addition, with a singular apparatus for withstanding the fury of the surge, and securing itself from dangerous collisions, which might easily destroy the brittle texture of its shell. The object of this apparatus is to prepare a great number of threads, which are fastened at various points to the adjacent rocks, and then tightly drawn by the animal, just as a ship is moored in a convenient station, to avoid the buffeting of the storm. The foot of this bivalve is cylindrical, and has, connected with its base, a round tendon, of nearly the same length as itself, the office of which is to retain all the threads in firm adhesion with it, and concentrate their power, on one point. The threads themselves are composed of a glutinous matter, prepared by a particular organ. They are not spun by being drawn out of the body like the threads of the silk-worm, or of the spider, but they are cast in a mould, where they harden, and acquire a certain consistence before they are employed. This mould is curiously constructed; there is a deep groove which passes along the foot, from the root of the tendon to its other extremity, and the sides of this groove are formed so as to fold and close over it, thereby converting it into a canal. The glutinous secretion, which is poured into this canal, dries into a solid thread; and, when it has acquired sufficient tenacity the foot is protruded, and the thread it contains is applied to the object to which it is to be fixed, its extremity being carefully attached to the solid surface of that object. The canal of the foot is then opened along its whole length, and the thread, which adheres by its other extremity to the large tendon at the base of the foot, is disengaged from the canal. Lastly, the foot is retracted, and the same operation is repeated.

Thread after thread is thus formed, and applied in different directions around the shell. Sometimes the attempt fails, in consequence of some imperfection in the thread; but the animal, as if aware of the importance of ascertaining the strength of each thread, on which its safety depends, tries every one of them as soon as it has been fixed, by swinging itself round, so as to put it fully on the stretch; an action which probably also assists in elongating the thread. When once the threads have been fixed, the animal does not appear to have the power of cutting or breaking them off. The liquid matter out of which they are formed, is so exceedingly glutinous as to attach itself firmly to the smoothest bodies. It is but slowly produced, for it appears that no Pinna is capable of forming more than four, or at most five threads, in the course of a day and night. The threads which are formed in haste, when the animal is disturbed in its operations, are more slender than those which are constructed at its leisure. In Sicily, and other parts of the Mediterranean, these threads have been manufactured into gloves, and other articles, which resemble silk.—*Abridged from Dr Roget's Bridgewater Treatise.*

like those of the snail kind; and in this manner its languid circulation is carried on.[1]

But the organs of generation are what most deserve to excite our curiosity. These consist in each mussel of two ovaries, which are the female part of its furniture, and of two seminal vessels, resembling what are found in the male. Each ovary and each seminal vessel, has its own proper canal: by the ovary canal the eggs descend to the anus; and there also the seminal canals send their fluids to impregnate them. By this contrivance, one single animal suffices for the double purposes of generation; and the eggs are excluded and impregnated by itself alone.

As the mussel is thus furnished with a kind of self-creating power, there are few places where it breeds that it is not found in great abundance. The ovaries usually empty themselves of their eggs in spring, and they are replenished in autumn. For this reason they are found empty in summer, and full in winter. They produce in great numbers, as all bivalved shell-fish are found to do. The fecundity of the snail kind is trifling in comparison to the fertility of these. Indeed it may be asserted as a general rule in nature, that the more helpless and contemptible the animal, the more prolific it is always found. Thus all creatures that are incapable of resisting their destroyers, have nothing but their quick multiplication for the continuation of their existence.

The multitude of these animals in some places is very great; but from their defenceless state, the number of their destroyers are in equal proportion. The crab, the cray-fish, and many other animals, are seen to devour them; but the trochus is their most formidable enemy. When their shells are found deserted, if we then observe closely, it is most probable we shall find that the trochus has been at work in piercing them. There is scarcely one of them without a hole in it; and this probably was the avenue by which the enemy entered to destroy the inhabitant.

But notwithstanding the numbers of this creature's animated enemies, it seems still more fearful of the agitations of the element in which it resides; for if dashed against rocks, or thrown far on the beach, it is destroyed without a power of redress. In order to guard against these, which are to this animal the commonest and the most fatal accidents, although it has a power of slow motion, which I shall presently describe, yet it endeavours to become stationary, and to attach itself to any fixed object it happens to be near. For this purpose, it is furnished with a very singular capacity of binding itself by a number of threads to whatever object it approaches; and these Reaumur supposed are spun artificially, as spiders their webs which they fasten against a wall. Of this, however, later philosophers have found very great reason to doubt. It is therefore supposed that these threads, which are usually called the beard of the mussel, are the natural growth of the animal's body, and by no means produced at pleasure. Indeed the extreme length of this beard in some, which far exceeds the length of the body, seems impossible to be manufactured by the thrusting out and drawing in of the tongue, with the glutinous matter of which the French philosopher supposed those threads were formed. It is even found to increase with the growth of the animal; and as the mussel becomes larger and older, the beard becomes longer, and its filaments more strong.[2] Be this as it will, nothing is more certain than that the mussel is found attached by these threads to every fixed object; sometimes, indeed, for want of such an object, these animals are found united to each other; and though thrown into a lake separately, they are taken out in bunches of many together.

To have some fixed resting place where the mussel can continue, and take its accidental food, seems the state that this animal chiefly desires. Its instruments of motion, by which it contrives to reach the object it wants to bind itself to, is that muscular substance resembling a tongue, which is found long in proportion to the size of the mussel. In some it is two inches long, in others not a third part of these dimensions. This the animal has a power of thrusting out of its shell; and with this it is capable of making a slight furrow in the sand at the bottom. By means of this furrow it can erect itself upon the edge of its shell; and thus continuing to make the furrow in proportion as it goes forward, it reaches out its tongue, that answers the purpose of an arm, and thus carries its shell edge-ways, as in a groove, until it reaches the point intended. There, where it determines to take up its residence, it fixes the ends of its beard, which are glutinous, to the rock or the object, whatever it be; and thus, like a ship at anchor, braves all the agitations of the water. Sometimes the animal is attached by a large number of threads; sometimes but by three or four, that seem scarce able to retain it. When the mussel is fixed in this manner, it lives upon the little earthy particles that the water transports to its shells, and perhaps the flesh of the most diminutive animals. However, it does not fail to grow considerably; and some of this kind have been found a foot long. I have seen the beards a foot and a half; and of

[1] M. Mery. Anat. des Moules d'Etang.

[2] Mercier du Paty, sur le Bouchots a Moules. Tom. ii. de l'Academie de la Rochelle.

this substance the natives of Palermo sometimes make gloves and stockings.

These shell-fish are found in lakes, rivers, and in the sea. Those of the lake often grow to a very large size; but they seem a solitary animal, and are found generally separated from each other. Those of rivers are not so large, but yet in greater abundance; but the sea-mussel of all others is perhaps the most plenty. These are often bred artificially in salt-water marshes that are overflowed by the tide; the fishermen throwing them in at the proper seasons; and there being undisturbed by the agitations of the sea, and not preyed upon by their powerful enemies at the bottom, they cast their eggs, which soon become perfect animals, and these are generally found in clusters of several dozen together. It requires a year for the peopling of a mussel bed; so that, if the number consists of forty thousand, a tenth part may annually be left for the peopling the bed anew. Mussels are taken from their beds from the month of July to October; and they are sold at a very moderate price.[1]

From this animal the oyster differs very little, except in the thickness of its shell, and its greater imbecility. The oyster, like the mussel, is formed with organs of life and respiration, with intestines which are very voluminous, a liver, lungs, and heart. Like the mussel, it is self-impregnated; and the shell, which the animal soon acquires, serves it for its future habitation. Like the mussel, it opens its shell to receive the influx of water; and like that animal is strongly attached to its shell both above and below.

But it differs in many particulars. In the first place, its shells are not equal, the one being cupped, the other flat: upon the cupped shell it is always seen to rest; for if it lay upon the flat side it would then lose all its water. It differs also in the thickness of its shells, which are so strongly lined and defended, that no animal will attempt to pierce them. But though the oyster be secured from the attacks of the small reptiles at the bottom, yet it often serves as an object to which they are attached. Pipe-worms, and other little animals, fix their habitation to the oyster's sides, and in this manner continue to live in security. Among the number of these is a little red worm, that is often found upon the shell; which some, from never seeing oysters copulate, erroneously supposed to be the male by which their spawn was impregnated.

The oyster differs also from the mussel, in being utterly unable to change its situation. The mussel, as we have observed, is capable of erecting itself on an edge, and going forward with a slow laborious motion. The oyster is wholly passive, and endeavours by all its powers to rest fixed to one spot at the bottom. It is entirely without that tongue which we saw answering the purposes of an arm in the other animal; but nevertheless is often attached very firmly to any object it happens to approach. Rocks, stones, pieces of timber, or sea-weeds, all seem proper to give it a fixture, and to secure it against the agitation of the waves. Nothing is so common in the rivers of the tropical climates as to see oysters growing even amidst the branches of the forest. Many trees which grow along the banks of the stream often bend their branches into the water, and particularly the mangrove, which chiefly delights in a moist situation. To these the oysters hang in clusters, like apples upon the most fertile tree; and in proportion as the weight of the fish sinks the plant into the water, where it still continues growing, the number of oysters increase, and hang upon the branches. Thus there is nothing that these shell-fish will not stick to; they are often even found to stick to each other. This is effected by means of a glue proper to themselves, which, when it cements, the joining is as hard as the shell, and is as difficultly broken. The joining substance, however, is not always of glue; but the animal grows to the rocks, somewhat like the mussel, by threads; although these are only seen to take root in the shell, and not, as in the mussel, to spring from the body of the fish itself.

Oysters usually cast their spawn in May, which at first appear like drops of candle-grease, and stick to any hard substance they fall upon. These are covered with a shell in two or three days; and in three years the animal is large enough to be brought to market. As they invariably remain in the places where they are laid, and as they grow without any other seeming food than the afflux of sea-water, it is the custom at Colchester, and other parts of the kingdom, where the tide settles in marshes on land, to pick up great quantities of

[1] Some shell-fish are poisonous when eaten. This is frequently the case with mussels. In the month of June, 1827, a great number of the poor in Leith were poisoned by eating these shell-fish, which they procured from the docks. "The town," says Dr Combe, "was in a ferment, and the magistrates, with great propriety, issued a warning against the use of the mussels. Many deaths were reported, and hundreds of individuals were stated to be suffering under it. Luckily, matters were not so deplorable; but we ascertained that in addition to the man mentioned before, the companion of our patient, an elderly woman, had died. In all, about thirty cases occurred, with great uniformity of symptoms, but varying very much in severity: but none, so far as I know, have left any permanent bad effects." To what cause these deleterious effects are to be ascribed is uncertain. Some attribute them to disease in the fish, or to its being in a state of putrefaction; others to its having fed on some poisonous articles, more particularly on the ores of copper.

small oysters along the shore, which, when first gathered, seldom exceed the size of a sixpence. These are deposited in beds where the tide comes in, and in two or three years grow to a tolerable size. They are said to be better tasted from being thus sheltered from the agitations of the deep; and a mixture of fresh water entering into these repositories, is said to improve their flavour, and to increase their growth and fatness.[1]

The oysters, however, which are prepared in this manner, are by no means so large as those found sticking to rocks at the bottom of the sea, usually called *rock oysters*. These are sometimes found as broad as a plate, and are admired by some as excellent food. But what is the size of these compared to the oysters of the East-Indies, some of whose shells I have seen two feet over! The oysters found along the coast of Coromandel are capable of furnishing a plentiful meal to eight or ten men; but it seems universally agreed, that they are no way comparable to ours for delicacy of flavour.[2]

Thus the mussel and the oyster appear to have but few distinctions, except in their shape and the power of motion in the former. Other bivalved shell-fish, such as the cockle, the scallop, and the razor shell, have differences equally minute. The power of changing place, which some of them effect in a manner quite peculiar to themselves, makes their greatest difference. The scallop is particularly remarkable for its method of moving forward upon land, or swimming upon the surface of the water. When this animal finds itself deserted by the tide, it makes very remarkable efforts to regain the water, moving towards the sea in a most singular manner. It first gapes with its shell as widely as it can, the edges being often an inch asunder; then it shuts them with a jerk, and by this the whole animal rises five or six inches from the ground. It thus tumbles any how forward, and then renews the operation until it has attained its journey's end. When in the water, it is capable of supporting itself upon the surface; and there opening and shutting its shells, it tumbles over and over, and makes its way with some celerity.

The Pivot, or Razor-shell, has a very different kind of motion. As the former moves laboriously and slowly forward, so the razor-shell has only a power of sinking point down-

[1] *Oysters.*—Oysters are said to be in season in every month of the year that has an R in its name, beginning with September and ending with April; but the season in many places extends from August to May. Every city has its favourite oyster-bank. In London, the Colchester and Milton oysters are held in most esteem; Edinburgh has her "whiskered Pandores," and, latterly, Aberdour oysters; and Dublin, the Carlingford and "Powldoodies of Burran." For the convenience of obtaining a ready supply of oysters, they are often transported from their original beds, and laid down on proper places of the coast; but these exiles are seldom found in such perfection as those which are called *natives*—that is, such as have never been rudely torn from their native homes, and sent on voyages of profit. Oysters, when just dredged, may be so packed in small barrels as to keep good for a week or ten days; and in this state they are sent to distant places. They may also be preserved good for some time by *feeding;* and custom, which brings *gourmands* to admire game most when in a state of putridity, has taught them to relish the flavour of stale oysters better than those recently taken from the beds. The fresher oysters are, they are the better, but when to be kept, lay them, bottom downwards, in a tub, or any vessel suited to the quantity to be preserved, and cover them with water in which a good deal of salt is dissolved;—change the water every twelve hours. Most cooks direct that this delicate animal should be fed with oatmeal or flour sprinkled in the water; and others, on the principle which leads a mother of the parish of St Giles to bathe her new-born darling in a drop of gin, are for feeding them with white wine and bread crumbs! It is said, by those who have the charge of fish-ponds, that "fish will eat nothing but what comes out of the sea;" now, though we are not perfectly convinced of this fact, we can at least believe that salt-water gruel is not over well suited to the delicate stomach of an oyster. Those large, fat oysters, called Pandores, which are so much prized in Edinburgh, are said to owe their superior excellence to the blackish contents of the pans of the adjacent salt-works of Prestonpans flowing out upon the beds, a subject worthy the serious investigation of the oyster amateur, who may here receive some excellent hints for fattening and improving the quality of his favourite morsel.

Shell-fish, and the oyster above all, have long been deemed highly restorative and easy of digestion: they are therefore recommended for the food of the delicate and declining, and of those whose digestive powers have been impaired by excess. When eaten for health, an oyster is best swallowed with its own liquor, the moment the shell is opened: or if found too cold for the stomach, a sprinkling of black pepper may be allowed. Vinegar counteracts the effect of eating oysters to enrich the blood, or render it more balsamic; and ought, therefore, to be avoided by the declining. As there are no reasonable bounds to oyster-eating, it may be useful to notice here that, when too many of these or other shell-fish are swallowed, the unpleasant feeling may be removed by drinking half a pint of hot milk. Consumptive persons are recommended to use hot milk after their oysters at all times.

Of the *univalved* shells, the *periwinkle* (Turbo littoreus) and common *whelk* (Buccinum lapillus, *Lin.*) frequently furnish to the poorer classes of our sea-coast towns and villages a repast, perhaps sufficiently wholesome, and certainly not destitute of relish. But, even to them these may be regarded merely in the light of luxuries: it is far otherwise with the still poorer inhabitants of several of the Western isles of Scotland. Periwinkles and limpets (Patella vulgata), which so profusely stud the rocks of their shores, are their daily fare, and on which they are sometimes reduced to the necessity of altogether subsisting. In the Isle of Sky, for example, we are told that there is almost annually a degree of famine, when the poor are left to Providence's care, and prowl, like other animals, along the shores, to pick up limpets and other shell-fish: "the casual repast," adds Mr Pennant, "of hundreds, during part of the year, in these unhappy islands."

[2] The shell here alluded to is probably the *Giant Chama*, a native of the Indian ocean, and the largest shell at present known.

ward. The shells of this animal resemble nothing so much as the haft of a razor; and by this form it is better enabled to dive into the soft sand at the bottom. All the motions of this little animal are confined to sinking or rising a foot downwards or upwards in the sand, for it never leaves the spot where it first was planted. From time to time it is seen to rise about half way out of its hole; but if any way disturbed, it sinks perpendicularly down again. Just over the place where the razor buries itself, there is a small hole like a chimney, through which the animal breathes, or imbibes the sea-water. Upon the desertion of the tide, these holes are easily distinguished by the fishermen who seek for it; and their method of enticing the razor up from the depth of its retreat, is by sprinkling a little sea-salt upon the hole. This melting no sooner reaches the razor below, than it rises instantly strait upwards, and shows about half its length above the surface. This appearance, however, is instantaneous; and if the fisher does not seize the opportunity, the razor buries itself with great ease to its former depth. There it continues secure: no salt can allure it a second time; but it remains unmolested, unless the fisher will be at the trouble of digging it out sometimes two feet below the surface.

Such are the minute differences between bivalved shell-fish; but in the great outlines of their nature they exactly resemble each other. It is particularly in this class of shell-fish that pearls are found in greatest abundance; and it is in the internal parts of those shells that are of a shining silvery colour, that these gems are usually generated; but the pearl is also found to breed as well in the mussel or the scallop as in the oyster. In fact, it is found in all bivalved shells, the insides of which resemble that well-known substance called mother-of-pearl.

Whether pearls be a disease or an accident in the animal is scarcely worth inquiry. The common opinion is, that they are a kind of calculose concretion in the body of the animal, somewhat resembling a stone in the bladder, and are consequently to be considered as a disorder. It is said, in confirmation of this opinion, that those coasts upon which pearls are fished, are very unhealthy; and therefore most probably oysters share the general influence of the climate; it is also added, that those oysters in which pearls are found are always ill-tasted, which is a sign of their being unsound: and, lastly, it is asserted, that the pearl grows sometimes so big as to keep the shells of the animal from shutting, and that thus it dies by being exposed. It is easy to see the weakness of these assertions, which seem neither true nor amusing. To answer them in their own way: If a stone in the bladder be a disorder, a stone in the stomach of an ostrich is a benefit, and so it may be in the shell of an oyster. If the shores where the pearls are fished be unwholesome to man, that, instead of being disadvantageous, is so much the more lucky for the oyster. If the pearl oysters are the worst tasted, so are kites and ravens among birds; and yet we know that they are healthy and long-lived animals. If the oyster had never its shell kept asunder by the pearl within it, that would be a disease indeed; but this, in reality, never happens, for the oyster that breeds a large pearl always breeds a large shell, and the shell itself indents to receive its impression. The pearl upon the whole seems bred from no disorder in the animal, but accidentally produced by the same matter that goes to form the shell. This substance, which is soft at first, quickly hardens; and thus, by successive coats, layer over layer, the pearl acquires its dimensions. If cut through, it will be found to consist of several coats, like an onion; and sometimes a small speck is seen in the middle, upon which the coats were originally formed.

All oysters, and most shell-fish, are found to contain pearls; but that which particularly obtains the name of the pearl oyster, has a large strong whitish shell, wrinkled and rough without, and within smooth and of a silver colour. From these the mother-of-pearl is taken, which is nothing more than the internal coats of the shell, resembling the pearl in colour and consistence. This is taken out, and shaped into that variety of utensils which are found so beautiful: but the pearl itself is chiefly prized; being found but in few oysters, and generally adhering; sometimes making a print in the body of the shell, sometimes at large within the substance of the fish.

There are a great number of pearl fisheries in America and Asia: but as pearls bear a worse price than formerly, those of America are in a great measure discontinued. The most famous of all the Asiatic fisheries is in the Persian Gulf, near the isle of Bahreen.[1] There

[1] *Pearls.*—The Persian Gulf, the shores of Japan, and the Bay of Condatchy in Ceylon, are the situations where pearls are found in greatest abundance at the present day, and where the most extensive fisheries are carried on. The Ceylon coast, in particular, yields in successful seasons a great produce, the revenue derived being sometimes nearly two hundred thousand pounds. In some years, however, the produce falls far short of this, and this deficiency is generally occasioned by the exhaustion, for the time, of the oyster beds. To prevent this, the bays where they are found are marked out into divisions called banks, of which a certain number only are fished each year, the rest being allowed to lie untouched. The fishing season lasts about two months, commencing in February and ending in April; and the particular banks to be wrought upon are put up to auction by government, and farmed out to the highest bidder. Pre-

is another between the coast of Madura and the island of Ceylon; and there was a third on the coast of Japan: but as these noble islanders have a contempt for jewels, and an abhorrence for such Europeans as come in pursuit of them, that fishery, which is thought to be the most valuable of all others, is discontinued. The diving business is now

viously to this, the banks are surveyed, and the beds ascertained to have reached a state of maturity.

The oysters are brought out of the sea, not by means of dredging nets, as in common fisheries, but by men trained to the practice of diving. They proceed in boats to the quarter allotted for the season's operations, each boat containing twenty men, ten of whom are divers, while ten row the boats and assist their companions in reaching the surface of the water after diving. Five of the divers descend at a time, and when they come up, the other five go down; by which alternation the whole have a certain time to recruit between each exertion. The fishing commences at sunrise, and ceases on account of the rising sea-breeze at noon, and during the whole of the intervening period, the divers pursue their hazardous occupation. To facilitate their descent, each of them has a weight attached round his body, or to his feet, in such a way that he can relieve himself of it easily. A bag of network is grasped with his toes, the right hand holds a rope, the left keeps the nostrils closed, and in this condition the diver fearlessly plunges in, and speedily reaches the bottom. Hanging the bag around his neck, he collects as many oysters as he can, generally about a hundred at one time, and on making a signal, is drawn up to the surface; the stone or weight which assisted his descent is hauled out afterwards. The length of time he continues under water is from one to two minutes, although instances have been known of divers who could remain four and even five minutes; and the longest period ever known was that of a diver who could prolong his stay under water full six minutes. The sea at the oyster banks is generally from four to ten fathoms deep, which is a descent easily accomplished by the divers. One boat, with the complement of men we have described, has been known, when the oysters were abundant, to bring to land thirty-three thousand in one day, while at other times a hundred or two are the whole day's produce. The divers on the Asiatic coasts are all natives, trained to this employment from infancy, and so expert from custom that they will make from forty to fifty plunges a-day; but the exertion is so violent, that water, and occasionally blood gushes from the mouth, nose, and ears. Some of the divers use no precautionary means whatever, while others rub their bodies with oil, and stuff their ears and noses to prevent the entrance of the water. They take no food while in the boats, nor till they have bathed themselves with fresh water, after returning to land. The only danger which the divers appear to apprehend in the course of their occupation, is from the shark, particularly the ground shark, which is a native of the Asiatic seas. Some of the divers are so expert in their movements as to avoid this enemy, even when they have been under water for a considerable time; but the chief reliance for security is on the priests and conjurors, some of whom always accompany the boats, by order of government, to inspire courage by their presence. Upon the whole, it must be admitted that few of the divers pursue their occupation voluntarily, but rather act under the compulsion of their employers and masters.

As soon as the boats land with the oysters an immense number of labourers, men, women, and children, rush to them, and carry off the produce of the day's fishing. Every speculator has his own group of huts, and in the midst of each of these is a *couttó*, or space of ground enclosed with poles and transverse pieces of bamboo, but open to the air. In these *couttós* are deposited the oysters as they are landed, and there they are left to putrefy, which they soon do under a burning sun. It is a curious fact, that though these numerous *couttós*, each containing an enormous mass of oysters, all putrefy together on a narrow extent of soil, and emit the most detestable odours, yet the health of the precarious but crowded population gathered there is in no ways affected. "During two consecutive years," says M. de Noé, "that I did duty at the fishery, I never saw a soldier of my regiment sick: Europeans and Sepoys all equally enjoyed good health." And Mr Marshall has observed to us, that in this climate, where the effects of vegetable decomposition are so fatal and so rapid, those of animal decomposition are almost innocuous. As soon as the putrefaction is sufficiently advanced, the oysters are taken from the *couttó*, and placed in troughs, made of the trunk of trees, hollowed; sea-water is then thrown over them. In this putrid state the oysters easily render the pearls they contain; and a number of men, all standing on the same side of the trough, rapidly shake them out and wash them. Inspectors stand at each end of the trough to see that the labourers secrete none of the pearls, and others are in the rear to examine whether the shells thrown out as worthless may not contain some of the precious substance. The workmen are prohibited, under penalty of a beating, to lift their hands to their mouths while they are washing the pearls. Notwithstanding these precautions and the vigilance of the inspectors, a man sometimes contrives to swallow a pearl of high price.

The various operations in preparing pearls for the market, occupy in Ceylon a great number of the inhabitants. After being thoroughly cleansed, they are rounded, and polished with a powder made of the pearls themselves, and arranged into classes according to their various sizes. They are then drilled and strung together, the largest classes being generally sent to the Indian, while the smaller meet with a ready sale in the European, market. The operation of drilling is an exceedingly nice one, and is performed with great expertness by the black people. The drilling instrument is a wooden machine in the form of an inverted cone, in the upper flat surface of which are pits, or depressions, to receive the pearls. The holes are made by spindles of various sizes, which revolve in a wooden head, by the action of a bow handle to which they are attached. During the operation, which is performed with one hand, while the other presses on the machine, the pearls are moistened occasionally, and the whole is done with astonishing rapidity. The colour of the pearls is in general a bluish or silvery white, but they are met with of a variety of hues, transparent, semi-transparent, opaque, brown and black.

The pearl fishery at the Bahreen Islands, in the Persian Gulf, is the most extensive in the world, but very little of its produce is brought to Europe. The pearls are of a golden yellow tint, and are held in great estimation by the Asiatics, on account of their retaining permanently their colour, whereas the white ones are liable to tarnish, and to lose their lustre. The oyster shells from this fishery are of a finer character than usual, and are sent to Constantinople, and to China, where they are manufactured into a great variety of useful and ornamental articles. Long before the discovery of America, pearls were highly valued by the natives; and the Spaniards, on their landing in the country, found large quantities of them in different quarters. The early colonists established regular fisheries, and a great revenue was derived by the Spanish monarchy from their importation into Europe. In one year 697 lbs. of pearls were brought over, many of them of great size and beauty.

carried on only in those countries where the wretchedness of one part of mankind goes to support the magnificence of the other.

The chief fishery, as was said, is carried on in the Persian Gulf, and the most valuable pearls are brought from thence. The value of these jewels increases not only in proportion to their size, but also their figure and colour; for some pearls are white, others are yellowish, others of a lead colour; and some affirm they have been found as black as jet. What it is that gives these different tinctures to pearls is not known: Tavernier ascribes it to their lying two or three weeks upon the shore after the oyster is taken: Reaumur thinks it proceeds from the colour of that part of the fish's body upon which the pearl lies. It is most probable that this colour proceeds, like the spots frequently found on the internal surface of the shell itself, from some accident while the pearl is growing.

The best coloured pearls, and the roundest are brought from the East: those of America are neither so white nor so exactly oval. All pearls, however, in time become yellow; they may be considered as an animal substance converted into a stony hardness, and, like ivory, taking a tincture from the air. They have been even found to decay when in damp or vaulted places, and to moulder into a substance scarcely harder than chalk. When the daughters of Stilicon, who were both betrothed, one after the other, to the emperor Honorius, were buried, much of their finery was also deposited with them in the same tomb. In this manner they remained buried for above eleven hundred years, till the foundations of the church of St Peter were laying. Their tomb was then discovered, and all their finery was found in tolerable preservation except the pearls, which were converted by time and damps into a chalky powder.

The wretched people that are destined to fish for pearls, are either negroes or some of the poorest of the natives of Persia. The inhabitants of this country are divided into tyrants and slaves. The divers are not only subject to the dangers of the deep, to tempests, to suffocation at the bottom, to being devoured by sharks, but from their profession universally labour under a spitting of blood, occasioned by the pressure of air upon their lungs in going down to the bottom. The most robust and healthy young men are chosen for this employment, but they seldom survive it above five or six years. Their fibres become rigid; their eye-balls turn red; and they usually die consumptive.

It is amazing how very long they are seen to continue at the bottom. Some, as we are assured, have been known to continue three quarters of an hour under water without breathing; and to one unused to diving, ten minutes would suffocate the strongest.[1] Whether from some effort the blood bursts the old passage which it had in the fœtus, and circulates without going through the lungs, it is not easy to tell; but certain it is that some bodies have been dissected with this canal of communication open, and these extraordinary divers may be internally formed in that manner.

Be this as it may, no way of life seems so laborious, so dangerous, or so painful. They fish for pearls, or rather the oysters that contain them, in boats twenty-eight feet long; and of these there are sometimes three or four hundred at a time, with each seven or eight stones, which serve for anchors. There are from five to eight divers belonging to each, that dive one after another. They are quite naked, except that they have a net hanging down from the neck to put their oysters in, and gloves on their hands to defend them while they pick the oysters from the holes in the rocks; for in this manner alone can they

From the fishery of St Magueritta, one was sent to Philip II. weighing 250 carats, and valued at 150,000 dollars. From neglect and improper management, the American pearl fisheries now produce little or nothing, and all that is procured is from the gulfs of Panama and California. A fishery of no contemptible extent existed about a century ago in the river Tay, but, either from being exhausted, or from the market being better supplied from other quarters, neither at this point nor on any other part of the British shores does any establishment of the kind now exist.

Pearls are found on analysis to consist of calcareous or chalky matter, disposed in thin coats or layers, an arrangement which corroborates the opinion that they are gradually deposited by the animal upon a small nucleus of sand, or other foreign body, which, being admitted along with the food, causes irritation, to prevent which the animal covers them with a gelatinous fluid, that grows hard by degrees. A grain of sand is often found in the centre of the pearl, but many of the largest want it altogether: and hence we are left in doubt regarding the correctness of the theory. Whatever be the cause of the formation of the pearl, there seems little doubt that it is produced by an unnatural or morbid action; and it is not a little curious, upon the whole, that a little functional derangement in an oyster should generate a gem, which for ages has been an ornament of crowns and courts.

[1] From the previous Note, it will be seen, that the period during which pearl-divers are said to remain under water is here grossly exaggerated. Fifty seconds is about the time that men in the bay of Naples, who dive for *frutta di mare*, or small shell-fish, and the Greek islanders of the Archipelago, who dive for sponges, remain under water; and these two classes are the most famous divers in Europe, and likely, from their physical construction, sober way of living, and constant practice, to carry their art to its utmost natural limits. Ribeyro, a Portuguese officer, who was nineteen years on the island, says, that the Ceylon plunger could stay under water for the space of time in which two *credos* might be repeated, and the Catholic belief may be said over twice in about fifty seconds.

be gathered. Every diver is sunk by means of a stone, weighing fifty pounds, tied to the rope by which he descends. He places his foot in a kind of stirrup, and laying hold of the rope with his left hand, with his right he stops his nose to keep in his breath, as upon going down he takes in a very long inspiration. They are no sooner come to the bottom, but they give the signal to those who are in the boat to draw up the stone; which done, they go to work, filling their net as fast as they can; and then giving another signal, the boats above pull up the net loaded with oysters, and shortly after the diver himself, to take a new inspiration. They dive to the depth of fifteen fathoms, and seldom go deeper. They generally go every morning by break of day to this fatiguing employment, taking the land wind to waft them out to sea, and returning with the sea-breeze at night. The owners of the boats usually hire the divers, and the rest of the boat's crew, as we do our labourers, at so much a day. All the oysters are brought on shore, where they are laid in a great heap, till the pearl fishery is over, which continues during the months of November and December. When opportunity serves, they then examine every oyster, and it is accidental whether the capture turns out advantageous. Indeed no human being can wish well to a commerce, which thus chains such a number of fellow-creatures to the bottom, to pluck up a glittering mouldering pebble.

CHAP. VII.

OF MULTIVALVE SHELL-FISH.

Multivalve Shell-Fish may be considered as animals shut up in round boxes. To view their habitations externally, one would be little apt to consider them as the retreats of living creatures; and still less, to suppose that some of them carry their boxes with a tolerable share of swiftness, so as to escape their pursuers. Of these there are principally two kinds; such as move, and such as are stationary: the first are usually known in our cabinets by the name of Sea-eggs; the others are as often admired, from the cavities which they scoop out for their habitation in the hardest marble. The first are called by naturalists, Echini, or Urchins;[1] the latter are called Pholades, or File fish. Of both there are several sorts; but, by describing these two, we shall have a competent idea of all the rest.

On a slight view, the sea-urchin may be compared to the husk of a chestnut; being, like it, round, and with a number of bony prickles standing out on every side. To exhibit this extraordinary animal in every light—if we could conceive a turnip stuck full of pins on every side, and running upon these pins with some degree of swiftness, we should have some idea of this extraordinary creature The mouth is placed downwards; the vent is above; the shell is a hollow vase, resembling a scooped apple; and this filled with a soft muscular substance, through which the intestines wind from the bottom to the top. The mouth, which is placed undermost, is large and red, furnished with five sharp teeth, which are easily discerned. The jaws are strengthened by five small bones, in the centre of which is a small fleshy tongue; and from this the intestines make a winding of five spires, round the internal sides of the shell, ending at the top, where the excrements are excluded. But what makes the most extraordinary part of this animal's conformation, are its horns and its spines, that point from every part of the body, like the horns of a snail, and that serve at once as legs to move upon, as arms to feel with, and as instruments of capture and defence. Between these horns it has also spines that are not endued with such a share of motion. The spines and the horns issue from every part of its body; the spines being hard and prickly; the horns being soft, longer than the spines, and never seen except in the water. They are put forward and withdrawn like the horns of a snail, and are hid in the bases of the spines, serving, as was said before, for procuring food and motion. All this apparatus, however, is only seen when the animal is hunting its prey at the bottom of the water; for a few minutes after it is taken, all the horns are withdrawn into the body, and most of the spines drop off.

It is generally said of insects, that those which have the greatest number of legs always move the slowest; but this animal seems to be an exception to the rule; for though furnished with two thousand spines, and twelve hundred horns, all serving for legs, and from their number seeming to impede each other's motion, yet it runs with some share of swiftness at the bottom, and it is sometimes no easy matter to overtake it. It is often taken upon the ebb, by following it in shallow water, either in an osier basket, or simply with the hand. Both the spines and the horns assist its motion; and the animal is usually seen running with the mouth downward.

[1] The sea-urchins are very improperly placed in the multivalve division of shells, as they are very different from testaceous worms, not only in their functions, but also in the composition of their shells. They are placed by naturalists in the crustaceous order, the shells or crusts of Echini being composed of phosphate of lime with animal matter; those of the testaceous shells being carbonate of lime.

Some kinds of this animal are as good eating as the lobster; and its eggs, which are of a deep red, are considered as a very great delicacy. But of others the taste is but indifferent; and in all places, except the Mediterranean, they are little sought for, except as objects of curiosity.

Very different in motion, though not much different in shape, from these, are the Acorn Shell-Fish, the Thumb-footed Shell-Fish, and the imaginary Barnacle. These are fixed to one spot, and appear to vegetate from a stalk. Indeed, to an inattentive spectator, each actually seems to be a kind of fungus that grows in the deep, destitute of animal life, as well as motion. But the inquirer will soon change his opinion, when he comes to observe this mushroom-like figure more minutely. He will then see that the animal residing within the shell has not only life, but some degree of voraciousness; that it has a cover, by which it opens and shuts its shell at pleasure; that it has twelve long crooked arms, furnished with hair, which it thrusts forth for its prey; and eight smaller, which are generally kept in the shell. They are seen adhering to every substance that is to be met with in the ocean; rocks, roots of trees, ships' bottoms, whales, lobsters, and even crabs, like bunches of grapes clung to each other It is amusing enough to behold their operations.[1] They for some time remain motionless within their shell; but when the sea is calm, they are seen opening the lid, and peeping about them. They then thrust out their long neck, look round them for some time, and then abruptly retreat back into their box, shut their lid, and lurk in darkness and security. Some people eat them; but they are in no great repute at the tables of the luxurious, where their deformed figure would be no objection to their being introduced.

Of all animals of the shelly tribe, the Pholades are the most wonderful. From their great powers of penetration, compared with their apparent imbecility, they justly excite the astonishment of the curious observer. These animals are found in different places; sometimes clothed in their proper shell, at the bottom of the water; sometimes concealed in lumps of marly earth; and sometimes lodged, shell and all, in the body of the hardest marble. In their proper shell they assume different figures; but, in general, they somewhat resemble a mussel, except that their shell is found actually composed of five or more pieces, the smaller valves serving to close up the openings left by the irregular meeting of the two principal shells. But their penetration into rocks, and their residence there, makes up the most wonderful part of their history.

This animal, when divested of its shell, resembles a roundish soft pudding, with no instrument that seems in the least fitted for boring into stones, or even penetrating the softest substances. It is furnished with two teeth indeed: but these are placed in such a situation as to be incapable of touching the hollow surface of its stony dwelling: it has also two covers to its shell, that open and shut at either end; but these are totally unserviceable to it as a miner. The instrument with which it performs all its operations, and buries itself in the hardest rocks, is only a broad fleshy substance, somewhat resembling a tongue, that is seen issuing from the bottom of its shell. With this soft yielding instrument, it perforates the most solid marbles; and having, while yet little and young, made its way, by a very narrow entrance, into the substance of the stone, it then begins to grow bigger, and thus to enlarge its apartment.

The seeming unfitness, however, of this animal for penetrating into rocks, and there forming a habitation, has induced many philosophers to suppose that they entered the rock while it was yet in a soft state, and from the petrifying quality of the water, that the whole rock hardened round them by degrees. Thus any penetrating quality, it was thought, was unjustly ascribed to them, as they only bored into a soft substance, that was hardened by time. This opinion, however, has been confuted, in a very satisfactory manner, by Dr Bohads, who observed that many of the pillars of the temple of Serapis at Puteoli were penetrated by these animals. From thence he very justly concludes, that the pholades must have pierced into them since they were erected; for no workman would have laboured a pillar into form, if it had been honey-combed by worms in the quarry. In short, there can be no doubt but that the pillars were perfectly sound when erected; and that the pholades have attacked them, during the time in which they continued buried under water, by means of the earthquake that swallowed up the city.[2]

From hence it appears that, in all nature, there is not a greater instance of perseverance and patience than what this animal is seen to exhibit. Furnished with the bluntest and sofest auger, by slow successive applications, it effects what other animals are incapable of performing by force; penetrating the hardest bodies only with its tongue. When, while yet naked, and very small, it has effected an entrance, and has buried its body in the stone, it there continues for life at its ease; the sea-water that enters at the little aperture supplying it with luxurious plenty. When the

[1] Anderson's History of Greenland.

[2] Bohadsch de Animalibus Marinis, p. 153.

animal has taken too great a quantity of water, it is seen to spurt it out of its hole with some violence. Upon this seemingly thin diet it quickly grows larger, and soon finds itself under a necessity of enlarging its habitation and its shell. The motion of the pholas is slow beyond conception; its progress keeps pace with the growth of its body; and, in proportion as it becomes larger, it makes its way farther into the rock. When it has got a certain way in, it then turns from its former direction, and hollows downward; till at last, when its habitation is completed, the whole apartment resembles the bowl of a tobacco pipe; the hole in the shank being that by which the animal entered.

Thus immured, the pholas lives in darkness, indolence, and plenty; it never removes from the narrow mansion into which it has penetrated; and seems perfectly content with being inclosed in its own sepulchre. The influx of the sea-warer that enters by its little gallery satisfies all its wants; and, without any other food, it is found to grow from seven to eight inches long, and thick in proportion.

But they are not supplied only with their rocky habitation; they have also a shell to protect them: this shell grows upon them in the body of the rock, and seems a very unnecessary addition to their defence, which they have procured themselves by art. These shells take different forms, and are often composed of a different number of valves; sometimes six, sometimes but three; sometimes the shell resembles a tube with holes at either end, one for the mouth, and the other for voiding the excrements.

Yet the pholas thus shut up, is not so solitary an animal as it would at first appear; for though it is immured in its hole without egress, though it is impossible for the animal, grown to a great size, to get out by the way it made in, yet many of this kind often meet in the heart of the rock, and like miners in a siege, who sometimes cross each other's galleries, they frequently break in upon each other's retreats. Whether their thus meeting be the work of accident or of choice, few can take upon them to determine: certain it is, they are most commonly found in numbers in the same rock; and sometimes above twenty are discovered within a few inches of each other.[1]

As to the rest, this animal is found in greatest numbers at Ancona, in Italy; it is found along the shores of Normandy and Poitou, in France; it is found also upon some of the coasts of Scotland: and, in general, is considered as a very great delicacy at the tables of the luxurious.

---

[1] *Molluscæ*.—Many may have probably noticed, in their ramblings along the sea beach, certain gelatinous transparent masses deposited by the receding tide upon the sands. They resemble very large planoconvex lenses, and are devoid of colour, except in a few minute points, which appear like grains of yellow sand, or the eggs of some shells embedded in their substance. This has led many to consider them as the spawn of some marine animal. If one of these jellies be placed in a tub of brine immediately after it reaches the shore, the observer, will be surprised to find it possessed of animation. The superior, or convex part, will expand like the top of an umbrella, and from its under surface several fringed and leaf-like membranes will be developed. The remains of numerous threads, or tendrils, will float out from the margin of the umbrella, following the motions of the animal as it swims around the tub. These threads are often several feet in length before they are broken by the sand; they are probably employed both to entice and secure the prey, and they produce a sharp, stinging sensation, when applied to the skin. It is from the appearance and offensive power of these last organs, that seamen have given the animal the title of the sea nettle, and naturalists the generic name *Medusa*.

The medusa is a familiar example of the class of animated beings which are the subjects of the following remarks. They are all alike gelatinous and transparent, and many of them melt and flow away when exposed in the open air to the direct rays of the sun.

Of all the tribes of molluscæ which are scattered over every part of the ocean, the most splendid and the best known is the *Portuguese man-of-war* (*Physalia*). This is an oblong animated sack of air, elongated at one extremity into a conical neck, and surmounted by a membraneous expansion running nearly the whole length of the body, and rising above into a semicirclar sail, which can be expanded or contracted to a considerable extent, at the pleasure of the animal. From beneath the body are suspended from ten to fifty or more little tubes, from half an inch to an inch in length, open at their lower extremity, and formed like the flower of the blue-bottle. These have been regarded as temporary receptacles for food, like the first stomach of cattle; but as the animal is destitute of any visible mouth or alimentary canal, and as I have frequently seen fish in their cavities apparently half digested, I cannot but consider them as proper stomachs; nor indeed is it a greater paradox in zoology that an animal should possess many independent stomachs; than that the strange carnivorous vegetable, the saracinea, should make use of its leaves apparently for a similar purpose. From the centre of this group of stomachs depends a little cord, never exceeding the fourth of an inch in thickness, and often forty times as long as the body. The size of the Portuguese man-of-war varies from half an inch to six inches in length. When it is in motion, the sail is accommodated to the force of the breeze, and the elongated neck is curved upward, giving to the animal a form strongly resembling the little glass swans which we sometimes see swimming in goblets.

The mode in which the animal secures his prey has been a subject of much speculation, for the fish and crabs that are frequently found within the little tubes are often large enough to tear them in pieces could they retain their natural vigour during the contest. Deceived by the extreme pain which is felt when the cable is brought into contact with the back of the hand, naturalists have concluded, I think too hastily, that this organ secretes a poisonous or acrid fluid, by which it benumbs any unfortunate fish or other animal that ventures within its toils, allured by the hope of making a meal upon what, in its ignorance, it has mistaken for a worm. The secret will be better explained by a more careful examination of the organ itself. The cord is composed of a narrow layer of contractile fibres, scarcely visible when relaxed, on account of its transparency. If the animal be large, this layer of fibres will sometimes extend itself to the length

of four or five yards. A spiral line of blue bead-like bodies, less than the head of a pin, revolves around the cable from end to end, and under the microscope these beads appear covered with minute prickles, so hard and sharp, that they will readily enter the substance of wood, adhering with such pertinacity that the cord can rarely be detached without breaking. It is to these prickles that the man-of-war owes its power of destroying animals much its superior in strength and activity. When any thing becomes impaled upon the cord the contractile fibres are called into action, and rapidly shrink from many feet in length to less than the same number of inches, bringing the prey within reach of the little tubes by one of which it is immediately swallowed.

I might now proceed to describe many analogous animals scarcely inferior in interest, but it is time to notice some individuals of another tribe, residing beneath the surface, and therefore less generally known.

The grandest of these is the *beroe*. In size and form it precisely resembles a purse, the mouth, or orifice, answering to one of the modern metallic clasps. It is perfectly transparent ; and in order to distinguish its filmy outlines, it is necessary to place it in a tumbler of brine held between the observer and the light. In certain directions the whole body appears faintly irridescent, but there are several longitudinal narrow lines which reflect the full rich tints of the rainbow in the most vivid manner, for ever varying and mingling the hues, even while the animal remains at rest. Under the microscope these lines display a succession of innumerable coloured scales or minute fins, which are kept unceasingly in motion, thus producing the play of colours by continually changing the angle of reflection. The movements of the beroe are generally retrograde, and are not aided by the coloured scales, but depend upon the alternate contraction and dilatation of the mouth. The lips are never perfectly closed, and the little fish and shrimps which play around them are continually entering and leaving them at pleasure. The animal is dependent for its food upon such semi-animated substances as it draws within its grasp by moving slowly backwards in the water, and retains them in consequence of their own feebleness and inability to escape the weakest of snares.

Another tribe of the *sea-purses* (*Salpa*), though much smaller than the beroe, are more complex in structure, and possesses a higher interest in consequence of the singular habits of some of the species. They are double sacks, resembling the beroe in general form, but destitute of irridescence. The outer sack, or mantle, rarely exceeds an inch in length, and is commonly about half as wide. The inner sack is much smaller, and the interval between these forms a cavity for the water which they breathe, and for some of the viscera. Their visible organs are a transparent heart, which can only be seen in the strongest light ; a splendid double row of whitish bead-like cavities forming a spiral line near one extremity, and supposed to be either lungs or ovaries ; numerous broad, flat, pearly muscles, barely distinguished by their mistiness, and an alimentary canal as fine as horse-hair, with a slight enlargement at one spot, which has been called a stomach. This enlargement resembles both in size and colour a grain of sand. From the base of the animal arises two longer and four or five shorter conical spines of jelly, curved into hooks at the points, by means of which numerous individuals attach themselves together in double rows like the leaflets of a pinnated leaf. Cords of this kind, composed of forty or fifty animals, were often taken, but they separate and reattach themselves at pleasure.

To the gregarious habits of this little mollusque we owe a very singular and striking phenomena, which I have never seen noticed by naturalists, although we frequently witnessed it near the Cape of Good Hope. The animals are occasionally found associated together in such countless myriads that the sea is literally filled with them, sometimes over three or four square miles of surface, and to the depth of several fathoms. The yellow spots which have been described being the only coloured portions of their body, give to the whole tract the appearance of a shoal or sand-bank at some distance below the surface. The deception is heightened by the greater smoothness of the water at these places, particularly in calm weather ; for so closely are the animals crowded together, that the water is rendered in a manner less fluid ; the smaller billows break around the margin and are lost, while the heavy waves of the Southern ocean are somewhat opposed in their progress, and take on in a slight degree the usual appearance of the ground-swell. There can be but little doubt that many of the numerous shoals laid down in the charts of this region, but which have never been seen by any but the supposed discoverers, have been immense banks of these gregarious molluscæ. In sailing through a tract of this description, in which the progress of the ship was very sensibly retarded, I have dipt up with the ship's bucket a greater bulk of the animals than of the water in which they were suspended. How wonderful are the effects produced by the minute links of creation !"—*Dr Reynall Coates of Philadelphia.*

OF FROGS, LIZARDS, AND SERPENTS.

BOOK I.

OF FROGS AND TOADS.

CHAP. I.

OF FROGS AND TOADS IN GENERAL.

If we emerge from the deep, the first and most obvious class of amphibious animals that occur upon land are frogs and toads. These, wherever they reside, seem equally adapted for living upon land, and in the water, having their hearts formed in such a manner as to dispense with the assistance of the lungs in carrying on the circulation. The frog and the toad, therefore, can live several days under water, without any suffocation; they want but little air, and what is wanting is supplied by bags, like bladders, which are generally extended with wind, and answer all the purposes of a reservoir from whence to breathe.

To describe the form of animals so well known would be superfluous; to mark those differences that distinguish them from each other may be necessary. The frog moves by leaping; the toad crawls along the ground: the frog is, in general, less than the toad; its colour is brighter, and with a more polished surface; the toad is brown, rough and dusty. The frog is light and active, and its belly comparatively small; the toad is slow, swollen, and incapable of escaping. The frog, when taken, contracts itself so as to have a lump on its back; the toad's back is straight and even. Their internal parts are nearly the same, except that the lungs of the toad are more compact than those of the frog; they have fewer air-bladders, and, of consequence, the animal is less fitted for living under water. Such are the differences with respect to figure and conformation; their habitudes and manners exhibit a greater variety, and require a separate description.

CHAP. II.

OF THE FROG, AND ITS VARIETIES.

The external figure of the frog is too well known to need a description. Its power of taking large leaps is remarkably great, compared to the bulk of its body. It is the best swimmer of all four-footed animals; and nature hath finely adapted its parts for those ends, the arms being light and active, the legs and thighs long, and furnished with very strong muscles.

If we examine this animal internally, we shall find that it has a very little brain for its size; a very wide swallow; a stomach seemingly small, but capable of great distension. The heart in the frog, as in all other animals that are truly amphibious, has but one ventricle; so that the blood can circulate without the assistance of the lungs, while it keeps under water. The lungs resemble a number of small bladders joined together, like the cells of a honey-comb: they are connected to the back by muscles, and can be distended or exhausted at the animal's pleasure. The male has two testiculi lying near the kidneys; and the female has two ovaries lying near the same place; but neither male nor female have any of the external instruments of generation; the anus serving for that purpose in both. Such

are the most striking peculiarities in the anatomy of a frog; and in these it agrees with the toad, the lizard, and the serpent. They are all formed internally pretty much in the same manner, with spongy lungs, a simple heart, and are destitute of the external instruments that serve to continue the kind.

Of all those who have given histories of the frog, Mr Ræsal, of Nuremberg, seems the most accurate and entertaining. His plates of this animal are well known; his assiduity and skilfulness in observing its manners are still more deserving our esteem. Instead, therefore, of following any other, I will take him for my guide; and though it be out of my power to amuse the reader with his beautiful designs, yet there will be some merit in transcribing his history.

The common brown frog begins to couple early in the season, and as soon as the ice is thawed from the stagnating waters. In some places the cold protracts their genial appetite till April; but it generally begins about the middle of March. The male is usually of a grayish brown colour; the female is more inclining to yellow speckled with brown. When they couple, the colours of both are nearly alike on the back; but as they change their skins almost every eighth day, the old one falling off in the form of mucus, the male grows yellower, and the female more brown. In the males the arms and legs are much stronger than in the females; and at the time of coupling, they have upon their thumbs a kind of fleshy excrescence, which they fix firmly to the breast of the female. This Linnæus supposed to be the male instrument of generation; but, by closer inspection, it is found only of service in holding the female in a more strict embrace. It may be cut off, and the impregnation continue unimpaired: it is sometimes found in the opposite sex; and some of the males are found entirely without it; however, when it is cut off, the male cannot hold the female so strongly as before.

The sexes couple only once a year: and then continue united sometimes for four days together. At this time they both have their bellies greatly swollen; that of the female being filled with eggs; the male having the skin of the whole body distended with a limpid water, which is ejected in impregnation. As soon as the male has leaped upon the female, he throws his fore legs round her breast, and closes them so firmly, that it is impossible, with the naked hands, to loose them. The male clasps his fingers between each other, in the same manner as people when they are praying; the thumbs press with their thickest sides against the breast of the female; and though she should struggle ever so much, nothing can induce him to let go his hold. The grasp seems involuntary and convulsive; they cannot be easily torn asunder; and they swim, creep, and live united, for some days successively, till the female hath shed her spawn, which, at length, she does almost in an instant. But how the impregnation is performed, without any apparent instruments of generation, has long been an object of inquiry; and still continues in great obscurity. To investigate the difficulty as carefully as possible, our German philosopher continued to examine their mutual congress for three years together, and availed himself of all the lights that the knife, or analogy, could furnish.[1]

After having chosen twelve couple of frogs that were thus joined to each other, and having placed each couple in a glass vessel with water, he scarcely let them out of his sight day or night, and even sat up two nights together to examine their operations. The first day he observed nothing that deserved remark: but

[1] *Different developments of embryo of Frogs.*—During the cohesion of the two sexes, the female commences the deposition of the spawn, which is fecundated during its passage. When first expelled it consists of numerous small opaque globular bodies, enveloped in a small glairy, or glutinous mass. This latter substance soon absorbs a large quantity of water, and, in the course of an hour or two, each becomes not less than a quarter of an inch in diameter. The consequence of this augmentation in the bulk of the transparent mass, surrounding each embryo, is [illegible] all the latter are removed from each other by a wh[illegible]ter of each globe; and they appear like black d[illegible] distributed throughout a large mass of trans[illegible]

The deposit of th[illegible] at the bottom of the water, notwithst[illegible] but the [illegible]ion of some naturalists, and of Ræsel a[illegible] that they are expelled at the surface. The [illegible]e, probably, arose from the mass of eggs being generally found at the surface; but this arises merely from the disengagement of gas in the substance of the glairy envelope, in consequence of partial decomposition.

The changes which now begin to take place in the embryo are most interesting. They have been detailed in a very minute and satisfactory manner by Rusconi and I have taken considerable pains during the last spring to follow out his investigations, and by actual observation to correct or confirm his account. I may here observe, once for all, that with the exception of a few of the details in the earliest periods, I have been able to satisfy myself of his correctness; and in those points, I believe that I only failed to do so, partly by my not having obtained the ova immediately after their expulsion, and partly by the want of time to enter into all the necessary minutiæ of the investigation.

I have also to observe that the development of the young is more or less rapid, according to the temperature of the atmosphere; and that I was enabled to retard or hasten it by regulating this circumstance. I therefore kept my reservoir of eggs in a very cold situation, and occasionally brought a few of them into my drawing-room for the purpose of observation; in which place, being in an elevated temperature, the development became very rapid. As my object, therefore, was to ascertain positive facts, rather than the periods of the changes, which were dependant upon variable circumstances, I kept no register of the temperature or of the periods; and I shall, in both these particulars, give some of the statements of the accurate Rusconi.

the second they began to be agitated more than before; the males made a noise somewhat resembling the grunting of a hog; the females only kept sinking and rising in the water.

The embryo is found, in the first place, to consist of a small globular body, one side, or hemisphere, of which is of a dark brown colour, the other being much paler. In a very short period after the egg is deposited,—four hours, according to Rusconi,—a deep furrow across the dark hemisphere divides it into two equal parts, and this is soon afterwards crossed by another at right angles; a third and a fourth furrow are produced, and so on, until the whole surface of this side of the sphere is, as it were, granulated. This appearance, however, is but transitory, the surface soon becoming almost smooth. In the course of the second day, the sphere begins to elongate, and a groove, which had previously divided the upper part of it into two equal parts, begins to close up. The head becomes prominent, the tail begins to show itself, the little hooks by which it subsequently lays hold of objects and supports itself, begin to appear. At this period the examination becomes more easy, and more interesting. At somewhat more than fifty hours in an elevated temperature, the head is very well marked, the tail somewhat elongated, and even the rudiment of the membrane, or web, which is destined to form its fin, is visible. About this time, also, a small projection takes place on each side of the head, which is the earliest indication of the branchiæ, and the muscles of the spine may just be seen. In figure 2 of the woodcut, I have given an outline of the embryo in this condition. At this time the water is seen to flow in a distinct and rapid current to the branchial orifice over the rudiments of the branchiæ, which are now just visible, the course of which current I have indicated by arrows. These parts gradually become more developed; the body is more elongated, the branchiæ more distinct; the fin extends round the tail and partly over the back; and the head is distinguished from the body by a slight contraction at the neck; and a short period more suffices to bring it to

The male of the first couple ejected the humidity with which his body was swollen, by which the water in the glass was made muddy; and he soon after quitted the female.—Our philosopher continued for twelve hours to

the condition represented in figures 3, 4, of the woodcut, in which the branchiæ are seen to consist of two tubercles on each side, as yet simple and undivided; the holders, which are small simple organs placed near the situation of the future mouth, and which serve to enable the little animal to attach itself by means of a viscid secretion at their extremities, have become longer, the web, or fin, is also enlarged. By this time the first voluntary motion of the embryo is discovered on the application of any means of excitement or disturbance; but it consists only of a slight movement of the head or tail. The nostrils are seen more distinctly, but the mouth is scarcely yet observable, and shortly afterwards the eye, in a rudimentary state, may be just discerned. The next step in the development is a slight division of the branchiæ into lobes, and the appearance of that beautiful and interesting phenomenon, the circulation of the blood through these organs. The embryo, which is still confined to a curved position by the envelopes (fig. 1), is now seen frequently to extend itself by sudden jerks, as if to emancipate itself from its confinement, which it eventually does by tearing the membrane of the egg. The Tadpoles, we see, are now hatched (fig. 5). According to Rusconi, this takes place within four days after the deposit of the eggs, in a temperature varying only from 23° to 27° Centigr. (73°.4 to 80°.6 Fahr.); but certainly in our own climate, in the ordinary temperature of our spring, it does not take place until at least a month. As I before observed, the development may be greatly hastened by a constant elevation of temperature, and I was often surprised at the degree to which this was the case in the course of my own observations; but the comparatively low temperature of our spring, and the cold frosty nights which occur in March and April, may well account for such a discrepancy. If the eggs be deposited at the middle or latter end of March, it is generally, with us, the latter end of April before they are hatched. The situation of the mouth is now distinctly visible, though the opening is but small; and even when it becomes considerably enlarged it has no power of movement, and there are no distinct lips. The branchiæ now speedily enlarge, and each of the two branches on either side is seen to consist of about four leaves (figs. 6. 9); these are sessile upon the body or stem of the branchia; they are somewhat granular on the surface, and slightly irregular in their form; there is also frequently a short additional branch at the base of the posterior one, as is shown in the outline, figure 9. The present state of these organs, which have now arrived at their maximum of development, constitutes one of the most charming objects for microscopic observation which can be conceived, and to view which a very high power is not necessary, nor even desirable. The current of the blood poured in regular pulsations at each contraction of the heart, passes up each stem or main branch of the branchiæ, and a distinct stream is given off to each leaf; it is propelled to the extremity, and then returns down the opposite sides in the most regular manner, and the parts are so transparent that every globule of blood is distinctly and beautifully visible.

This state of things, however, is destined to last but a short time. No sooner have these interesting organs attained their greatest development than they begin to diminish in size; they become obtuse (fig. 7,) and are gradually so reduced as to be withdrawn within the branchial cavity, and concealed by a little operculum of the integument. The eyes are now perfectly formed. The holders have become much diminished in size; the

observe whether the female would cast her spawn; but finding her tardy, he dissected both her and the male: in the latter, the spermatic vessels were quite empty, as might naturally have been supposed; but for the female, her spawn still remained in her body. Upon its being extracted, and put into water, it perished without producing any animal whatever. From hence he justly concluded, that it required that the eggs should be ejected from the body of the female before they could be at all prolific. In another pair the male quitted the female, who did not eject her spawn till sixteen days after; and these, like the former, came to nothing. But it was very different with some of the rest. The females ejected their spawn while the male still remained in his station, and impregnated the masses at different intervals as they fell from her; and these all brought forth animals in the usual course of generation. From these observations it was easy to infer, that the female was impregnated neither by the mouth, as some philosophers imagined, nor by the excrescence at the thumbs, as was the opinion of Linnæus, but by the inspersion of the male seminal fluid upon the eggs, as they proceeded from the body.

A single female produces from six to eleven hundred eggs at a time; and, in general, she throws them all out together by a single effort; though sometimes she is an hour in performing this task. While she is thus bringing forth, it may be observed that the male acts the part of a midwife, and promotes the expulsion of the eggs by working with his thumbs, and compressing the female's body more closely. The eggs which were compressed in the womb, upon being emitted, expand themselves into a round form, and drop to the bottom of the water; while the male swims off, and strikes with his arms as usual, though they had continued so long in a state of violent contraction.

The egg, or little black globe, which produces a tadpole, is surrounded with two different kinds of liquor. That which immediately surrounds the globe is clear and transparent, and is contained in its proper membrane; that which surrounds the whole is muddy and mucous. The transparent liquor serves for the nourishment of the tadpole from time to time; and answers the same purposes that the white of the egg does to birds. The tadpoles, when this membrane is broken, are found to adhere with their mouth to part of it; and when they get free, they immediately sink to the bottom of the water, never being able to get to the top after, while they continue in their tadpole form.

But to return—When the spawn is emitted and impregnated by the male, it drops, as was said, to the bottom, and there the white quickly and sensibly increases. The eggs, which, during the four first hours, suffer no perceptible change, begin then to enlarge and grow lighter; by which means they mount to the surface of the water. At the end of eight hours the white in which they swim grows thicker, the eggs lose their blackness, and, as they increase in size, somewhat of their spherical form. The twenty-first day, the egg is seen to open a little on one side, and the beginning of a tail to peep out, which becomes more and more distinct every day. The thirty-ninth day the little animal begins to have motion; it moves at intervals its tail; and it is perceived that the liquor in which it is circumfused serves it for nourishment. In two days more some of these little creatures fall to the bottom; while others remain swimming in the fluid around them, while their vivacity and motion is seen to increase. Those which fall to the bottom remain there the whole day; but having lengthened themselves a little, for hitherto they are doubled up, they mount, at intervals, to the mucus which they had quitted, and are seen to feed upon it with great vivacity. The next day they acquire their tadpole form.[1] In three days more they are perceived to have two little fringes, that serve as fins beneath the head; and these, in four days after, assume a more perfect form. It is then, also, that they are seen to feed very greedily upon the pond-weed with which they are to be supplied; and, leaving their former food, on this they continue to subsist till they arrive at maturity. When they come to be ninety-two days old, two small feet are seen beginning to bourgeon near the tail: and the head appears to be separate from the body. The next day the legs are considerably enlarged: four days after

mouth has acquired movable lips, and has changed its position from the inferior part of the head to near the extremity, and the little creature which has hitherto derived its sustenance either from its own resources or by absorption, now seeks its food amid softened and decomposing vegetable matter. The caudal web (fig. 8) has, therefore, become considerably developed, and serves for very rapid as well as varied locomotion. The colour of the body, too, has undergone a considerable change, having become of a soft olive green, the abdomen being dotted with golden yellow. The Tadpole now undergoes but little change in its external form for a considerable time, but increases rapidly in bulk, and by and by a little tubercle appears on each side of the vent, which is the rudiment of the posterior extremity.—*Bell's History of British Reptiles.*

[1] The tadpole is furnished with a small tube beneath the lower jaw, which acts as a sucker, and by means of which it can, at pleasure, attach itself to the under surface of aquatic plants: from these plants it can also suspend itself, when very young, by a kind of glutinous thread, in the same manner as spiders drop from the ceiling to the ground.

they refuse all vegetable food; their mouth appears furnished with teeth; and their hinder-legs are completely formed. In two days more the arms are completely produced; and now the frog is every way perfect, except that it still continues to carry the tail. In this odd situation the animal, resembling at once both a frog and a lizard, is seen frequently rising to the surface, not to take food, but to breathe. In this state it continues for about six or eight hours, and then, the tail dropping off by degrees, the animal appears in its most perfect form.

Thus the frog, in less than a day, having changed its figure, is seen to change its appetites also. So extraordinary is this transformation, that the food it fed upon so greedily but a few days before, is now utterly rejected; it would even starve if supplied with no other. As soon as the animal acquires its perfect state, from having fed upon vegetables, it becomes carnivorous, and lives entirely upon worms and insects. But as the water cannot supply these, it is obliged to quit its native element, and seek for food upon land, where it lives by hunting worms, and taking insects by surprise. At first, being feeble and unable to bear the warmth of the sun, it hides among bushes and under stones; but when a shower comes to refresh the earth, then the whole multitude are seen to quit their retreats, in order to enjoy the grateful humidity. Upon many occasions the ground is seen perfectly blackened with their numbers; some hunting for prey, and some seeking secure lurking places. From the myriads that offer on such occasions, some have been induced to think that these animals were generated in the clouds, and thus showered down on the earth. But had they, like Derham, traced them to the next pool, they would have found out a better solution for the difficulty.

The frog lives for the most part out of the water; but when the cold nights begin to set in, it returns to its native element, always choosing stagnant waters, where it can lie without danger concealed at the bottom. In this manner it continues torpid, or with but very little motion, all the winter: like the rest of the dormant race, it requires no food; and the circulation is slowly carried on without any assistance from the air.

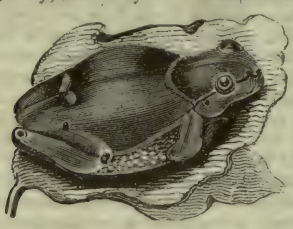
It is at the approach of spring that all these animals are roused from a state of slumber to a state of enjoyment. A short time after they rise from the bottom they begin to pair, while those that are as yet too young come upon land before the rest. For this reason, while the old ones continue concealed in the beginning of spring, the small ones are more frequently seen; the former remaining in the lake to propagate, while the latter are not yet arrived at a state of maturity.[1]

The difference of sexes, which was mentioned above, is not perceivable in these ani-

[1] There are various species of frogs, of which we may notice the more remarkable. The Common Frog of this country is called the Red Frog by the French. The *Green Frog* is the common frog of France, and is the one chiefly used at table. Its thighs are in great request there among the amateurs of good cheer, although in this country a stupid prejudice exists against it. Its colour is an olive green, distinctly marked with black patches on the back, and on its limbs with transverse bars of the same. From the tip of the nose three distinct stripes of a pale yellow extend to the extremity of the body, the middle one slightly depressed, and the lateral ones considerably elevated. The under parts are of a pale whitish colour tinged with green, and marked with irregular brown spots. Though not common in England, it is found in great plenty in Italy, France, and Germany. This species seldom deposits its spawn before the month of June. During this season the male is said to croak so loud as to be heard at a great distance. In some particular places, where these animals are numerous, their croaking is very oppressive to persons unaccustomed to it. The globules of spawn are smaller than those of the common frog; and the young are considerably longer in attaining their complete state, this seldom taking place till November. They arrive at their full growth in about four years, and live to the age of sixteen or seventeen. They are excessively voracious, frequently seizing young birds, and even mice, which, like the rest of their prey of snails, worms, &c. they swallow whole.

Edible frogs are brought from the country, thirty or forty thousand at a time, to Vienna, and sold to the great dealers, who have conservatories for them, which are large holes, four or five feet deep, dug in the ground, the mouth covered with a board, and in severe weather with straw. In these conservatories, even during a hard frost, the frogs never become quite torpid; when taken out, and placed on their backs, they are always sensible of the change, and have strength enough to turn themselves. They get together in heaps, one upon another, instinctively, and thereby prevent the evaporation of their humidity; for no water is ever put to them. In Vienna, in the year 1793, there were only three great dealers, by whom most of those persons were supplied who brought them to the market ready for the cook. As their spawning time is so very late in the year, those animals that are brought to market before the month of June for edible frogs, are supposed to be either common frogs, or sometimes toads.

The large water, or *Bull-frog*, is also edible, having as much on them as a young fowl. It frequently measures from the nose to the hind feet, a foot and a half, or upwards. Its colour is a dusky olive brown, marked with numerous dark spots, lighter beneath than above. The external membranes of the ears are large, round, and of a brownish red surrounded by a yellowish margin. This species is chiefly found in the anterior parts of America, where, at the springs and small rills, they are said to sit in pairs. Kalm, however, says, that they frequent only ponds and marshes. In Virginia they are in such abundance, that there is scarcely a single spring that has not a pair of them. The inhabitants, who respect them as genii of the fountains, imagine that they purify the water. The women, however, are no friends to them, because they kill and eat young ducks and goslings; and sometimes they carry off chickens that venture too near the pond. When suddenly surprised, by a long leap or two they enter their hole, at the bottom of which they lie perfectly secure. A full-grown bull-frog will sometimes leap three yards. Kalm relates the following story respecting one



mals, until they have arrived at their fourth year; nor do they begin to propagate, till they have completed that period. By comparing their slow growth with their other habitudes, it would appear that they live about twelve years; but having so many enemies, both by land and water, it is probable that few of them arrive at the end of their term.

Frogs live upon insects of all kinds; but

---

of them. The American Indians are known to be excellent runners, being almost able to equal the best horse in its swiftest course. In order, therefore, to try how well the bull-frog could leap, some Swedes laid a wager with a young Indian that he could not overtake one of them, provided it had two leaps beforehand. They carried a bull-frog, which they had caught in a pond, into a field, and burnt its tail. The fire and the Indian who endeavoured to get up to the frog, had together such an effect on the animal, that it made its long leaps across the field as fast as it could. The Indian pursued it with his might. The noise he made in running frightened the poor frog; probably it was afraid of being tortured with fire again, and therefore it redoubled its leaps, and by that means reached the pond, which was fixed on as their goal, before the Indian could overtake it. This animal is called the bull-frog on account of its croaking, which is said somewhat to resemble the hoarse lowing of a bull; and when, in a calm night, many of them are making a noise together, they may be heard to the distance of a mile and a half. The night is the time when they croak, and they are said to do it at intervals. In this act they are either hidden among the grass or rushes, or they are in the water, with their heads above the surface. Kalm informs us that, as he was one day riding out, he heard one of them roaring before him, and supposed it to be a bull hidden in the bushes at a little distance. The voice was, indeed, more hoarse than that of a bull, yet it was too loud for him to conceive that it could be emitted by so small an animal as a frog, and he was in considerable alarm for his safety. He was undeceived a few hours afterwards, by a party of Swedes, to whom he had communicated his fears.

The *Tree-frog*, which is a native of America, France, Germany, Italy, and many other European regions, but

never found in Britain, is small, and of a slender and very elegant shape. It is the only species found in Europe of a genus called *Hylæ*, which are distinguished from frogs and toads by the viscous cushions by which the toes are terminated. Its upper parts are green, and the abdomen is whitish, marked by numerous granules. The under surface of the limbs is reddish, and on each side of the body there is a longitudinal blackish or violet-coloured streak. The body is smooth above, and the hind legs are very long and slender. At the end of each toe is a round, fleshy, concave apparatus, not unlike the mouth of a leech, by means of which the animal is enabled to adhere even to the most polished surfaces. This animal, during the summer months, resides principally on the upper branches of the trees, where it wanders among the foliage in quest of insects. These it catches with great dexterity, stealing softly to them, as a cat does to a mouse, till at a proper distance, when it makes a sudden spring upon them of frequently more than a foot in height. It often suspends itself by its feet, or abdomen, to the upper parts of leaves, remaining thus concealed among the foliage. The skin of the abdomen

---

is covered with small glandular granules of such a nature as to allow the animal to adhere as well by these as by the toes. It will even stick to glass by pressing its belly against it. About the end of autumn the tree-frog retires to the water and lies concealed in a torpid state in the mud till the spring, when, on the return of warm weather, it emerges, like the rest of the genus, to deposit its spawn in the water. At this period the male inflates his throat in a surprising manner, forming a large sphere beneath his head; he also exerts a very loud and sharp croak, that may be heard to a vast distance. The tadpoles become perfected about the beginning of August, and they soon afterwards begin to ascend the adjacent trees. At this time they are particularly noisy in the evenings on the approach of rain; therefore, if kept in glasses in a room, and supplied with proper food, they will supply the place of barometers by affording sure presage of changes of weather.

Tree-frogs have been kept also by Dr Townson, who had them in a window, and appropriated to their use a bowl of water, in which they lived. They soon grew quite tame; and to two that he had had for a considerable length of time, and were particular favourites, the doctor gave the names of Damon and Musidora. In the evening they seldom failed to go into the water, unless the weather was cold and damp, in which case they would sometimes stay out a couple of days. When they were out of the water, if a few drops were thrown upon the board, they always applied their bodies as close to it as they could; and from this absorption through the skin, though they were flaccid before, they soon again appeared plump. A tree frog that had not been in the water during the night was weighed, and then immersed; after it had remained half an hour in the bowl it came out, and was found to have absorbed nearly half its own weight in water. From other experiments, it was discovered that these animals frequently absorbed nearly their whole weight of water; and that, as was clearly proved, by the under surface only of the body. They will even absorb water from wetted blotting paper. Sometimes they eject water with considerable force from their bodies, to the quantity of a fourth part or more of their weight. Before the flies had disappeared in autumn, the doctor collected for his favourite tree-frog, Musidora, a great quantity, as winter provision. When he laid any of them before her she took no notice of them, but the moment he moved them with his breath, she sprung upon and ate them. Once, when flies were scarce, the doctor cut some flesh of a tortoise into small pieces, and moved them by the same means; she seized them, but the instant afterwards rejected them from her tongue. After he had obtained her confidence, she ate from his fingers dead as well as living flies. Frogs will leap at the moving of any small object: and, like toads, they will also soon become sufficiently familiar to sit on the hand, and be carried from one side of a room to the other, to catch flies as they settle on the wall. This gentleman accordingly made them his guards at Gottingen, for keeping these troublesome creatures from his dessert of fruit, and they performed their task highly to his satisfaction. He has seen the small tree-frogs eat humble-bees, but this was never done without some contest; they are in general obliged to reject them, being incommoded by their stings and hairy roughness; but in each attempt the bee is further covered with the viscid matter from the frog's tongue, and when thus coated it is swallowed with facility.

A battle between a tree-frog and snake was seen in

they never eat any unless they have motion, They continue fixed and immovable till their prey appears; and just when it comes sufficiently near, they jump forward with great agility, dart out their tongues, and seize it with certainty. The tongue, in this animal, as in the toad, lizard, and serpent kinds, is extremely long, and formed in such a manner, that it swallows the point down its throat; so that a length of tongue is thus drawn out, like a sword from its scabbard, to assail its prey. This tongue is furnished with a glutinous substance; and whatever insect it touches, infallibly adheres, and is thus held fast till it is drawn into the mouth.

As the frog is thus supplied with the power of catching its prey, it is also very vivacious, and able to bear hunger for a very long time. I have known one of them continue a month in summer without any other food than the turf on which it was placed in a glass vessel. We are told of a German surgeon, that kept one eight years in a glass vessel, covered with a net. Its food was at all times but sparing: in summer he gave it fresh grass, which it is said to have fed upon; and, in the winter, hay, a little moistened; he likewise, now and then, put flies into the glass, which it would follow with an open mouth, and was very expert in catching them. In winter, when the flies were difficult to be found, it usually fell away, and grew very lean; but in the summer, when they were plenty, it soon grew fat again. It was kept in a warm room, and was always lively and ready to take its prey: however, in the eighth winter, when there were no flies to be found, it fell away and died. It is not certain how long it might have lived, had it been supplied with proper nourishment; but we are certain, that a very little food is capable of sufficing its necessities.

Nor is the frog less tenacious of life. It will live and jump about several hours after its head has been cut off. It will continue active, though all its bowels are taken out; and it can live some days, though entirely stripped of its skin. This cruel trick, which is chiefly practised among school-boys, of skinning frogs, an operation which is done in an instant, seems for some hours no way to abate their vigour. I am assured that some of them get a new skin, and recover, after this painful experiment.

The croaking of frogs is well known; and, from thence, in some countries, they are distinguished by the ludicrous title of Dutch Nightingales. Indeed, the aquatic frogs of Holland are loud beyond what one would imagine. We could hardly conceive that an animal, not bigger than one's fist, should be able to send forth a note that is heard at three miles' distance; yet such is actually the case.[1] The large water-frogs have a note as loud as the bellowing of a bull; and, for this purpose, puff up the cheeks to a surprising magnitude. Of all frogs, however, the male only croaks; the female is silent, and the voice in the other seems to be the call to courtship. It is certain, that at these times when they couple, the loudness of their croaking is in some places very troublesome; for then the whole lake seems vocal; and a thousand dissonant notes perfectly stun the neighbourhood. At other times, also, before wet weather, their voices are in full exertion: they are then heard with unceasing assiduity, sending forth their call, and welcoming the approaches of their favourite moisture. No weather-glass was ever so true as a frog in foretelling an approaching change; and, in fact, the German surgeon, mentioned above, kept his frog for that purpose. It was always heard to croak at the approach of wet weather; but was as mute as a fish when it threatened a continuance of fair. This may probably serve to explain an opinion which some entertain, that there is a month in the year, called *Paddock Moon*, in which the frogs never croak: the whole seems to be no more than that, in the hot season, when the moisture is dried away, and consequently, when these animals neither enjoy the quantity of

the top of a mangrove-tree, by one of the officers who was with Captain Stedman, when he was sailing up one of the rivers of Surinam in a canoe. When the captain first perceived them, the head and shoulders of the frog were in the jaws of the snake, which was about the size of a large kitchen poker. This creature had its tail twisted round a tough limb of the mangrove, while the frog, which appeared about the size of a man's fist, had laid hold of a twig with his hind feet. In this position they were contending, the one for life, the other for his dinner, forming one straight line between the two branches; and thus they continued for some time, apparently stationary, and without a struggle. Still it was hoped, that the poor frog might extricate himself by his exertions, but the reverse was the case. The jaws of the snake, gradually relaxing, and by their elasticity forming an incredible orifice, the body and fore legs of the frog by little and little disappeared, till finally nothing more was seen than the hinder feet and claws, which were at last disengaged from the twig, and its formidable adversary drew it down its throat by suction. The frog passed some inches further down the alimentary canal, and at last stuck, forming a knob or knot at least six times as thick as the snake, whose jaws and throat immediately contracted, and resumed their former natural shape.

The *Fire Frog*—The fire-frog is the least of all the European frogs, hardly ever equalling the tree-frog in size, and is a native of Germany, Italy, and many other parts of Europe, but is not found in England. Its colour on the upper part is of a dull olive brown, the skin being marked with large and small tubercles: round the edges of the mouth is placed a row of blackish streaks or perpendicular spots. The under parts both of the body and limbs are orange-coloured, spotted or variegated with irregular markings of dull blue. It is from the colour of the under surface of its body that this species has obtained the name of fire-frog.

[1] Rœsel. ibid.

health or food that at other times they are supplied with, they show, by their silence, how much they are displeased with the weather. All very dry weather is hurtful to their health, and prevents them from getting their prey. They subsist chiefly upon worms and snails; and as drought prevents these from appearing, the frog is thus stinted in its provisions, and also wants that grateful humidity which moistens its skin, and renders it alert and active.

As frogs adhere closely to the backs of their own species, so it has been found, by repeated experience, they will also adhere to the backs of fishes. Few that have ponds, but know that these animals will stick to the backs of carp, and fix their fingers in the corner of each eye. In this manner they are often caught together; the carp blinded and wasted away. Whether this proceeds from the desires of the frog, disappointed of its proper mate, or whether it be a natural enmity between frogs and fishes. I will not take upon me to say. A story told us by Walton, might be apt to incline us to the latter opinion.

"As Dubravius, a bishop of Bohemia, was walking with a friend by a large pond in that country, they saw a frog, when a pike lay very sleepily and quiet by the shore side, leap upon his head, and the frog having expressed malice or anger by his swoln cheeks and staring eyes, did stretch out his legs, and embraced the pike's head, and presently reached them to his eyes, tearing with them and his teeth those tender parts; the pike, irritated with anguish, moves up and down the water, and rubs himself against weeds, and whatever he thought might quit him of his enemy; but all in vain, for the frog did continue to ride triumphantly, and to bite and torment the pike till his strength failed, and then the frog sunk with the pike to the bottom of the water: then presently the frog appeared again at the top, and croaked, and seemed to rejoice like a conqueror; after which he presently retired to his secret hole. The bishop, that had beheld the battle, called his fisherman to fetch his nets, and by all means to get the pike, that they might declare what had happened. The pike was drawn forth, and both his eyes eaten out; at which, when they began to wonder, the fisherman wished them to forbear, and assured them he was certain that pikes were often so served."

CHAP. III.

OF THE TOAD, AND ITS VARIETIES.

If we regard the figure of the toad, there seems nothing in it that should disgust more than that of the frog. Its form and proportions are nearly the same; and it chiefly differs in colour, which is blacker; and its slow and heavy motion, which exhibits nothing of the agility of the frog: yet such is the force of habit, begun in early prejudice, that those who consider the one as a harmless playful animal, turn from the other with horror and disgust. The frog is considered as a useful assistant, in ridding our grounds of vermin; the toad, as a secret enemy, that only wants an opportunity to infect us with its venom.

The imagination, in this manner biassed by its terrors, paints out the toad in the most hideous colouring, and clothes it in more than natural deformity. Its body is broad; its back flat; covered with a dusky pimpled hide; the belly is large and swagging; the pace laboured and crawling; its retreat gloomy and filthy; and its whole appearance calculated to excite disgust and horror: yet, upon my first seeing a toad, none of all these deformities in the least affected me with sensations of loathing: born, as I was, in a country where there are no toads, I had prepared my imagination for some dreadful object; but there seemed nothing to me more alarming in the sight, than in that of a common frog; and indeed, for some time, I mistook, and handled the one for the other. When first informed of my mistake, I very well remember my sensations: I wondered how I had escaped with safety, after handling and dissecting a toad, which I had mistaken for a frog. I then began to lay in a fund of horror against th whole tribe, which, though convinced they are harmless, I shall never get rid of. My first imaginations were too strong not only for my reason, but for the conviction of my senses.

As the toad bears a general resemblance of figure to the frog, so also it resembles that animal in its nature and appetites. Like the frog, the toad is amphibious; like that animal it lives upon worms and insects, which it seizes by darting out its length of tongue; and in the same manner also it crawls about in moist weather. The male and female couple as in all the frog kind; their time of propagation being very early in the spring. Sometimes the females are seen upon land oppressed by the males; but more frequently they are

coupled in the water. They continue together some hours, and adhere so fast as to tear the very skin from the parts they stick to. In all this they entirely resemble the frog; but the assistance which the male lends the female, in bringing forth, is a peculiarity in this species that must not be passed over in silence. "In the evening of a summer's day, a French gentleman, being in the king's gardens at Paris, perceived two toads coupled together, and he stopped to examine them. Two facts equally new surprised him; the first was the extreme difficulty the female had in laying her eggs; the second was the assistance lent her by the male for this purpose. The eggs of the female lie in her body, like beads on a string; and after the first, by great effort, was excluded, the male caught it with his hinder paws, and kept working it till he had thus extracted the whole chain. In this manner the animal performed, in some measure, the functions of a midwife; impregnating, at the same time, every egg as it issued from the body.

It is probable, however, that this difficulty in bringing forth obtains only upon land; and that the toad, which produces its spawn in the water, performs it with as much ease as a frog. They propagate in England exactly in the manner of frogs; and the female, instead of retiring to dry holes, goes to the bottom of ponds, and there lies torpid all the winter, preparing to propagate in the beginning of spring. On these occasions, the number of males is found greatly to surpass that of the other sex, there being above thirty to one; and twelve or fourteen are often seen clinging to the same female.

When, like the frog, they have undergone all the variations of their tadpole state, they forsake the water; and are often seen, in a moist summer's evening, crawling up, by myriads, from fenny places, into dryer situations. There, having found out a retreat, or having dug themselves one with their mouth and hands, they lead a patient solitary life, seldom venturing out, except when the moisture of a summer's evening invites them abroad. At that time the grass is filled with snails, and the pathways covered with worms, which make their principal food. Insects also of every kind they are fond of; and we have the authority of Linnæus for it, that they sometimes continue immovable, with the mouth open, at the bottom of shrubs, where the butterflies, in some measure fascinated, are seen to fly down their throats.[1]

In a letter from Mr Arscott, there are some curious particulars relating to this animal, which throw great light upon its history. "Concerning the toad," says he, "that lived so many years with us, and was so great a favourite, the greatest curiosity was its becoming so remarkably tame; it had frequented some steps before our hall-door some years before my acquaintance commenced with it, and had been admired by my father for its size, (being the largest I ever met with,) who constantly paid it a visit every evening. I knew it myself above thirty years; and by constantly feeding it, brought it to be so tame, that it always came to the candle, and looked up, as if expecting to be taken up and brought upon the table, where I always fed it with insects of all sorts. It was fondest of flesh maggots, which I kept in bran; it would follow them, and when within a proper distance, would fix his eyes, and remain motionless for near a quarter of a minute, as if preparing for the stroke, which was an instantaneous throwing its tongue at a great distance upon the insect, which stuck to the tip by a glutinous matter. The motion is quicker than the eye can follow. I cannot say how long my father had been acquainted with the toad, before I knew it; but when I was first acquainted with it, he used to mention it as the old toad I have known so many years; I can answer for thirty-six years. This old toad made its appearance as soon as the warm weather came; and I always concluded it retired to some dry bank, to repose till spring. When we new layed the steps, I had two holes made in the third step, on each, with a hollow of more than a yard long for it; in which I imagine it slept, as it came from thence at its first appearance. It was seldom provoked. Neither that toad, nor the multitudes I have seen tormented with great cruelty, ever showed the least desire of revenge, by spitting or emitting any juice from their pimples. Sometimes, upon taking it up, it would let out a great quantity of clear water, which, as I have often seen it do the same upon the steps when quite quiet, was certainly its urine, and no more than a natural evacuation. Spiders, millipedes, and flesh maggots, seem to be this animal's favourite food. I imagine if a bee was to be put before a toad, it would certainly eat it to its cost;[2] but as bees are seldom stirring at the same time that toads are, they rarely come in their way; as they do not appear after sun-rising, or before sun-set. In the heat of the day they will come to the mouth of their hole, I believe for air. I once, from my parlour window, observed a large toad I had in the bank of a bowling-green, about twelve at noon in a very hot day, very busy and active upon the grass. So uncommon an appearance made me go out

[1] Amænit. vol. vi. p. 201.

[2] Ræsel tried a frog; it swallowed the bee alive: its stomach was stung, and the animal vomited it up again.

to see what it was; when I found an innumerable swarm of winged ants had dropped round his hole; which temptation was as irresistible as a turtle would be to a luxurious alderman. In respect to its end, had it not been for a tame raven, I make no doubt but it would have been now living. This bird, one day seeing it at the mouth of its hole, pulled it out, and, although I rescued it, pulled out one eye, and hurt it so, that notwithstanding its living a twelvemonth, it never enjoyed itself, and had a difficulty of taking its food, missing the mark for want of its eye. Before that accident, it had all the appearance of perfect health."

To this account of the toad's inoffensive qualities, I will add another from Valisnieri, to show that, even taken internally, the toad is no way dangerous. In the year 1692, some German soldiers, who had taken possession of the castle of Arceti, finding that the peasants of the country often amused themselves in catching frogs, and dressing them for the table; resolved to provide themselves with a like entertainment, and made preparations for frog fishing, in the same manner. It may easily be supposed that the Italians and their German guests were not very fond of each other; and indeed it is natural to think that the soldiers gave the poor people of the country many good reasons for discontent. They were not a little pleased, therefore, when they saw them go to a ditch where toads, instead of frogs, were found in abundance. The Germans, no way distinguishing in their sport, caught them in great numbers; while the peasants kept looking on, silently flattering themselves with the hopes of speedy revenge. After being brought home, the toads were dressed up after the Italian fashion: the peasants were quite happy at seeing their tyrants devour them with so good an appetite, and expected every moment to see them drop down dead. But what was their surprise to find that the Germans continued as well as ever, and only complained of a slight excoriation of the lips, which, probably, arose from some other cause than that of their repast."

I will add another story, from Solenander; who tells us, that a tradesman of Rome and his wife who had long lived together with mutual discontent; the man was dropsical, and the woman amorous: this ill-matched society promised soon, by the very infirm state of the man, to have an end; but the woman was unwilling to wait the progress of the disorder; and therefore concluded that, to get rid of her husband, nothing was left her but poison. For this purpose she chose out a dose that she supposed would be the most effectual; and having calcined some toads, mixed their powder with his drink. The man, after taking a hearty dose, found no considerable inconvenience, except that it greatly promoted urine. His wife, who considered this as a beginning symptom of the venom, resolved not to stint the next dose, but gave it in greater quantities than before. This also increased the former symptom; and, in a few days the woman had the mortification to see her detested husband restored to perfect health, and remained in utter despair of ever being a widow.

From all this it will appear with what injustice this animal has hitherto been treated. It has undergone every kind of reproach; and mankind have been taught to consider, as an enemy, a creature that destroys that insect-tribe which are their real invaders. We are to treat, therefore, as fables, those accounts that represent the toad as possessed of poison to kill at a distance; of its ejecting its venom, which burns wherever it touches; of its infecting those vegetables near which it resides; of its excessive fondness for sage, which is rendered poisonous by its approach; these, and a hundred others of the same kind, probably took their rise from an antipathy which some have to all animals of the kind. It is a harmless, defenceless creature, torpid and unvenomous, and seeking the darkest retreats, not from the malignity of its nature, but the multitude of its enemies.

Like all the frog kind, the toad is torpid in winter. It chooses then, for a retreat, either the hollow root of a tree, the cleft of a rock, or sometimes the bottom of a pond, where it is found in a state of seeming insensibility. As it is very long-lived, it is very difficult to be killed; its skin is tough, and cannot be easily pierced; and, though covered with wounds, the animal continues to show signs of life, and every part appears in motion. But what shall we say to its living for centuries lodged in the bosom of a rock, or cased within the body of an oak-tree, without the smallest access on any side either for nourishment or air, and yet taken out alive and perfect! Stories of this kind it would be as rash to contradict as difficult to believe; we have the highest authorities bearing witness to their truth, and yet the whole analogy of nature seems to arraign them of falsehood. Bacon asserts that toads are found in this manner; Dr Plot asserts the same. There is, to this day, a marble chimney-piece, at Chatsworth, with the print of a toad upon it, and a tradition of the manner in which it was found. In the Memoirs of the Academy of Sciences there is an account of a toad found alive and healthy in the heart of a very thick elm, without the smallest entrance or egress.[1] In the year 1731, there was another found, near Nantes,

[1] Vide the year 1719.

in the heart of an old oak, without the smallest issue to its cell; and the discoverer was of opinion, from the size of the tree, that the animal could not have been confined there less than eighty or a hundred years, without sustenance and without air. To all these we can only oppose the strangeness of the facts; the necessity this animal appears under of receiving air; and its dying, like all other animals, in the air-pump, when deprived of this all-sustaining fluid. But whether these be objections to weigh against such respectable and disinterested authority I will not pretend to determine; certain it is that if kept in a damp place, the toad will live for several months without any food whatsoever.[1]

To this extraordinary account, which is doubtful, I will add another not less so; which is, that of toads sucking cancerous breasts, and thus extracting the venom, and performing a cure. The first account we have of

[1] In 1777, Herissaut undertook some experiments to ascertain the truth of facts of this kind, which might appear fabulous. He shut up three toads in sealed boxes in plaster, and they were deposited in the Academy of Sciences. At the end of eighteen months one of these toads was dead, but the other two were still living. Nobody could doubt the authenticity of this fact, yet the experiments were severely criticised, as well as the observations which they seemed to confirm. It was contended that the air must have come to these animals through some imperceptible hole which escaped the notice of the observer. Some probability, however, was given to this circumstance by the researches of Dr Edwards, published in 1817. He observed that toads, shut up totally in plaster, and absolutely deprived of air, lived for a great number of days, and much longer than those which were forced to remain under water. This certainly is one of the most extraordinary phenomena which the history of reptiles can furnish. It appears an exception to the necessity of air, which is regarded as indispensable to the life of all animals, and seems to break the chain which united them under the most interesting relations of existence. It appears, however, that the air evidently penetrated through the plaster, as Dr Edwards proved, for the toads perished as soon as the plaster which enclosed them was placed under water. The opponents of Herissaut were therefore justified to some degree in their scepticism. Still the fact of animals existing so long under such circumstances, even with a little air, is most surprising, and calculated to produce very strange reflections. If these reptiles lived in this manner longer than they would have done in the open dry air, the reason is that they lost less by transpiration, and if they died much later than they would have done in water, it was because the air certainly had some access to them.

Professor Buckland has recently made some experiments in order to throw light on this obscure subject. Two blocks of stone were taken, one of porous oolite limestone, and one of a compact silicious sandstone; twelve cells, five inches wide, and six inches deep, were cut in the sandstone, and twelve others, five inches wide, and twelve inches deep, in the limestone. In November, 1825, one live toad was placed in each of the twenty-four cells, its weight being previously ascertained with care. A glass plate was placed over each cell as a cover, with a circular slate above to protect it; and the two blocks of stone, with the immured toads, were buried in Dr Buckland's garden under three feet of earth. They were uncovered after the lapse of a year, in December, 1826. All the toads in the small cells of compact sandstone were dead, and their bodies so much decayed as to prove that they had been dead for some months. The greater number of the toads in the larger cells of porous limestone were alive; but they were all a good deal emaciated, except two, which had increased in weight, the one from one thousand one hundred and eighty-five grains to one thousand two hundred and sixty-five, the other from nine hundred and eighty-eight to one thousand one hundred and sixteen. With regard to these two, Dr Buckland thinks they had both been nourished by insects, which had got into the one cell through a crack found in the glass cover, and into the other probably by some small aperture in the luting, which was not carefully examined. No insects were found in either cell, but an assemblage of insects were found on the outside of another glass, and a number within one of the cells whose cover was cracked, and where the animal was dead. Of the emaciated toads, one had diminished in weight from nine hundred and twenty-four grains to six hundred and ninety-eight, and one from nine hundred and thirty-six to six hundred and fifty-two. "The results of the experiments," says Dr Buckland, "amount to this:—All the toads, both large and small, enclosed in the sandstone, and the small toads inclosed in the limestone also, were dead at the end of thirteen months. Before the expiration of the second year, all the large ones also were dead. These were examined several times, during the second year, through the glass covers of the cells, but without removing them to admit air. They appeared always awake, with their eyes open, and never in a state of torpor, their meagerness increasing at each interval, until at length they were found dead. Those which had gained an increase of weight at the end of the first year, and were then carefully closed up again, were emaciated and dead before the expiration of the second year." Four toads, inclosed in cavities cut in the trunk of an apple tree, and closed up by plugs so tightly as to exclude insects, and "apparently air," were found dead at the end of a year.

The phenomena, then, of live toads inclosed in rocks, he explains in this way. The young toad, as soon as it leaves its tadpole state, and emerges from the water, seeks shelter in holes and crevices of rocks and trees. One may thus enter a small opening in a rock, and when there find food, by catching the insects which seek shelter in the same retreat; and its increase of size may prevent it from getting out again by the same opening. It is probable that there are some small apertures in all the stones in which toads are found, though they escape the notice of the workmen, who have no motive to induce them to make a narrow examination. In other cases, there may have been an opening, which had been closed up, after the animal was immured, by stalactitic incrustation. Deprived of food and air, it might fall into that state of torpor, or suspended animation, to which certain animals are subject in winter; but how long it might continue in this state is uncertain.

The Rev. George Young, in his *Geological Survey of the Yorkshire Coast*, second edition, 1828, mentions several recent instances of living toads having been found within solid blocks of sandstone. "We are the more particular in recording these facts," he observes, "because some modern philosophers have attempted to explode such accounts as wholly fabulous." Mr Jesse informs us, that he knew a gentleman who put a toad into a small flower-pot, and secured it, so that no insect could penetrate it, and then buried it so deep in his garden that it was secured against the influence of frost. At the end of twenty years he took it up, and found the toad increased in bulk, and healthy.

this is in a letter to the bishop of Carlisle from Dr Pitfield, who was the first person of consequence that attended the experiment. His letter is as follows:—

"Your lordship must have taken notice of a paragraph in the papers with regard to the application of toads to a cancered breast. A patient of mine has sent to the neighbourhood of Hungerford, and brought down the very woman on whom the cure was done. I have, with all the attention I am capable of, attended the operation for eighteen or twenty days, and am surprised at the phenomenon. I am in no expectation of any great service from the application; the age, constitution, and thoroughly cancerous condition, of the person, being unconquerable barriers to it. How an aliment of that kind, absolutely local, in an otherwise sound habit, and of a likely age, might be relieved, I cannot say. But as to the operation, thus much I can assert, that there is neither pain nor nauseousness in it. The animal is put into a linen bag all but its head, and that is held to the part. It has generally instantly laid hold of the foulest part of the sore, and sucked with greediness until it dropped off dead. It has frequently happened that the creature has swollen immediately, and from its agonies, appeared to be in great pain. I have weighed them for several days together, before and after the application, and found their increase of weight, in the different degrees, from a drachm to near an ounce. They frequently sweat exceedingly, and turn quite pale, sometimes they disgorge, recover, and become lively again: I think the whole scene is surprising, and a very remarkable piece of natural history. From the constant inoffensiveness which I have observed in them, I almost question the truth of their poisonous spitting. Many people here expect no great good from the application of toads to cancers; and where the disorder is not absolutely local, none is to be expected. When it is seated in any part not to be well come at for extirpation, I think it is hardly to be imagined, but that the having it sucked clean as often as you please, must give great relief. Every body knows that dogs licking of sores cures them; which is, I suppose, chiefly by keeping them clean. If there be any credit to be given to history, poisons have been sucked out. *Pallentia vulnera lambit ore venena trahens*, are the words of Lucan on the occasion. If the people to whom these words are applied did their cure by immediately following the injection of the poison, the local confinement of another poison brings the case to a great degree of similarity. I hope I have not tired your lordship with my long tale: as it is a true one, and, in my apprehension, a curious piece of natural history, I could not forbear communicating it to you. I own I thought the story in the papers to be an invention; and when I considered the instinctive principle in all animals of self-preservation, I was confirmed in my disbelief; but what I have related I saw; and all theory must yield to fact. It is only the Rubeta, the land-toad, which has the property of sucking: I cannot find any, the least, mention of the property in any one of the old naturalists. My patient can bear to have but one applied in twenty-four hours. The woman who was cured had them on day and night, without intermission, for five weeks. Their time of hanging at the breast has been from one to six hours."

Other remarks made upon their method of performing this extraordinary operation are as follow: "Some toads die very soon after they have sucked; others live about a quarter of an hour, and some much longer. For example, one that was applied about seven o'clock sucked till ten, and died as soon as it was taken from the breast; another that immediately succeeded continued till three o'clock, but dropped dead from the wound: each swelled exceedingly, and grew of a pale colour. They do not seem to suck greedily, and often turn their heads away; but during the time of their sucking, they were heard to smack their lips like a young child."[1]

From this circumstantial account of the progress of this extraordinary application, one could hardly suppose that any doubt could remain of the ingenious observer's accuracy; and yet, from information which I have received from authority still more respectable, there is much reason, as yet, to suspend our assent. A lady, who was under the care of the present president of the College of Physicians, was induced by her friends to try the experiment; and as he saw the case was desperate, and that it would quiet her mind as well as theirs, he permitted the trial. During the whole continuance of their application, she could never thoroughly perceive that they sucked her; but that did not prevent their swelling and dying, as in the former instances. Once indeed, she said, she thought that one of them seemed to suck; but the physician, and those who attended, could not perceive any appearance of it. Thus, after all, it is a doubt whether these animals die by the internal or the external application of the cancerous poison.

Of this animal there are several varieties; such as the water and the land toad, which probably differ only in the ground-colour of their skin. In the first, it is more inclining to ash-colour, with brown spots; in the other, the colour is brown, approaching to black.

[1] British Zoology, vol. iii. p. 338.

The water toad is not so large as the other; but both equally breed in that element. The size of the toad, with us, is generally from two to four inches long; but in the fenny countries of Europe I have seen them much larger, and not less than a common crab, when brought to table. But this is nothing to what they are found in some of the tropical climates, where travellers often, for the first time, mistake a toad for a tortoise. Their usual size is from six to seven inches: but there are some still larger, and as broad as a plate. Of these some are beautifully streaked and coloured; some studded over, as with pearls; others bristled with horns or spines; some have the head distinct from the body, while others have it so sunk in that the animal appears without a head.[1] All these are found in the tropical climates in great abundance; and particularly after a shower of rain. It is then that the streets seem entirely paved with them; they then crawl from their retreats, and go into all places to enjoy their favourite moisture. With us the opinion of its raining toads and frogs has long been justly exploded; but it still is entertained in the tropical countries; and that not only by the savage natives, but the more refined settlers, who are apt enough to add the prejudices of other nations to their own.

It would be a tedious, as well as useless task, to enter into all the minute discriminations of these animals, as found in different countries or places; but the *pipa*, or *Surinam toad*, is too strange a creature not to require

an exact description. There is not, perhaps, in all nature, a more extraordinary phenomenon than that of an animal breeding and hatching its young in its back; from whence, as from a kind of hot-bed, they crawl one after the other when come to maturity.

The pipa is, in form, more hideous than even the common toad; nature seeming to have marked all those strange mannered animals with peculiar deformity. The body is flat and broad; the head small; the jaws, like those of a mole, are extended, and evidently formed for rooting in the ground: the skin of the neck forms a sort of wrinkled collar: the colour of the head is of a dark chestnut, and the eyes are small: the back, which is very broad, is of a lightish gray, and seems covered over with a number of small eyes, which are round, and placed at nearly equal distances. These eyes are very different from what they seem; they are the animal's eggs, covered with their shells, and placed there for hatching. These eggs are buried deep in the skin, and in the beginning of incubation but just appear; and are very visible when the young animal is about to burst from its confinement. They are of a reddish shining yellow colour; and the spaces between them are full of small warts resembling pearls.[2]

This is their situation, previous to their coming forth; but nothing so much demands our admiration as the manner of their production. The eggs, when formed in the ovary, are sent by some internal canals, which anatomists have not hitherto described to lie, and come to maturity, under the bony substance of the back; in this state they are impregnated by the male, whose seed finds its way by pores very singularly contrived, and pierces not only the skin but the periosteum. The skin, however, is still apparently entire, and forms a very thick covering over the whole brood; but as they advance to maturity, at different intervals, one after another, the egg seems to start forward and bourgeon from the back, becomes more yellow, and at last breaks, when the young one puts forth its head: it still, however, keeps its situation, until it has acquired a proper degree of strength, and then it leaves the shell, but still continues to keep upon the back of the parent. In this manner the pipa is seen travelling with her wondrous family on her back, in all the different stages of maturity. Some of the strange progeny, not yet come to sufficient perfection, appear quite torpid, and as yet without life in the egg: others seem just beginning to rise through the skin; here peeping forth from the shell; and there, having entirely forsaken their prison; some are sporting at large upon the parent's back; and others descending to the ground, to try their own fortune below.

Such is the description given of this strange

[1] Among this numerous family there is one which, for horrid and deformed appearance, probably, exceeds all other created beings. This is the horned toad, of South America. The colour is cinereous, with brown stripes. The eye-lids project in a singular manner, and give it the appearance as if the eyes were placed at the bottom of a pair of sharp pointed horns: the head is very large, and the mouth is so enormous, as to exceed half the length of its body. To add to its lothesome appearance, it is likewise clothed all over, except the head and feet, with short sharp spines.

[2] It is now demonstrated that the female lays its eggs after the manner of toads, but that the male, fastened on her back, fecundates them, and then places them on the back of the mother; she then repairs to the water, where her skin swells, and forms rounded alveoli, in which these eggs are lodged, to be subsequently disclosed. The pipa lives in the fresh waters of South America, and sometimes in the obscure parts of houses at Cayenne and Surinam. The negroes are said sometimes to use the pipa as food.

production by Seba, in which he differs from Ruysch, who affirms, that the young ones are bred in the back of the male only, where the female lays her eggs. I have followed Seba, however, not because he is better authority, but because he is more positive of the truth of his account, and asserts, assuredly, that the eggs are found on the back of the female only. Many circumstances, however, are wanting towards completing his information; such as a description of the passage by which the egg finds its way into the back; the manner of its fecundation; the time of gestation; as also a history of the manners of this strange animal itself; but, by a prolixity that much prevails among naturalists at present, he leaves the most interesting object of curiosity to give us a detailed description of the legs and claws of the pipa, about which we have very little concern.

The male pipa is every way larger than the female, and has the skin less tightly drawn round the body. The whole body is covered with pustules resembling pearls; and the belly, which is of a bright yellow, seems as if it were sewed up from the throat to the vent, a seam being seen to run in that direction. This animal, like the rest of the frog kind, is most probably harmless; though we are told of the terrible effects resulting from its powder when calcined. This, however, must certainly be false; no creature whatever, when calcined, can be poisonous; for the fire burns away whatever might have been dangerous in their composition: all animal substances, when calcined, being entirely the same.

OF FROGS, LIZARDS, AND SERPENTS.

BOOK II.

OF LIZARDS.

CHAP. I.

OF LIZARDS IN GENERAL.

There is scarcely a naturalist, who has treated of lizards, but has a particular manner of ranking them in the scale of animated nature. Ray, rather struck with the number of their legs than their habits and conformation, has exalted them among quadrupeds; while Linnæus, attentive only to their long slender forms, has degraded them among serpents. Brisson gives them a distinct class by themselves, under the name of *reptiles*. Klein gives them a class inferior to beasts, under the name of *naked quadrupeds*. Some, in short, from their scaly covering, and fondness for the water, have given them to the fishes; while there have not been wanting naturalists who have classed them with insects, as the smaller kinds of this class seem to demand.

It is indeed no easy matter to tell to what class in nature lizards are chiefly allied. They are unjustly raised to the rank of beasts, as they bring forth eggs, dispense with breathing, and are not covered with hair. They cannot be placed among fishes, as the majority of them live upon land: they are excluded from the serpent tribe by their feet, upon which they run with some celerity: and from the insects, by their size; for though the Newt may be looked upon in this contemptible light, a Crocodile would be a terrible insect indeed. Thus lizards are, in some measure, excluded from every rank, while they exhibit somewhat of the properties of all; the legs and celerity of the quadruped; a facility of creeping through narrow and intricate ways, like the serpent; and a power of living in the water, like fishes; however, though endued with these various powers, they have no real advantages over any other class of animated nature; for what they gain in aptitude for one element, they lose in their fitness for another. Thus, between both, they are an awkward ungainly tribe; neither so alert upon land, nor so nimble in the water, as the respective inhabitants of either abode: and, indeed, this holds throughout all nature, that in proportion as the seeming advantages of inferior animals are multiplied, their real ones are abridged; and all their instincts are weakened and lost by the variety of channels into which they are divided.

As lizards thus differ from every other class of animals, they also differ widely from each other. With respect to size, no class of beings has its ranks so opposite. What, for instance, can be more removed than the small cameleon, an inch long, and the alligator of the river Amazon, above twenty-seven feet? To an inattentive observer, they would appear entirely of different kinds; and Seba wonders how they ever came to be classed together.

The colour of these animals also is very various, as they are found of a hundred different hues—green, blue, red, chestnut, yellow, spotted, streaked, and marbled. Were colour alone capable of constituting beauty, the lizard would often please; but there is something so repressing in the animal's figure, that the brilliancy of its scales, or the variety of its spots, only tend to give an air of more exquisite venom or greater malignity. The figure of these animals is not less various; sometimes swollen in the belly; sometimes pursed up at the throat; sometimes with a rough set of spines on the back, like the teeth of a saw; sometimes with teeth, at others with none; sometimes venomous, at others harmless, and even philanthropic: sometimes smooth and even; sometimes with a long slender tail; and often with a shorter blunt one.[1]

[1] The whole of this tribe is perfectly destitute of poi-

But their greatest distinction arises from the manner of bringing forth their young. First, some of them are viviparous. Secondly, some are oviparous; and which may be considered in three distinct ways. Thirdly, some bring forth small spawn, like fishes. The crocodile, the iguana, and all the larger kinds, bring forth eggs, which are hatched by the heat of the sun; the animals that issue from them are complete upon leaving the shell; and their first efforts are to run to seek food in their proper element. The viviparous kinds, in which are all the salamanders, come forth alive from the body of the female, perfect and active, and suffer no succeeding change. But those which are bred in the water, and as we have reason to think, from spawn, suffer a very considerable change in their form. They are produced with an external skin or covering that sometimes incloses their feet, and gives them a serpentine appearance. To this false skin fins are added, above and below the tail, that serve the animal for swimming; but when the false skin drops off, these drop off also; and then the lizard, with its four feet, is completely formed, and forsakes the water.

From hence it appears, that, of this tribe, there are three distinct kinds, differently produced, and, most probably, very different in their formation. But the history of these animals is very obscure; and we are, as yet, incapable of laying the line that separates them. All we know, as was said before, is, that the great animals of this kind are *mostly* produced perfect from the egg; the salamanders are *generally* viviparous; and *some* of the water lizards imperfectly produced. In all these most unfinished productions of Nature, if I may so call them, the varieties in their structure increase in proportion to their imperfections. A poet would say, that Nature grew tired of the nauseous formation, and left accident to finish the rest of her handy-work.

However, the three kinds have many points of similitude; and, in all their varieties of figure, colour, and production, this tribe is easily distinguished, and strongly marked. They have all four short legs; the two forefeet, somewhat resembling a man's hand and arm. They have tails almost as thick as the body at the beginning, and that generally run tapering to a point. They are all amphibious also; equally capable of living upon land and water; and formed, internally, in the same manner with the tortoise, and other animals, that can continue a long time without respiration: in other words, their lungs are not so necessary to continue life and circulation, but that their play may be stopped for some considerable time, while the blood performs its circuit round the body by a shorter communication.

These are differences that sufficiently separate lizards from all other animals; but it will be very difficult to fix the limits that distinguish the three kinds from each other. The *crocodile* tribe, and its affinities, are sufficiently distinguished from all the rest by their size and fierceness; the *salamander* tribe is distinguished by their deformity, their frog-like heads, the shortness of their snouts, their swollen bellies, and their viviparous production. With regard to the rest, which we may denominate the cameleon or lizard kind, some of which bring forth from the egg, some of which are imperfectly formed from spawn, we must group them under one head, and leave time to unravel the rest of their history.

son, and except the crocodile and alligator, quite inoffensive to mankind. Those that are bred in waters undergo a metamorphosis, and pass through a tadpole form.

CHAP. II.

OF THE CROCODILE, AND ITS AFFINITIES [1]

The Crocodile is an animal placed at a happy distance from the inhabitants of Europe, and formidable only in those regions where men are scarce, and arts are but little known. In all the cultivated and populous

[1] *Crocodiles and Alligators.*—The *true crocodile* is found in the river Nile, but by no means in such plenty as in the times of the Pharaohs. The species which is domesticated by the priests, and magnificently provided for in a temple in Memphis, was of a green colour. It was an object of profound worship, called a God, and embalmed when it died. On the other hand, the *alligator* is exclusively found in America; and instead of having an uninterrupted series of teeth round both jaws, as in the crocodile, the fourth tooth of the under jaw shuts into a corresponding socket in the upper one. This law is so universal, that any person by remembering this fact, may with certainty designate the one from the other.

The term *alligator* is applied to the various species of crocodiles that are found in America, while the name *Gavial* has been given to such as inhabit the East Indies and the islands of the Indian ocean, and the original word is more especially used when speaking of that species which abounds in the Nile. In the central parts of Africa, the crocodiles attain a very large size, in many instances being found as much as thirty feet in length.

The crocodile swallows its prey whole, and feeds indifferently on fish or small quadrupeds; and the upper teeth, instead of resting with their points upon the under when the mouth is closed, enter between them, and thus prevent all chance of escape. It but rarely attacks mankind. On either side of the under part of the lower jaw, a small opening is found, from which the creature can force, at will, a liquid possessing the smell of musk. This property has been lately noticed by Mr Thomas Bell, in a paper inserted in the *Transactions of the Royal Society of London*, and, in his opinion, the reptile employs it for the purpose of attracting fish into the places it haunts.

parts of the world, the great animals are entirely banished, or rarely seen. The appearance of such raises at once a whole country up in arms to oppose their force; and their lives generally pay the forfeit of their temerity. The crocodile, therefore, that was once so terrible along the banks of the river Nile, is now neither so large, nor its numbers so great

---

The following cut represents *the Double Crested Crocodile*. It is the most common species in all the rivers

that lead to the Indian ocean. It is found in Java and even in China.

The most remarkable distinguishing character of alligators (as already said) is the shape of the head. The gavials have it the most produced, the crocodiles the next, and the alligators have it shortest. In them the length of the jaws from the articulation is only one-half more than the greatest breadth. The teeth have a ragged appearance, as some of them are long and others short. There are never fewer than nineteen in each side of either jaw, and sometimes two more in each side of the under one. These grow with the growth of the animal; and receiving cavities are formed for them in the upper jaw, especially from those fourth from the front, which are longer than any of the others. The body is low and squat; the hind legs are nearly round in their section, and have no membrane on their sides; the webs of the toes also extend only half the length; and the holes behind the orbits, which are understood to secrete a musky fluid in the crocodiles, are small and obscure, or wanting. From the structure of the feet, and the want of fringed or pectinated membranes on the hind legs, which are both a lessening of the pelagic structure, alligators keep more to the fresh waters, the rivers, and lagunes, than the crocodiles; so that those in the bays of the West India islands, though popularly known as alligators or *caymans*, are rather to be considered as crocodiles, even in the popular sense of that term.

There are four species or more, of alligators, all natives of the warmer parts of the American continent, but varying in their appearance, so as in some of the species to resemble the crocodiles, and in others the gavials. The species which, in the written accounts at least, is the most ferocious and formidable to man, is that which inhabits the Mississippi and the other rivers of the southern parts of North America, and the swamps and lagunes which these rivers form when they are swollen by floods. It is the *pike-headed alligator* (*Alligator lucius*) of Cuvier,

so called because its head, in shape at least, bears some resemblance to that of the common pike. This species has been seen as long as fifteen feet, with the head two feet long, and the gape nearly the same. The jaws are more elongated than in some other species, the breadth at the articulation not being in those of the size mentioned much more than one foot. The snout is flattened on the upper surface, and slightly turned up at the extremity, which is bluntly pointed; but the sides of the jaws are, for the greater portion of the length of the gape, nearly parallel. The teeth are large and irregular, with the fourth from the front in each side of the under jaw much larger than the rest, so that they can penetrate through a substance of considerable thickness, and, with their points received into the sockets in the upper jaw, hold on against a very considerable strain. It is by this means that the animal is said to master the larger mammalia, when they come to the shores to quench their thirst. The alligator, having observed its prey, swims slowly towards it, with the snout barely above the water. When within reach, it seizes the upper lip and nose; and at the same time incurvating its body with more than ordinary exertion, hits a violent blow on the shoulder with its thick and scaly tail. The bite and the blow together bring the animal to its knees, tumble it headlong and helpless; and as the alligator does not quit its hold while the animal continues to struggle, and also contrives to keep the head under water, the prey soon expires of pain and suffocation. The smaller mammalia are generally foundered by the blow of the tail, and then seized by the head and drawn under water till they are suffocated. But in what state soever prey of this description is eaten, whether recent or after it has been partially decomposed by time, it is always eaten on land. They do not feed under water, any more than they breathe in that situation.

The *Varied Monitor*, of which the following is a representation, resembles the crocodile as to form, but is

different in its habits. It swims with difficulty, runs with considerable swiftness, and climbs trees with dexterity. It conceals itself in burrows, and bites desperately. Its flesh and eggs are eaten. Its length is from four to five feet. It inhabits the savannahs and marshy soils of South America, particularly Guiana.

There is, perhaps, no country in which the alligator more generally abounds, than in India. It is found in most of the rivers, in the large tanks, and frequently, during the monsoons, in small pools of water scarcely larger than the common pond of an English farm-yard. In the larger tanks these creatures are commonly fed by the Hindoos, who venerate, though they do not, like the ancient Egyptians, worship them. They become so tame when daily supplied with food by the superstitious Brahmins of the temples near which they take up their undisturbed abode, that any person may fearlessly bathe in the tanks, without the slightest chance of molestation, these usually voracious reptiles being so pampered, as to have no further relish for human flesh.

In the Ganges, these creatures may be almost daily seen watching the numerous carcasses which constantly float down that river, awaiting the moment when they shall have attained a state of luxurious maturity. Sometimes a solitary vulture appears sailing down the current,

as formerly. The arts of mankind have, through a course of ages, powerfully operated to its destruction; and, though it is sometimes seen, it appears comparatively timorous and feeble.

To look for this animal in all its natural terrors, grown to an enormous size, propagated in surprising numbers, and committing unceasing devastations, we must go to the uninhabited regions of Africa and America, to

---

perched upon a human body, which the mistaken attachment of superstitious friends had committed to the stream to send on its roads to paradise, tearing the scarcely cold flesh from the bones, until chased from its horrid repast by the more dominant and not less voracious alligator.

It is a very common thing for the native princes of India, living in the neighbourhood of large rivers where alligators abound, to have them caught for the purpose of entertaining their court and guests, by making them fight, or causing them to be attacked by other animals. Captain Basil Hall has given the following animated account of a fight of this kind, got up for the amusement of the Admiral, Sir R. Hood, and performed by a corps of Malays in the British service.

Very early (he says) in the morning, the party were summoned from their beds, to set forth on the expedition. In other countries, the hour of getting up may be left to choice; in India, when any thing active is to be done, it is a matter of necessity; for after the sun has gained even a few degrees of altitude, the heat and discomfort, as well as the danger of exposure, become so great, that all pleasure is at an end. The day, therefore, had scarcely begun to dawn, when we all cantered up to the scene of action.

The ground lay as flat as a marsh for many leagues, and was spotted with small stagnant lakes connected by sluggish streams, scarcely moving over beds of mud, between banks fringed with a rank crop of draggled weeds. The chill atmosphere of the morning felt so thick and clammy, it was impossible not to think of agues, jungle-fevers, and all the hopeful family of malaria. The hardy native soldiers who had occupied the ground during the night, were drawn up to receive the Admiral, and a very queer guard of honour they formed. The whole regiment had stripped off their uniform, and every other stitch of clothing, save a pair of short trousers, and a kind of sandal. In place of a firelock, each man bore in his hand a slender pole, about six feet in length, to the extremity of which was attached the bayonet of his musket. His only other weapon, was the formidable Malay crease, a sort of dagger, or small two-edged sword.

Soon after the commander-in-chief came to the ground, the regiment was divided into two main parties, and a body of reserves. The principal columns, facing, one to the right, the other to the left, proceeded to occupy different points in one of the sluggish canals, connecting the pools scattered over the plain. These detachments being stationed about a mile from one another, enclosed an interval where, from some peculiar circumstances known only to the Malays, who are passionately fond of the sport, the alligators were sure to be found in great numbers. The troops formed themselves across the canals, in three parallel lines, ten to twelve feet apart; but the men in each line stood side by side, merely leaving room enough to wield their pikes. The canal may have been about four or five feet deep, in the middle of the stream, if stream it can be called, which scarcely moved at all. The colour of the water, when undisturbed, was a shade between ink and coffee; but no sooner had the triple line of Malays set themselves in motion, than the consistence and colour became like those of peas-soup.

On every thing being reported ready, the soldiers planted their pikes before them in the mud, each man crossing his neighbour's weapon, and at the word "march" away they all started in full cry, sending forth a shout, or war-whoop, sufficient to curdle the blood of those on land, whatever effect it may have had on the inhabitants of the deep. As the two divisions of the invading army gradually approached each other in pretty close column, screaming, and yelling, and striking their pikes deep in the slime before them, the startled animals naturally retired towards the unoccupied centre. Generally speaking, the alligators, or crocodiles, had sense enough to turn their long tails upon their assailants, and to scuttle off, as fast as they could, towards the middle part of the canal. But every now and then, one of the terrified monsters floundered backwards, and, by retreating in the wrong direction, broke through the first, second, and even third line of pikes. This was the perfection of sport to the delighted Malays. A double circle of soldiers was speedily formed round the wretched aquatic who had presumed to pass the barrier. By means of well-directed thrusts with numberless bayonets, and the pressure of some dozens of feet, the poor brute was often fairly driven beneath his native mud. When once there, his enemies half-choked and half-spitted him, till at last they put an end to his miserable days, in regions quite out of sight, and in a manner as inglorious as can well be conceived.

The intermediate space was now pretty well crowded with alligators, swimming about in the utmost terror, at times diving below, and anon showing their noses above the surface of the dirty stream; or occasionally making a furious bolt, in sheer despair, right at the phalanx of Malays. On these occasions, half-a-dozen of the soldiers were often upset, and their pikes either broken or twisted out of their hands, to the infinite amusement of their companions, who speedily closed up the broken ranks. There were none killed, but many wounded; yet no man flinched in the least.

The perfection of the sport appeared to consist in detaching a single alligator from the rest, surrounding and attacking him separately, and spearing him till he was almost dead. The Malays, then, by main strength, forked him aloft, over their heads, on the end of a dozen pikes, and, by a sudden jerk, pitched the conquered monster far on the shore. As the alligators are amphibious, they kept to the water no longer than they found they had an advantage in that element; but on the two columns of their enemy closing up, the monsters lost all discipline, floundered up the weedy banks, scuttling away to the right and left, helter-skelter. "Sauve qui peut!" seemed to be the fatal watch-word for their total rout. That prudent cry would, no doubt, have saved many of them, had not the Malays judiciously placed beforehand their reserve on each side of the river, to receive the distracted fugitives, who, bathed in mud, and half dead with terror, but still in a prodigious fury, dashed off at right angles from the canal, in hopes of gaining the shelter of a swampy pool, overgrown with reeds and bulrushes, but which most of the poor beasts were never doomed to reach. The concluding battle between these retreating and desperate alligators, and the Malays of the reserve, was formidable enough. Indeed, had not the one party been fresh, the other exhausted, one confident, the other broken in spirit; it is quite possible that the crocodiles might have worsted the Malays. It was difficult, indeed, to say which of the two looked at that moment the more savage; the triumphant natives, or the flying troop of alligators wallopping away from the water. Many on both sides were wounded, and all covered with slime and weeds. There could not have been fewer than thirty or forty alligators killed. The

those immense rivers that roll through extensive and desolate kingdoms, where arts have never penetrated, where force only makes distinction, and the most powerful animals exert their strength with confidence and security. Those that sail up the river Amazon, or the river Niger, well know how numerous and terrible those animals are in such parts of the world. In both these rivers, they are found from eighteen to twenty-seven feet long; and sometimes lying as close to each other as rafts of timber upon one of our streams. There they indolently bask on the surface, no way disturbed at the approach of an enemy, since, from the repeated trials of their strength, they found none that they were not able to subdue.

Of this terrible animal there are two kinds; the Crocodile, properly so called, and the Cayman or Alligator. Travellers, however, have rather made the distinctions than Nature; for in the general outline, and in the nature of these two animals, they are entirely the same. It would be speaking more properly to call these animals the Crocodiles of the eastern and western world; for, in books of voyages, they are so entirely confounded together, that there is no knowing whether the Asiatic animal be the crocodile of Asia, or the alligator of the western world. The distinctions usually made between the crocodile and alligator are these: the body of the crocodile is more slender than that of the alligator; its snout runs off tapering from the forehead, like that of a grayhound; while that of the other is indented, like the nose of a lapdog. The crocodile has a much wider swallow, and is of an ash-colour; the alligator is black, varied with white, and is thought not to be so mischievous. All these distinctions, however, are very slight; and can be reckoned little more than minute variations.

This animal grows to a great length, being sometimes found thirty feet long, from the tip of the snout to the end of the tail; its most usual length, however, is eighteen. One which was dissected by the Jesuits at Siam, was of the latter dimensions; and the description which is given of it, both externally and internally, is the most accurate known of this noted animal. I must beg leave to give it as I find it, though somewhat tedious. It was eighteen feet and a half, French measure, in length; of which the tail was no less than five feet and a half, and the head and neck above two feet and a half. It was four feet nine inches in circumference, where thickest. The fore legs had the same parts and conformation as the arms of a man, both within and without. The hands, if they may be so called, had five fingers; the two last of which had no nails, and were of a conical figure. The hinder legs, including the thigh and paw, were two feet two inches long; the paws, from the joint to the extremity of the longest claws, were above nine inches; they were divided into four toes, of which three were armed with large claws, the longest of which was an inch and a half; these toes were united by a membrane, like those of a duck, but much thicker. The head was long, and had a little rising at the top; but the rest was flat, and especially towards the extremity of the jaws. It was covered by a skin, which adhered firmly to the skull and to the jaws. The skull was rough and unequal in several places; and about the middle of the forehead there were two bony crests, about two inches high: the skull between these two crests was proof against a musket-ball; for it only rendered the part a little white that it struck against. The eye was very small, in proportion to the rest of the body, and was so placed within its orbit, that the outward part, when the lid was closed, was only an inch long, and the line running parallel to the opening of the jaws. It was covered with a double lid, one within and one without: that within, like the nictitating membrane in birds, was folded in the great corner of the eye, and had a motion towards the tail, but being transparent, it covered the eye without hindering the sight. The iris was very large in proportion to the globe of the eye, and was of a yellowish gray colour. Above the eye the ear was placed, which opened from above downwards, as if it were by a kind of spring, by means of a solid, thick, cartilaginous substance. The nose was placed in the middle of the upper jaw, near an inch from its extremity, and was perfectly round and flat, being near two inches in diameter, of a black, soft, spongy substance, not unlike the nose of a dog. The jaws seemed to shut one within another; and nothing can be more false than that the animal's under jaw is without motion; it moves like the lower jaw in all other animals, while the upper is fixed to the skull, and absolutely immovable. The animal had twenty-seven cutting teeth in the upper jaw, and fifteen in the lower, with several void spaces between them: they were thick at the bottom, and sharp at the point, being all of different sizes, except ten large hooked ones, six of which were in the lower jaw, and four in the upper. The mouth was fifteen inches in length, and eight and a half in breadth, where broadest. The distance of the two jaws, when opened

largest measured ten feet in length, and four feet girth, the head being exactly two feet long. Besides these great fellows, a multitude of little ones, nine inches long, were caught alive, many of which, being carried on board, became great favourites amongst the sailors, whose queer taste in the choice of pets has frequently been noticed.

as wide as they could be, was fifteen inches and a half; this is a very wide yawn, and could easily enough take in the body of a man. The colour of the body was of a dark brown on the upper part, and of a whitish citron below, with large spots of both colours on the sides. From the shoulders to the extremity of the tail, the animal was covered with large scales, of a square form, disposed like parallel girdles, and fifty-two in number; but those near the tail were not so thick as the rest. The creature was covered not only with these, but all over with a coat of armour; which, however, was not proof against a musket-ball, contrary to what has been commonly asserted: however, it must be confessed, that the attitude in which the animal was placed, might contribute to render the skin more penetrable; for, probably, if the ball had struck obliquely against the shell it would have flown off. Those parts of the girdles underneath the belly were of a whitish colour, and were made up of scales of divers shapes, but not so hard as those on the back.

With respect to the internal parts of the animal, the gullet was large in proportion to the mouth; and a ball of wood, as large as one's head, readily ran down, and was drawn up again. The guts were but short, in comparison, being not so long as the animal's body. The tongue, which some have erroneously asserted this animal was without, consisted of a thick, spongy, soft flesh, and was strongly connected to the lower jaw. The heart was of the size of a calf's, of a bright red colour, the blood passing as well from the veins to the aorta as into the lungs. There was no bladder; but the kidneys sent the urine to be discharged by the anus. There were sixty-two joints in the back-bone, which, though very closely united, had sufficient play to enable the animal to bend like a bow to the right and the left; so that what we hear of escaping the creature by turning out of the right line, and of the animal not being able to wheel readily after its prey, seems to be fabulous. It is most likely the crocodile can turn with ease, for the joints of its back are not stiffer than those of other animals, which we know, by experience, can wheel about very nimbly for their size.

Such is the figure and conformation of this formidable animal, that unpeoples countries, and makes the most navigable rivers desert and dangerous. They are seen, in some places, lying for whole hours, and even days, stretched in the sun, and motionless; so that one not used to them might mistake them for trunks of trees, covered with a rough and dry bark; but the mistake would soon be fatal, if not prevented; for the torpid animal, at the near approach of any living thing, darts upon it with instant swiftness, and at once drags it down to the bottom. In the times of inundation, they sometimes enter the cottages of the natives, where the dreadful visitant seizes the first animal it meets with. There have been several examples of their taking a man out of a canoe in the sight of his companions, without their being able to lend him any assistance.

The strength of every part of the crocodile is very great; and its arms, both offensive and defensive, irresistible. We have seen, from the shortness of its legs, the amazing strength of the tortoise: but what is the strength of such an animal compared to that of the crocodile, whose legs are very short, and whose size is so superior! The back-bone is jointed in the firmest manner; the muscles of the fore and hinder legs are vigorous and strong; and its whole form calculated for force. Its teeth are sharp, numerous, and formidable; its claws are long and tenacious; but its principal instrument of destruction is the tail: with a single blow of this it has often overturned a canoe, and seized upon the poor savage its conductor.

Though not so powerful, yet it is very terrible even upon land. The crocodile seldom, except when pressed by hunger, or with a view of depositing its eggs, leaves the water. Its usual method is to float along upon the surface, and seize whatever animals come within its reach; but when this method fails, it then goes closer to the bank. Disappointed of its fishy prey, it there waits, covered up among the sedges, in patient expectation of some land animal that comes to drink; the dog, the bull, the tiger, or man himself. Nothing is to be seen of the insidious destroyer as the animal approaches; nor is its retreat discovered, till it be too late for safety. It seizes the victim with a spring, and goes at a bound much farther than so unwieldly an animal could be thought capable of exerting; then having secured the creature with both teeth and claws, it drags it into the water, instantly sinks with it to the bottom, and in this manner quickly drowns it.

Sometimes it happens that the creature the crocodile has thus surprised escapes from its grasp wounded, and makes off from the river side. In such a case the tyrant pursues with all its force, and often seizes it a second time; for, though seemingly heavy, the crocodile runs with great celerity. In this manner it is sometimes seen above half a mile from the bank, in pursuit of an animal wounded beyond the power of escaping, and then dragging it back to the river-side, where it feasts in security.

It often happens, in its depredations along the bank, that the crocodile seizes on a crea-

ture as formidable as itself, and meets with a most desperate resistance. We are told of frequent combats between the crocodile and the tiger. All creatures of the tiger kind are continually oppressed by a parching thirst, that keeps them in the vicinity of great rivers, whither they descend to drink very frequently. It is upon these occasions that they are seized by the crocodile; and they die not unrevenged. The instant they are seized upon, they turn with the greatest agility, and force their claws into the crocodile's eyes, while he plunges with his fierce antagonist into the river. There they continue to struggle for some time, till at last the tiger is drowned.

In this manner the crocodile seizes and destroys all animals, and is equally dreaded by all. There is no animal but man alone that can combat it with success. We are assured by Labat, that a negro, with no other weapons than a knife in his right hand, and his left arm wrapped round with a cow-hide, ventures boldly to attack this animal in his own element. As soon as he approaches the crocodile, he presents his left arm, which the animal swallows most greedily; but sticking in his throat, the negro has time to give it several stabs under the throat; and the water also getting in at the mouth, which is held involuntarily open, the creature is soon bloated up as big as a tun, and expires.

To us who live at a distance from the rapacity of these animals, these stories appear strange, and yet most probably are true. From not having seen any thing so formidable or bold in the circle of our own experience, we are not to determine upon the wonderful transactions in distant climates. It is probable that these, and a number of more dreadful encounters, happen every day among those forests and in those rivers where the most formidable animals are known to reside; where the elephant and rhinoceros, the tiger and the hippopotamus, the shark and the crocodile, have frequent opportunities of meeting, and every day of renewing their engagements.

Whatever be the truth of these accounts, certain it is that crocodiles are taken by the Siamese in great abundance. The natives of that empire seem particularly fond of the capture of all the great animals with which their country abounds. We have already seen their success in taking and taming the elephant; nor are they less powerful in exerting their dominion over the crocodile. The manner of taking it in Siam, is by throwing three or four strong nets across a river, at proper distances from each other; so that if the animal breaks through the first, it may be caught by one of the rest. When it is first taken, it employs the tail, which is the grand instrument of strength, with great force; but after many unsuccessful struggles, the animal's strength is at last exhausted. Then the natives approach their prisoner in boats, and pierce him with their weapons in the most tender parts, till he is weakened by the loss of blood. When he has done stirring, they begin by tying up his mouth, and with the same cord they fasten his head to his tail, which last they bend back like a bow. However, they are not yet perfectly secure from his fury; but, for their greater safety, they tie his fore-feet, as well as those behind, to the top of his back. These precautions are not useless: for if they were to omit them, the crocodile would soon recover strength enough to do a great deal of mischief.

The crocodile, thus brought into subjection, or bred up young, is used to divert and entertain the great men of the East. It is often managed like a horse; a curb is put into his mouth, and the rider directs it as he thinks proper. Though awkwardly formed, it does not fail to proceed with some degree of swiftness; and it is thought to move as fast as some of the most unwieldly of our own animals, the hog or the cow.[1] Some, indeed, assert, that no animal could escape it, but for its difficulty in turning; but to this resource we could wish none would trust who are so unhappy as to find themselves in danger.

Along the rivers of Africa this animal is sometimes taken in the same manner as the shark. Several Europeans go together in a large boat, and throw out a piece of beef upon a hook and strong fortified line, which the crocodile seizing and swallowing, is drawn along, floundering and struggling until its strength is quite exhausted, when it is pierced in the belly, which is its tenderest part; and thus, after numberless wounds, is drawn ashore. In this part of the world also, as well as at Siam, the crocodile makes an object of savage pomp near the palaces of their monarchs. Philips informs us that at Sabi, on the slave coast, there are two pools of water, near the royal palace, where crocodiles are bred, as we breed carp in our ponds in Europe.

Hitherto I have been describing the crocodile as it is found in unpeopled countries, and

[1] Waterton, in his interesting Wanderings in South America, gives an account of a ride he had on a crocodile's back. He and his Indians having secured a monster of the Essequibo, by a baited hook fastened to a long rope, "they pulled the cayman," as he describes (p. 231), "within two yards of me. I saw he was in a state of fear and perturbation; I instantly dropped the mast, sprung up, and *jumped on his back*, turning half round as I vaulted, so that I gained my seat with my face in a right position. I immediately seized his fore legs and by main force twisted on his back; thus they served me for a bridle."—This was at first laughed at as incredible, but it is now known to be a feat of not unusual occurrence.

undisturbed by frequent encounters with mankind.[1] In this state it is fierce and cruel, attacking every object that seems endued with motion: but in Egypt, and other countries long peopled, where the inhabitants are civilized, and the rivers frequented, this animal is solitary and fearful. So far from coming to attack a man, it sinks at his approach with the utmost precipitation; and, as if sensible of superior power, ever declines the engagement. We have seen more than one instance in animated nature of the contempt which at first the lower orders of the creation have for man, till they have experienced his powers of destruction. The lion and the tiger among beasts, the whale among fishes, the albatross and the penguin among birds, meet the first encounters of man without dread or apprehension; but they soon learn to acknowledge his superiority, and take refuge from his power in the deepest fastnesses of nature. This may account for the different characters which have been given us of the crocodile and the alligator, by travellers at different times; some describing them as harmless and fearful, as ever avoiding the sight of a man, and preying only upon fishes: others ranking them among the destroyers of nature; describing them as furnished with strength, and impelled by malignity, to do mischief; representing them as the greatest enemies of mankind, and particularly desirous of human prey. The truth is, the animal has been justly described by both; being such as it is found in places differently peopled or differently civilized. Wherever the crocodile has reigned long unmolested, it is there fierce, bold, and dangerous; wherever it has been harassed by mankind, its retreats invaded, and its numbers destroyed, it is there timorous and inoffensive.

In some places, therefore, this animal, instead of being formidable, is not only inoffensive, but is cherished and admired. In the river San Domingo, the crocodiles are the most inoffensive animals in nature; the children play with them, and ride about on their backs; they even beat them sometimes, without receiving the smallest injury. It is true the inhabitants are very careful of this gentle breed, and consider them as harmless domestics.

It is probable that the smell of musk, which all these animals exhale, may render them agreeable to the savages of that part of Africa. They are often known to take the part of this animal which contains the musk, and wear it as a perfume about their persons. Travellers are not agreed in what part of the body these musk-bags are contained; some say in the ears; some, in the parts of generation; but the most probable opinion is, that this musky substance is amassed in glands under the legs and arms. From whatsoever part of the body this odour proceeds, it is very strong and powerful, tincturing the flesh of the whole body with its taste and smell. The crocodile's flesh is at best very bad tough eating; but unless the musk bags be separated it is insupportable. The negroes themselves cannot well digest the flesh; but then, a crocodile's egg is to them the most delicate morsel in the world. Even savages exhibit their epicures as well as we; and one of true taste will spare neither pains nor danger to furnish himself with his favourite repast. For this reason, he often watches the places where the female comes to lay her eggs, and upon her retiring seizes the booty.

All crocodiles breed near fresh waters; and though they are sometimes found in the sea, yet that may be considered rather as a place of excursion than abode. They produce their young by eggs, as was said above; and for this purpose the female, when she comes to lay, chooses a place by the side of a river, or some fresh-water lake, to deposit her brood in. She always pitches upon an extensive sandy shore, where she may dig a hole without danger of detection from the ground being fresh turned up. The shore must also be gentle and shelving to the water, for the greater convenience of the animal's going and returning; and a convenient place must be found near the edge of the stream, that the young may have a shorter way to go. When all these requisites are adjusted, the animal is seen cautiously stealing upon shore to deposit her burden. The presence of a man, a beast, or even a bird, is sufficient to deter her at that time; and if she perceives any creature looking on, she infallibly returns. If, however, nothing appears, she then goes to work, scratching up the sand with her fore-paws, and making a hole pretty deep in the shore. There she deposits from eighty to a hundred eggs, of the size of a tennis-ball, and of the same figure, covered with a tough white skin like parchment. She takes above an hour to perform this task; and then covering up the place so artfully that it can scarcely be perceived, she goes back to return again the next day. Upon her return, with the same precaution as before, she lays about the same number of eggs; and the day following also a like number. Thus having deposited her whole quantity, and having covered them close up in the sand, they are soon vivified by the

[1] It is a very remarkable observation, that the crocodile, when it appears out of the water, is almost surrounded by various large birds, particularly the pelican. It has been asked, whether there exists the same sympathy between these birds (especially the pelican) and the crocodile, which the heron has for buffaloes, oxen, and cows?

heat of the sun ; and at the end of thirty days, the young ones begin to break open the shell. At this time the female is instinctively taught that her young ones want relief; and she goes upon land to scratch away the sand, and set them free. Her brood quickly avail themselves of their liberty : a part run unguided to the water; another part ascend the back of the female, and are carried thither in greater safety. But the moment they arrive at the water, all natural connection is at an end ; when the female has introduced her young to their natural element, not only she, but the male, become among the number of their most formidable enemies, and devour as many of them as they can. The whole brood scatters into different parts of the bottom ; by far the greatest number is destroyed, and the rest find safety in their agility or minuteness.

But it is not the crocodile alone that is thus found to thin their numbers; the eggs of this animal are not only a delicious feast to the savage, but are eagerly sought after by every beast and bird of prey. The ichneumon was erected into a deity among the ancients for its success in destroying the eggs of these monsters : at present that species of the vulture called the Gallinazo is their most prevailing enemy. All along the banks of great rivers, for thousands of miles, the crocodile is seen to propagate in numbers that would soon overrun the earth, but for the vulture, that seems appointed by Providence to abridge its fecundity. These birds are ever found in greatest numbers where the crocodile is most numerous: and hiding themselves within the thick branches of the trees that shade the banks of the river, they watch the female in silence, and permit her to lay all her eggs without interruption. Then when she has retired, they encourage each other with cries to the spoil; and flocking all together upon the hidden treasure, tear up the eggs, and devour them in a much quicker time than they were deposited. Nor are they less diligent in attending the female while she is carrying her young to the water; for if any one of them happens to drop by the way, it is sure to receive no mercy.

Such is the extraordinary account given us by late travellers of the propagation of this animal ; an account adopted by Linnæus and the most learned naturalists of the age.[1] Yet, if one might argue from the general analogy of nature, the crocodile's devouring her own young when she gets to the water seems doubtful. This may be a story raised from the general idea of this animal's rapacious cruelty ; when, in fact, the crocodile only seems more cruel than other animals, because it has more power to do mischief. It is probable that it is not more divested of parental tenderness than other creatures, and I am the more led to think so from the peculiar formation of one of the crocodile kind. This is called the Open-Bellied Crocodile, and is furnished with a false belly like the oppossum, where the young creep out and in, as their dangers or necessities require. The crocodile thus furnished at least cannot be said to be an enemy to her own young, since she thus gives them more than parental protection. It is probable, also, that this open-bellied crocodile is viviparous, and fosters her young that are prematurely excluded in this second womb, until they come to proper maturity.[2]

How long the crocodile lives we are not certainly informed : if we may believe Aristotle, it lives the age of a man : but the ancients so much amused themselves in inventing fables concerning this animal, that even truth from them is suspicious. What we know for certain from the ancients is, that among the various animals that were produced to fight in the amphitheatre at Rome, the combat of the crocodile was not wanting.[3] Marcus Scarus produced them living in his unrivalled exhibitions; and the Romans considered him as their best citizen, because he furnished them with the most expensive entertainments. But entertainment at that corrupt time was their only occupation.

CHAP. III.

OF THE SALAMANDER.[4]

The ancients have described a lizard that is bred from heat, that lives in the flames, and

[1] Ulloa.

[2] None of the lizard tribe have any thing like an abdominal pouch for the safety of their young.

[3] Plin. lib. viii. c. 26.

[4] *The Salamander.*—The Salamander belongs to that order of reptiles called *Batrachians*, from their resemblance, to a certain extent, to the frog tribes. The *Batrachia* include all the reptiles with naked bodies, without the hard covering of the tortoises, or scales like serpents. The whole of this order are without nails on the toes, and they all undergo various changes or metamorphoses; the different changes in the organization of the salamanders nearly resemble those which occur in the case of the frogs and toads.

The body of the salamander is covered with pores, from which, when alarmed, or suffering from pain, an acrid watery humour exudes, which is at times able so far to quench the fury of the flames as to give the poor creature time to escape, and in this simple fact consists the whole of the mysterious power that has been attributed to it.

The salamanders are divided into two sections, the aquatic, that rarely leave the water, (our common eft is an example,) and the terrestrial, who only remain in that element during their tadpole state. The aquatic

feeds upon fire as its proper nourishment. As they saw every other element, the air, the earth, and water, inhabited, fancy was set to work to find or make an inhabitant in fire; and thus to people every part of nature. It will be needless to say that there is no such animal existing; and that of all others, the modern salamander has the smallest affinity to such an abode.

Whether the animal that now goes by the name of Salamander be the same with that described by Pliny, it is a doubt with me; but this is not a place for the discussion. It is sufficient to observe, that the modern salamander is an animal of the lizard kind, and under this name is comprehended a large tribe that all go by the same name. There have been not less than seven sorts of this animal described by Seba; and to have some idea of the peculiarity of their figure, if we suppose the tail of a lizard applied to the body of a frog, we shall not be far from precision. The common lizard is long, small, and taper; the salamander, like the frog, has its eyes towards the back of the head; like the frog, its snout is round, and not pointed, and its belly thick and swollen. The claws of its toes are short and feeble; its skin rough; and the tongue, unlike that of the smallest of the lizard kind, in which it is long and forked, is short, and adhering to the under jaw.

But it is not in figure that this animal chiefly differs from the rest of the lizard tribe; for it seems to differ in nature and conformation. In nature it is unlike, being a heavy torpid animal; whereas the lizard tribe are active, restless, and ever in motion; in conformation it is unlike, as the salamander is produced alive from the body of its parent, and is completely formed the moment of its exclusion. It differs from them also in its general reputation of being venomous: however, no trials that have been hitherto made seem to confirm the truth of the report.

Not only this, but many others of the lizard tribe, are said to have venom; but it were to be wished that mankind, for their own happiness, would examine into the foundation of this reproach. By that means many of them, that are now shunned and detested, might be found inoffensive; their figure, instead of either exciting horror or disgust, would then only tend to animate the general scene of nature; and speculation might examine their manners in confidence and security. Certain it is, that all the lizard kind, with which we are acquainted in this country, are perfectly harmless; and it is equally true that, for a long time, till our prejudices were removed, we considered not only the Newt, but the Snake and the Blind-worm, as fraught with the most destructive poison. At present we have got over these prejudices; and, it is probable, that if other nations made the same efforts for information, it would be found, that the malignity of most, if not all, of the lizard tribe, was only in the imagination.

With respect to the salamander, the whole tribe, from the Moron to the Gekko, are said to be venomous to the last degree; yet, when experiments have been tried, no arts, no provocations, could excite these animals to the rage of biting. They seem timid and inoffensive, only living upon worms and insects; quite destitute of fangs, like the viper, their teeth are so very small that they are hardly able to inflict a wound. But as the teeth are thus incapable of offending, the people of the countries where they are found have recourse to a venomous slaver, which, they suppose, issues from the animal's mouth; they also tell us of a venom issuing from the claws: even Linnæus seems to acknowledge the fact; but thinks it a probable supposition that this venom may proceed from their urine.

Of all animals, the Gekko is the most notorious for its powers of mischief; yet we are

---

salamanders have a tail flattened sideways, so as to assist them in swimming.

The experiments of Spallanzani, on their astonishing power of reproducing a limb, have rendered them famous. The same limb can be reproduced several times in succession, after it has been cut off, and that with all its bones, muscles, &c. Another faculty, not less singular, is that of remaining a long time encompassed with ice without perishing.

The salamanders were erroneously placed by Linnæus among the lizards, but they have been most properly transferred to the order to which they now belong, and to which they bear a much greater affinity, especially from their transformations. The following cut represents the *Gigantic Salamander*.

Although it is called gigantic, in reference to the size of most of the genus, it does not exceed eighteen inches in length. Some few years back, however, a salamander was discovered in Japan, to which the name gigantic might be applied with much greater propriety. A living specimen was taken, and conveyed to the museum at Leyden five years since; it was then about twelve inches long, but it has since then grown to the length of two feet and a half, although confined in a wooden vessel containing water. It is of a very dark olive-green colour, and covered with tubercles, nearly resembling in form the species represented in the engraving. It feeds sparingly on small living fish which are placed in its prison; its appetite, however, only recurs at long intervals, and its destined prey seem perfectly unconscious of the presence of an enemy, and when alarmed, take refuge under the very jaws of the reptile.

told by those who load it with that calumny, that it is very friendly to man, and though supplied with the most deadly virulence, is yet never known to bite. It would be absurd in us, without experience, to pronounce upon the noxious or inoffensive qualities of animals, yet it is probable, from an inspection of the teeth of lizards, and from their inoffensive qualities in Europe, that the gekko has been unjustly accused; and that its serpent-like figure has involved it in one common reproach with serpents.

The salamander best known in Europe, is from eight to eleven inches long, usually black, spotted with yellow; and, when taken in the hand, feeling cold to a great degree.—There are several kinds. Our Black Water-Newt is reckoned among the number. The idle report of its being inconsumable in fire, has caused many of these poor animals to be burnt; but we cannot say as philosophical martyrs, since scarcely any philosopher could think it necessary to make the experiment. When thrown into the fire, the animal is seen to burst with the heat of its situation, and to eject its fluids. We are gravely told, in the Philosophical Transactions, that this is a method the animal takes to extinguish the flames!

When examined internally, the salamander exhibits little difference from other animals of the lizard kind. It is furnished with lungs that sometimes serve for the offices of breathing; with a heart that has its communications open, so that the animal cannot easily be drowned. The ovary in the female is double the size of what it is in others of this tribe; and the male is furnished with four testiculi instead of two. But what deserves particular notice is the manner of this animal's bringing forth its young alive.[1] "The salamander," says my author, "begins to show itself in spring, and chiefly during heavy rains. When the warm weather returns, it disappears; and never leaves its hole, during either great heats or severe colds, both which it equally fears. When taken in the hand, it appears like a lump of ice; it consequently loves the shade, and is found at the feet of old trees surrounded with brushwood at the bottom. It is fond of running along new ploughed grounds: probably to seek for worms, which are its ordinary food. One of these," continues my author, "I took alive some years ago in a ditch that had been lately made. I laid it at the foot of the stairs upon coming home, and there it disgorged from the throat a *worm* three inches long, that lived for an hour after, though wounded as I suppose by the teeth of the animal. I afterwards cut up another of these lizards, and saw not less than fifty young ones, resembling the parent, come from its womb, all alive, and actively running about the room." It were to be wished the author had used another word besides that of *worm*; as we now are in doubt whether he means a real worm, or a young animal of the lizard species: had he been more explicit, and had it appeared that it was a real young lizard, which I take to be his meaning, we might here see a wonder of Nature brought to the proof, which many have asserted, and many have thought proper to deny; I mean the refuge which the young of the shark, the lizard, and the viper kinds, are said to take, by running down the throat of the parent, and there finding a temporary security. The fact, indeed, seems a little extraordinary; and yet it is so frequently attested by some, and even believed by others, whose authority is respectable, among the number of whom we find Mr Pennant, that the argument of strangeness must give way to the weight of authority.

However this be, there is no doubt of the animal's being viviparous, and producing above fifty at a time. They come from the parent in full perfection, and quickly leave her to shift for themselves. These animals, in the lower ranks of nature, want scarcely any help when excluded; they soon complete the little circle of their education; and in a day or two are capable of practising all the arts of subsistence and evasion practised by their kind.

They are all amphibious, or at least are found capable of subsisting in either element, when placed there: if those taken from land are put into water, they continue there in seeming health: and, on the contrary, those taken from the water will live upon land. In water, however, they exhibit a greater variety in their appearance; and what is equally wonderful with the rest of their history, during the whole spring and summer, this water-lizard changes its skin every fourth or fifth day; and during the winter every fifteen days. This operation they perform by means of the mouth and the claws: and it seems a work of no small difficulty and pain. The cast skins are frequently seen floating on the surface of the water: they are sometimes seen also with a part of their old skin still sticking to one of their limbs, which they have not been able to get rid of; and thus, like a man with a boot half drawn, in some measure crippled in their own spoils. This also often corrupts, and the leg drops off; but the animal does not seem to feel the want of it, for the loss of a limb to all the lizard kind is but a trifling calamity. They can live several hours even after the loss of

[1] Acta Hafniensia, ann. 1676. Observ. 11. Memoires de l'Academie Royale des Sciences, tom. iii. part 3. p. 80.

their head: and for some time under dissection, all the parts of this animal seem to retain life: but the tail is the part that longest retains its motion. Salt seems to be much more efficacious in destroying these animals than the knife; for upon being sprinkled with it, the whole body emits a viscous liquor, and the lizard dies in three minutes, in great agonies.

The whole of the lizard kind are also tenacious of life in another respect, and the salamander among the number. They sustain the want of food in a surprising manner. One of them, brought from the Indies, lived nine months, without any other food than what it received from licking a piece of earth on which it was brought over;[1] another was kept by Seba in an empty vial for six months, without any nourishment; and Rhedi talks of a large one, brought from Africa, that lived for eight months, without taking any nourishment whatever. Indeed, as many of this kind, both salamanders and lizards, are torpid, or nearly so, during the winter, the loss of their appetite for so long a time is the less surprising.

CHAP. IV.

OF THE CAMELEON, THE IGUANA, AND LIZARDS OF DIFFERENT KINDS.

It were to be wished that animals could be so classed, that by the very mentioning their rank, we should receive some insight into their history. This I have endeavoured in most instances; but in the present chapter all method is totally unserviceable. Here distribution gives no general ideas: for some of the animals to be here mentioned produce by eggs; some by spawn; and some are viviparous. The peculiar manner of propagating in each, is very indistinctly known. The Iguana and the Cameleon, we know bring forth eggs; some others also produce in the same manner; but of the rest, which naturalists make amount to above fifty, we have but very indistinct information.

In the former divisions of this tribe, we had to observe upon animals, formidable from their size, or disgusting from their frog-like head and appearance; in the present division, all the animals are either beautiful to the eye, or grateful to the appetite. The lizards, properly so called, are beautifully painted and mottled; their frolicsome agility is amusing to those who are familiar with their appearance; and the great affection which some of them show to man, should, in some measure, be repaid with kindness. Others, such as the Iguana, though not possessed of beauty, are very serviceable, furnishing one of the most luxurious feasts the tropical climates can boast of. Those treated of before were objects of curiosity, because they were apparently objects of danger; most of these here mentioned have either use or beauty to engage us.

Directly descending from the crocodile, we find the Cordyle, the Tockay, and the Tejuguacu, all growing less in order, as I have named them. These fill up the chasm to be found between the crocodile and the African Iguana.

The Iguana, which deserves our notice, is about five feet long, and the body about as thick as one's thigh; the skin is covered with small scales, like those of a serpent; and the back is furnished with a row of prickles, that stand up, like the teeth of a saw: the eyes seem to be but half opened, except when the animal is angry, and then they appear large and sparkling: both the jaws are full of very sharp teeth, and the bite is dangerous, though not venomous, for it never lets loose till it is killed. The male has a skin hanging under his throat, which reaches down to his breast; and, when displeased, he puffs it up like a bladder; he is one-third larger and stronger than the female; though the strength of either avails them little towards their defence. The males are ash-coloured, and the females are green.[2]

[1] Phil. Trans. ann. 1661. N. 21. art. 7.

[2] The *Common American Iguana* is from four to five feet long. It is very common in all the warm parts of America, where it remains in the woods, at the environs of rivers, and sources of spring-water. It passes most part of its time on trees, sometimes going to the water, and living on fruits, grain, and leaves. Without being either venomous or dangerous, its bite is exceedingly painful; and when it is angry, the goitre which it has under its neck becomes distended and expanded. This reptile has great tenacity and endurance of life, and will resist the blows of a stick or cudgel very well. Accordingly, it is usually hunted with the bow or the gun.

The females are smaller than the males, but their colours are much more brilliant. They lay eggs in the sand, about as large as those of pigeons, but a little longer, and of equal thickness at both ends. The shell of these eggs is white, even, and soft. They are entirely filled by the yolk, and can hardly be said to have any albumen. They never harden by fire, but only become a little pasty. But their flavour is very agreeable, and they are constantly eaten in Surinam and Guiana. A single female will lay about six dozen.

The flesh of the iguana is considered as delicious, and is in great estimation throughout all the warm parts of America. It is white and delicate. Many persons, however, consider it as unwholesome, especially for those who are infected with syphilis, some symptoms of which, such as pains in the bones, &c. it is supposed to aggravate or cause the return of. At Paramaraibo, it is sold extremely dear, and highly thought of by epicures. Pison, and many others of the old travellers in America, have spoken in high terms of the virtues of the bezoar of the iguana, a kind of stone, found, say they, in the stomach or cranium of this reptile. But, at the present day,

The flesh of these may be considered as the greatest delicacy of Africa and America; and the sportsmen of those climates go out to hunt the iguana, as we do in pursuit of the pheasant or the hare. In the beginning of the season, when the great floods of the tropical climates are passed away, and vegetation starts into universal verdure, the sportsmen are seen, with a noose and a stick, wandering along the sides of the rivers to take the iguana. The animal, though apparently formed for combat, is the most harmless creature of all the forest: it lives among the trees, or sports in the water, without ever offering to offend; there, having fed upon the flowers of the mahot, and the leaves of the mapou, that grow along the banks of the stream, it goes to repose upon the branches of the trees that hang over the water. Upon the land the animal is swift of foot; but when once in possession of a tree, it seems conscious of the security of its situation, and never offers to stir. There the sportsman easily finds it, and as easily fastens his noose round its neck: if the head be placed in such a manner that the noose cannot readily be fastened, by hitting the animal a blow on the nose with the stick, it lifts the head, and offers it in some measure to the noose. In this manner, and also by the tail, the iguana is dragged from the trees, and killed by repeated blows on the head.

The Cameleon is a very different animal; and as the iguana satisfies the appetites of the epicure, this is rather the feast of the philosopher. Like the crocodile, this little animal proceeds from an egg; and it also nearly resembles that formidable creature in form; but it differs widely in its size and its appetites; being not above eleven inches long, and delighting to sit upon trees, being afraid of serpents, from which it is enabled to escape on the ground.

The head of a large cameleon is almost two inches long; and from thence to the beginning of the tail, four and a half: the tail is five inches long, and the feet two and a half: the thickness of the body is different at different times; for sometimes, from the back to the belly, it is two inches, and sometimes but one; for it can blow itself up, and contract itself at pleasure. This swelling and contraction is not only of the back and belly but of the legs and tail.

These different tumors do not proceed from a dilatation of the breast in breathing, which rises and falls by turns; but are very irregular, and seem adopted merely from caprice. The cameleon is often seen, as it were, blown up for two hours together; and then it continues growing less and less insensibly; for the dilatation is always more quick and visible than the contraction. In this last state the animal appears extremely lean; the spine of the back seems sharp, and all the ribs may be counted; likewise the tendons of the legs and arms may be seen very distinctly.

This method of puffing itself up, is similar to that in pigeons, whose crops are sometimes

---

this substance is fallen into the most absolute disrepute among all medical practitioners.

The *slate-coloured Iguana* is but three feet in length. It inhabits the same places as the former species, and may be merely a variety of it, in age or sex. Seba derives it from the island of Formosa.

The *horned Iguana* of St Domingo is about four feet long. It is frequently found in the hills of St Domingo, between Artibonite and Gonaives. It lives on fruits, insects, and small birds, which it seizes with marvellous agility, and during the day it couches on trees and rocks to watch for its prey. During the night, and the entire season of the great heats, it retires into the hollows of rocks, or into the holes of old trees, and it passes about five or six months of the year there in a state of lethargy. This reptile is considered by the negroes as a delicious meat, and is accordingly sought after by them with great avidity. According to the report of the colonists, its flesh resembles in flavour that of the roebuck, and the maroon dogs make great slaughter among these reptiles. The colours of this iguana are not precisely known.

Some authors place here the *iguana fasciata*. Its colour is deep blue, with transverse bands of a clearer tint. The goitre is moderate, and not denticulated. There is no large scale at the angle of the jaw. This iguana belongs to the island of Java. It may probably be the reptile which Bontius has named *cameleon*. It is also probable, that to this species must be referred the very large iguanas which are found at Batavia, and which are sometimes as thick as a man's thigh. In his voyage with Captain Cook, Sir Joseph Banks killed one of these, which was five feet in length.

Under the name of *Basilisk* is at present designated a genus of reptiles, of this saurian order, which exhibits many affinities with the iguanas and monitors. No animal, perhaps, has been the subject of so great a number of prejudices as the one now under consideration. The most ancient authors have spoken of the basilisk, as of a serpent which had the power of striking its victim dead by a single glance. Others have pretended that it could not exercise this faculty, unless it first perceived the object of its vengeance before it was itself perceived by it. It was also most absurdly imagined to proceed from the eggs of old cocks. Aldrovandus, and several other writers have given figures of it. They have represented it with eight feet, a crown on the head, and a hooked and recurved beak. Pliny assures us that the serpent named basilisk has a voice so terrible, that it strikes terror into all other species, that it thus chases them from the spot which it inhabits, and of which it retains the sole and undisputed dominion. The name, indeed, of basilisk, Βασιλικος, signifies royal. The fantastic forms, and fabulous properties thus attributed to an animal, which most probably never had any existence, rendered this name too celebrated for naturalists not to endeavour to apply it to another species, which accordingly they did. Seba has figured a species of lizard, whose head is surmounted with projecting lines, and the back furnished with a broad vertical crest, which extends as far over the tail, and which that author believed to be intended for the purposes of flight. He has designated it under the name of basilisk, or dragon of America, a flying amphibious animal. This is the animal which has subsequently been described in all works of natural history under the name of basilisk.—*Supplement to the English edition of Cuvier.*

greatly distended with air. The cameleon has a power of driving the air it breathes over every part of the body; however, it only gets between the skin and the muscles; for the muscles themselves are never swollen. The skin is very cold to the touch; and though the animal seems so lean, there is no feeling the beating of the heart. The surface of the skin is unequal, and has a grain not unlike shagreen, but very soft, because each eminence is as smooth as if it were polished. Some of these little protuberances are as large as a pin's head, on the arms, legs, belly, and tail; but on the shoulders and head they are of an oval figure, and a little larger; those under the throat are ranged in the form of a chaplet, from the lower lip to the breast. The colour of all these eminences, when the cameleon is at rest in a shady place, is of a bluish gray, and the space between is of a pale red and yellow.

But when the animal is removed into the sun, then comes the wonderful part of its history. At first it appears to suffer no change of colour, its grayish spots still continuing the same: but the whole surface soon seems to imbibe the rays of light; and the simple colouring of the body changes into a variety of beautiful hues. Wherever the light comes upon the body, it is of a tawny brown; but that part of the skin on which the sun does not shine, changes into several brighter colours, pale yellow, or vivid crimson; which forms spots of the size of half one's finger: some of these descend from the spine half way down the back; and others appear on the sides, arms, and tail. When the sun has done shining, the original gray colour returns by degrees, and covers all the body. Sometimes the animal becomes all over spotted with brown spots, of a greenish cast. When it is wrapt up in a white linen cloth for two or three minutes, the natural colour becomes much lighter; but not quite white, as some authors have pretended: however, from hence it must be concluded that the cameleon assumes the colour of the objects which it approaches; this is entirely an error, and probably has taken its rise from the continual changes it appears to undergo.[1]

[1] The skin of the cameleon is composed of a sort of small, scaly grains, and, under ordinary circumstances, is of a greenish-gray colour. The general form of the body reminds one of the lizard, but the trunk is compressed, and the back highly ridged or cutting. The occiput, or hinder part of the head, is elevated pyramidically; the eyes are large, projecting far outwards, yet almost entirely covered over by the skin, except immediately opposite the pupil. What is still more singular, the eyes are capable of moving independently of each other, taking different directions at the same moment; there is no visible external ear; the tongue is fleshy, round, and capable of being greatly lengthened; the teeth are three-pronged. Each of the feet has five toes, but these are separated into two portions (one containing two and the other three toes) by the skin, which covers them entirely to the nails. The tail is long and round, and capable of grasping twigs or branches, to sustain the animal. The lungs of the chameleon are so large, that when inflated to the utmost, the whole body becomes almost transparent. With the different degrees of inflation, the surface undergoes changes of colour, owing to the variations produced in the distribution of the blood, and not, as has been fabled, by the animal assuming the colour of the body upon which it happens to be placed.

It is scarcely possible to witness any thing more curious or beautiful than the transitions from hue to hue, exhibited by the cameleon, when aroused to motion. The cameleons are all exceedingly slow, dull and almost torpid. The only part which they move with celerity is their long tongue. This organ is clothed, at its extremity, with a viscid, gluey mucus, and is darted out for the purpose of capturing insects, upon which the animal subsists. As they feed but seldom, and are frequently seen inhaling the air, to inflate their bodies as above-mentioned, ancient observers concluded that they fed altogether on air; but closer attention to their habits has shown that they require a diet rather more substantial. Three or four species are well known, and are natives of Africa and the Molucca islands. They pass their lives altogether upon trees, feeding upon small insects, for which their construction shows them to be perfectly adapted.

Le Bruyn, in his Voyage to the Levant, has given us a very ample description of the cameleon. During his stay at Smyrna, he bought several of this kind; and to try how

The *Variegated Lizard*.—This, which is by far the largest in this division of the genus, sometimes exceeds the guana in size. The head is covered, as in the green lizard, with large scales or plates; the body with small and somewhat square scales, which are so disposed as to mark the sides into numerous tapering annuli or striæ, passing from the back perpendicularly downwards, and from the sides perpendicularly upwards, the narrow end of each row alternating with the broader end of the opposite one; and in the younger animals a kind of plated appearance, or continued lateral wrinkle appears to pass along each side of the animal; the tail, which is very long, is surrounded by extremely numerous rings of small square scales, and tapers to a slender point. The colour in the larger animals is highly beautiful, consisting of an elegant, and in general somewhat minute variegation of brown, or blackish and purple spots, on a pale bluish-white, and in some parts yellowish ground. The whole form of the animal is rather thick or plump, in comparison with many other lizards: the tongue is broad, flat, long, forked at the tip, and curiously serrated on each side; the head shaped like that of the Arneivo, to which this species is nearly allied. It is a native of South America.

The *Green Lizard*.—The common green lizard is a native of both Europe and India. This species is also extremely nimble; it basks on the sides of dry banks, or under old trees in the hot weather, but, on being observed, immediately retreats to its hole. The food of this, as well as all other British lizards, is insects; and they themselves are devoured by birds of prey. They are all perfectly harmless, yet their form strikes almost every beholder with disgust, and has occasioned great obscurity in their history. Mr Pennant mentions a lizard killed in Worcestershire, in the year 1714, which was two feet six inches long, and four inches in girth; the fore-legs were placed eight inches from the head, the hind-legs five inches behind those; the legs were two inches long; and the feet divided into four toes,

long they could live, kept four of them in a cage, permitting them at times to run about the house. The fresh sea-breeze seemed to give them most spirits and vivacity; they opened their mouths to take it in; he never perceived that they eat any thing, except now and then a fly, which they took half an hour to swallow: he observed their colour often to change, three or four times successively, without being able to find out any cause for such alterations; their common colour he found to be gray, or rather a pale mouse colour; but its most frequent changes were into a beautiful green, spotted with yellow; sometimes the animal was marked all over with dark brown; and this often changes into a lighter brown: some colours, however, it never assumed; and contrary to what was said above, he found red to be among the number.

Though our traveller took the utmost care, he was unable to preserve any of them alive above five months; and many of them died in four. When the cameleon changes place, and attempts to descend from an eminence, it moves with the utmost precaution, advancing one leg very deliberately before the other, still securing itself by holding whatever it can grasp by the tail. It seldom opens its mouth, except for fresh air; and when that is supplied, discovers its satisfaction by its motions, and the frequent changes of its colour. The tongue is sometimes darted out after its prey, which is flies; and this is as long as the whole body. The eyes are remarkably little, though they stand out of the head; they have

each furnished with a sharp claw. Another of the same kind was afterwards killed in that county: but whether these large lizards were natives of other countries, and imported into England, or whether they were of British growth, is uncertain, though the former is more probable, as in this country they scarcely ever exceed six inches. This species has a pretty long verticulated tail, with sharp scales, and a scaly collar.

The green lizard of Carolina is denominated from its colour. It is very slender; the tail nearly double the length of the body; and the whole length above five inches. It inhabits Carolina, where it is domestic, familiar, and harmless. It sports on the tables and windows, and amuses with its agility in catching flies. Cold affects its colours: in that uncertain climate, when there is a quick transition in the same day from hot to cold, it changes instantly from the most brilliant green to a dull brown. They are a prey to cats and ravenous birds. They appear chiefly in summer; and at the approach of cold weather they retire to their winter recesses, and lie torpid in the holes and crevices of hollow trees. It frequently happens, that a few warm sunshiny days so invigorate them, that they will come out of their holes and appear abroad; when on a sudden the weather changes to cold, they become so feeble as to be unable to return to their retreats, and consequently expire.

The *Nimble Lizard.*—This elegant little creature, which is known in almost every part of the temperate regions of Europe, seems to be the most gentle and inoffensive, and at the same time, the most useful of all the lizard tribe. It is fond of basking in the sun; but, unable to bear extensive heat, in the hottest weather it seeks for shelter. In spring, during fine weather, it may sometimes be seen luxuriously extended on a sloping green bank, or on a wall exposed to the sun. In these situations it enjoys the full effects of the reviving warmth, expressing its delight by gently agitating its slender tail; and its lively and brilliant eyes are animated with pleasure.—Should any of the minute animals, on which it feeds, appear, it springs upon them with the quickness of thought; and if any danger occurs, the creature itself seeks a more secure retreat with equal rapidity. On the least noise it turns suddenly round, drops down, and seems, for a moment, perfectly stupified by its fall; or else it suddenly shoots away among the bushes or thick grass. Its wonderful rapidity of motion is chiefly to be observed in warm countries, for in the temperate regions its evolutions are much more languid. This gentle and peaceful animal excites no sensations of terror; and, when taken into the hand, makes not the smallest attempt either to bite or offend. In some countries, children use it as a play-thing; and, in consequence of its natural gentleness of disposition, it becomes in a great measure tame and familiar.

The *Sand Lizard.*—This species is found on sandy

heaths in some parts of England. Its colour is in general brown, and its length seven inches. It is more sluggish than the common lizard, and will attempt to bite any one who handles it.

The *Frilled Lizard*, of which the following cut re-

presents the figure, is a curious species found in Australia. Little is known of its habits.

a single eye-lid, like a cap with a hole in the middle, through which the sight of the eye appears, which is of a shining brown; and round it there is a little circle of a gold colour: but the most extraordinary part of their conformation is, that the animal often moves one eye, when the other is entirely at rest: nay sometimes one eye will seem to look directly forward, while the other looks backward; and one will look upward, while the other regards the earth.

To this class of lizards, we may refer the Dragon, a most terrible animal, but most probably not of Nature's formation. Of this death-dealing creature all people have read; and the most barbarous countries, to this day, paint it to the imagination in all its terrors, and fear to meet it in every forest. It is not enough that nature has furnished those countries with poisons of various malignity; with serpents forty feet long; with elephants, lions, and tigers; to make their situation really dangerous, the capricious imagination is set at work to call up new terrors; and scarce a savage is found that does not talk of winged serpents of immoderate length, flying away with the camel or the rhinoceros, or destroying mankind by a single glare. Happily, however, such ravagers are no where found to exist at present; and the whole race of dragons is dwindled down to the Flying Lizard, a little harmless creature, that only preys upon insects, and even seems to embellish the forest with its beauty.

The Flying Lizard of Java perches upon fruit-trees, and feeds upon flies, ants, butterflies, and other small insects. It is a very harmless creature, and does no mischief in any respect. Gentil, in his voyage round the World, affirms, that he has seen these lizards at the island of Java, in the East Indies. He observed they flew very swiftly from tree to tree; and having killed one, he could not but admire the skin, which was painted with several beautiful colours: it was a foot in length, and had four paws, like the common lizards: but its head was flat, and had a small hole in the middle; the wings were very thin, and resembled those of a flying fish. About the neck were a sort of wattles, not unlike those of cocks, which gave it no disagreeable appearance. He intended to have preserved it, in order to bring it into Europe; but it was corrupted by the heat, before the close of the day; however, they have since been brought into England, and are now common enough in the cabinets of the curious.

The last animal of the lizard kind that I shall mention, is the Chalcidian Lizard of Aldrovandus, very improperly called the Seps by modern historians, This animal seems to make the shade that separates the lizard from the serpent race. It has four legs, like the lizard; but so short, as to be utterly unserviceable in walking: it has a long slender body, like the serpent; and is said to have the serpent's malignity also. The fore legs are very near the head; the hind legs are placed far backward; but before and behind they seem rather useless incumbrances, than instruments serving to assist the animal in its motions, or in providing for its subsistence. These animals are found above three feet long, and thick in proportion, with a large head and pointed snout. The whole body is covered with scales; and the belly is white mixed with blue. It has four crooked teeth, as also a pointed tail, which, however, can inflict no wound. Whether the teeth be similar to the viper's fangs, we are not told; though Volateranus says, they are covered with a membrane; by which I am apt to think he means a venom-bag, which is found at the root of teeth of all serpents that are poisonous. It is viviparous; fifteen young ones having been taken alive out of its belly. Upon the whole, it appears to bear a strong affinity to the viper; and, like that animal, its bite may be dangerous.

OF FROGS, LIZARDS, AND SERPENTS.

BOOK III.

OF SERPENTS, ETC.

CHAP. I.

OF SERPENTS IN GENERAL.[1]

We now come to a tribe, that not only their deformity, their venom, their ready malignity, but also our prejudices, and our very religion, have taught us to detest. The serpent has, from the beginning, been the enemy of man; and it has hitherto continued to terrify and annoy him, notwithstanding all the arts that have been practised to destroy it. Formidable in itself, it deters the invader from the pursuit; and, from its figure, capable of finding shelter in a little space, it is not easily discovered by those who would venture to try the encounter. Thus possessed at once of potent arms and inaccessible or secure retreats, it baffles all the arts of man, though never so earnestly bent upon its destruction.

For this reason, there is scarce a country in the world that does not still give birth to this poisonous brood, that seem formed to quell human pride, and repress the boasts of security. Mankind have driven the lion, the tiger, and the wolf from their vicinity; but the snake

[1] The serpent tribes are distinguished from all other animals by a peculiar character, in which their figure, motion, and habits, so repulsive and disgusting, form a striking contrast to the beautiful and variegated colours with which their skin is studded, adding, if possible, to their subtile and venomous appearance; while their crawling motion strikingly exemplifies the *decree of the Creator*, made after the temptation and fall of man:—"Because thou hast done this, cursed art thou above all cattle, and every bird of the field; upon thy belly shalt thou go, and dust thou shalt eat all the days of thy life."

The tribes are very numerous, and have been divided by Lacepede into eight genera, each of which are subdivided, and contain many species. The genera comprise the Boas, containing 11 species; the Rattle-snake, 6 species; the Vipers, 196 species; the Snakes, 24 species; the Amphisbœna, 5 species; Langrata, 1; Cœcilia, 2; and Acrochord, 1.

Although destitute of feet and wings, few animals are so active as serpents, or can transport themselves from place to place with equal agility. Whether to seize its prey, or escape from danger, the serpent moves with the velocity of an arrow, and surpasses several species of birds in the ease and rapidity with which it gains the summits of the highest trees, twisting and untwisting its flexible body around their trunks and branches with such celerity, that the quickest eye can scarcely follow its rapid motion. Their size greatly varies; some are but a few inches long, while others are forty, or even fifty feet in length. All are covered with scales, or scaly tubercles. Their brain case is weak and shallow; and hence serpents are easily killed by a blow on the head. The formation and conjunction of the vertebræ are well adapted for mobility.

All parts of their body have great force, agility, and elasticity. They are most abundant in warm and temperate regions; but increase in size and numbers, in proportion to the heat and moisture, and to the freedom of their range. They have less blood than quadrupeds, a lower animal heat, and less interior activity of system. They are more animated in times of tempest and hurricane, when the electricity of the atmosphere is in the greatest perturbation. Their sense of hearing is dull, but their vision acute. Their sense of taste is probably of considerable delicacy, as the tongue is very slender, and divided into two joints, which admit of its being readily applied to sapid bodies. Their sense of touch is probably obscure. They give many indications of high instinct and sensibility, and have the faculty of existing a long period without food.

They have no voice, but a hiss, which is uttered softer or stronger according to the exciting cause. It is exerted exclusively in the declaration of their fiercer passions —the milder sensibilities are not accompanied by any vocal annunciation.

Serpents have great strength from the peculiar construction of their body. They are very tenacious of life. They have been, from all antiquity, and in most countries, celebrated for their great cunning and sagacity; which is chiefly displayed in their mode of evading their enemies, or of obtaining their prey. Some serpents are eminently noted for their brilliant colours, of which several display fine iridescent changes. It is a curious distinction of these animals, which has lately been made by M. de la Borde, of Cayenne, that nearly all the species of serpents of which the young are hatched within the mother, and which are therefore born alive, are venomous.

and the viper still defy their power, and frequently punish their insolence.

Their numbers, however, are thinned by human assiduity; and it is possible some of the kinds are wholly destroyed. In none of the countries of Europe are they sufficiently numerous to be truly terrible; the philosopher can meditate in the fields without danger; and the lover seek the grove without fearing any wounds but those of metaphor. The various malignity that has been ascribed to European serpents of old is now utterly unknown; there are not above three or four kinds that are dangerous, and their poison operates in all in the same manner. A burning pain in the part, easily removable by timely applications, is the worst effect that we can experience from the bite of the most venomous serpents of Europe. The drowsy death, the starting of the blood from every pore, the insatiable and burning thirst, the melting down the solid mass of the whole form into one heap of putrefaction, these are horrors with which we are entirely unacquainted.

But though we have thus reduced these dangers, having been incapable of wholly removing them, in other parts of the world they still rage with all their ancient malignity. Nature seems to have placed them as centinels, to deter mankind from spreading too widely, and from seeking new abodes, till they have thoroughly cultivated those at home. In the warm countries that lie within the tropics, as well as in the cold regions of the north, where the inhabitants are few, the serpents propagate in equal proportion. But of all countries, those regions have them in the greatest abundance where the fields are unpeopled and fertile, and where the climate supplies warmth and humidity. All along the swampy banks of the river Niger or Oroonoko, where the sun is hot, the forests thick, and the men but few, the serpents cling among the branches of the trees in infinite numbers, and carry on an unceasing war against all other animals in their vicinity. Travellers have assured us, that they have often seen large snakes twining round the trunk of a tall tree, encompassing it like a wreath, and thus rising and descending at pleasure. In these countries, therefore, the serpent is too formidable to become an object of curiosity, for it excites much more violent sensations.

We are not, therefore, to reject, as wholly fabulous, the accounts left us by the ancients of the terrible devastations committed by a single serpent. It is probable, in early times, when the arts were little known, and mankind were but thinly scattered over the earth, that serpents, continuing undisturbed possessors of the forests, grew to an amazing magnitude: and every other tribe of animals fell before them. It then might have happened, that serpents reigned the tyrants of a district for centuries together. To animals of this kind, grown by time and rapacity to a hundred or a hundred and fifty feet in length, the lion, the tiger, and even the elephant itself, were but feeble opponents. The dreadful monster spread desolation round him; every creature that had life was devoured, or fled to a distance. That horrible *fœtor*, which even the commonest and the most harmless snakes are still found to diffuse, might, in these larger ones, become too powerful for any living being to withstand; and while they preyed without distinction, they might thus also have poisoned the atmosphere around them. In this manner, having for ages lived in the hidden and unpeopled forest, and finding as their appetites were more powerful, the quantity of their prey decreasing, it is possible they might venture boldly from their retreats, into the more cultivated parts of the country, and carry consternation among mankind, as they had before desolation among the lower ranks of nature. We have many histories of antiquity, presenting us such a picture; and exhibiting a whole nation sinking under the ravages of a single serpent. At that time, man had not learned the art of uniting the efforts of many, to effect one great purpose. Opposing multitudes only added new victims to the general calamity, and increased mutual embarrassment and terror. The animal was, therefore, to be singly opposed by him who had the greatest strength, the best armour, and the most undaunted courage. In such an encounter hundreds must have fallen; till one, more lucky than the rest, by a fortunate blow, or by taking the monster in its torpid interval, and surcharged with spoil, might kill, and thus rid his country of the destroyer. Such was the original occupation of heroes: and those who first obtained that name, from their destroying the ravagers of the earth, gained it much more deservedly than their successors, who acquired their reputation only for their skill in destroying each other. But as we descend into more enlightened antiquity, we find these animals less formidable, as being attacked in a more successful manner. We are told, that while Regulus led his army along the banks of the river Bagrada, in Africa, an enormous serpent disputed his passage over. We are assured by Pliny, who says, that he himself saw the skin, that it was a hundred and twenty feet long, and that he had destroyed many of the army. At last, however, the battering engines were brought out against it; and these assailing it at a distance, it was soon destroyed. Its spoils were carried to Rome, and the general was decreed an ovation for his success. There are, perhaps, few facts better ascertained in history

than this: an ovation was a remarkable honour; and was given only for some signal exploit that did not deserve a triumph: no historian would offer to invent that part of the story at least, without being subject to the most shameful detection. The skin was kept for several years after in the capitol; and Pliny says, he saw it there: now, though Pliny was a credulous writer, he was by no means a *false* one; and whatever he says he has seen, we may very safely rely on. At present, indeed, such ravages from serpents are scarcely seen in any part of the world; not but that in Africa and America some of them are powerful enough to brave the assaults of men to this day.

But, happily for us, we are placed at such a distance as to take a view of this tribe without fearing for our safety; we can survey their impotent malignity with the same delight with which the poet describes the terrors of a dead monster.

> Nequeant expleri corda tuendo
> Terribiles oculos villosaque setis pectora.

To us their slender form, their undulating motion, their vivid colouring, their horrid stench, their forky tongue, and their envenomed fangs, are totally harmless; and in this country their uses even serve to counterbalance the mischief they sometimes occasion.

If we take a survey of serpents in general, they have marks by which they are distinguished from all the rest of animated nature. They have the length and the suppleness of the eel, but want fins to swim with: they have the scaly covering and pointed tail of the lizard, but they want legs to walk with; they have the crawling motion of the worm, but, unlike that animal, they have lungs to breathe with: like all the reptile kind, they are resentful when offended; and nature has supplied them with terrible arms to revenge every injury.

Though they are possessed of very different degrees of malignity, yet they are all formidable to man, and have a strong similitude of form to each other; and it will be proper to mark the general character before we descend to particulars. With respect to their conformation, all serpents have a very wide mouth, in proportion to the size of the head; and, what is very extraordinary, they can gape and swallow the head of another animal which is three times as big as their own. I have seen a toad taken out of the belly of a snake, at lord Spencer's, near London, the body of which was thrice the diameter of the animal that swallowed it. However, it is no way surprising that the skin of the snake should stretch to receive so large a morsel: the wonder seems how the jaws could take it in. To explain this, it must be observed that the jaws of this animal do not open as ours, in the manner of a pair of hinges, where bones are applied to bones, and play upon one another; on the contrary, the serpent's jaws are held together at the roots by a stretching muscular skin; by which means they open as widely as the animal chooses to stretch them, and admit of a prey much thicker than the snake's own body. The throat, like stretching leather, dilates to admit the morsel; the stomach receives it in part; and the rest remains in the gullet, till putrefaction and the juices of the serpent's body unite to dissolve it.

As to the teeth, I will talk more of them when I come to treat of the viper's poison; it will be sufficient here to observe, that some serpents have fangs, or canine teeth, and others are without them. The teeth in all are crooked and hollow; and, by a peculiar contrivance, are capable of being erected or depressed at pleasure.

The eyes of all serpents are small, if compared to the length of the body; and though differently coloured in different kinds, yet the appearance of all is malign and heavy; and, from their known qualities, they strike the imagination with the idea of a creature meditating mischief. In some, the upper eye-lid is wanting, and the serpent winks only with that below; in others, the animal has a nictitating membrane or skin, resembling that which is found in birds, which keeps the eye clean, and preserves the sight. The substance of the eye in all is hard and horny; the crystalline humour occupying a great part of the globe.

The holes for hearing are very visible in all: but there is no conduits for smelling; though it is probable that some of them enjoy that sense in tolerable perfection.

The tongue in all these animals is long and forky. It is composed of two long fleshy substances, which terminate in sharp points, and are very pliable. At the root it is connected very strongly to the neck by two tendons, that give it a variety of play. Some of the viper kind have tongues a fifth part of the length of their bodies; they are continually darting them out, but they are entirely harmless, and only terrify those who are ignorant of the real situation of their poison.

If from the jaws we go on to the gullet, we shall find it very wide for the animal's size, and capable of being distended to a great degree; at the bottom of this lies the stomach, which is not so capacious, and receives only a part of the prey, while the rest continues in the gullet for digestion. When the substance in the stomach is dissolved into chyle, it passes into the intestines, and from thence goes to nourishment, or to be excluded by the vent.

Like most other animals, serpents are furnished with lungs, which, I suppose, are serviceable in breathing, though we cannot perceive the manner in which this operation is performed; for though serpents are often seen, apparently, to draw in their breath, yet we cannot find the smallest signs of their ever respiring it again. Their lungs, however, are long and large, and doubtless are necessary to promote their languid circulation. The heart is formed as in the tortoise, the frog, and the lizard kinds, so as to work without the assistance of the lungs. It is single, the greatest part of the blood flowing from the great vein to the great artery by the shortest course. By this contrivance of nature we easily gather two consequences—that snakes are amphibious, being equally capable of living on land and in the water; and that also they are torpid in winter, like the bat, the lizard, and other animals formed in the same manner.

The vent in these animals serves for the emission of the urine and the fæces, and for the purposes of generation. The instrument of generation in the male is double, being forked like the tongue; the ovaries in the female are double also; and the aperture is very large, in order to receive the double instrument of the male. They copulate in their retreats; and it is said by the ancients, that, in this situation, they appear like one serpent with two heads: but how far this remark is founded in truth, I do not find any of the moderns that can resolve me.

As the body of this animal is long, slender, and capable of bending in every direction, the number of joints in the back-bone are numerous beyond what one would imagine. In the generality of quadrupeds, they amount to not above thirty or forty; in the serpent kind they amount to a hundred and forty-five from the head to the vent, and twenty-five more from that to the tail.[1] The number of these joints must give the back-bone a surprising degree of pliancy; but this is still increased by the manner in which each of these joints are locked into the other. In man and quadrupeds, the flat surfaces of the bones are laid one against the other, and bound tight by sinews: but in serpents, the bones play one within the other, like ball and socket, so that they have full motion upon each other in every direction.[2] Thus, if a man were to form a machine composed of so many joints as are found in the back of a serpent, he would find it no easy matter to give it such strength and pliancy at the same time. The chain of a watch is but a bungling piece of workmanship in comparison.

Though the number of joints in the back-bone is great, yet that of the ribs is still greater; for, from the head to the vent there are two ribs to every joint, which makes their number two hundred and ninety in all. These ribs are furnished with muscles, four in number; which being inserted into the head, run along to the end of the tail, and give the animal great strength and agility in all its motions.

The skin also contributes to its motions, being composed of a number of scales, united to each other by a transparent membrane, which grows harder as it grows older, until the animal changes, which is generally done twice a year. This cover then bursts near the head, and the serpent creeps from it, by an undulatory motion, in a new skin, much more vivid than the former. If the old slough be then viewed, every scale will be distinctly seen, like a piece of net-work, and will be found greatest where the part of the body they covered was largest.

There is much geometrical neatness in the disposal of the serpent's scales for assisting the animal's sinuous motion. As the edges of the foremost scales lie over the ends of their following scales, so those edges, when the scales are erected, which the animal has a power of doing in a small degree, catch in the ground, like the nails in the wheel of a chariot, and so promote and facilitate the animal's progressive motion. The erecting these scales is by means of a multitude of distinct muscles, with which each is supplied, and one end of which is tacked each to the middle of the foregoing.

In some of the serpent kind there is the exactest symmetry in these scales; in others, they are disposed more irregularly. In some, there are larger scales on the belly, and often answering to the number of ribs; in others, however, the animal is without them. Upon this slight difference Linnæus has founded his distinctions of the various classes of the serpent tribe. Human curiosity, however, and even human interest, seem to plead for a very different method of distribution. It is not the number of scales on a formidable animal's belly, nor their magnitude or variety, that any way excite our concern. The first question that every man will naturally ask, when he hears of a snake, is, whether it be large? the second, whether it be venomous? In other words, the strongest lines in the animal's history are those that first excite our attention; and these it is every historian's business to display.

When we come to compare serpents with each other, the first great distinction appears in their size; no other tribe of animals differing so widely in this particular. What, for instance, can be so remotely separated as the Great Liboya of Surinam, that grows to thirty-six feet long; and the Little Serpent, at the

[1] Vide Charat. Anatom. [2] Derham, p. 396.

Cape of Good Hope, and the north of the river Senegal, that is not above three inches, and covers whole sandy deserts with its multitudes! This tribe of animals, like that of fishes, seems to have no bounds put to their growth: their bones are, in a great measure, cartilaginous, and they are, consequently, capable of great extension: the older, therefore, a serpent becomes, the larger it grows; and as they seem to live to a great age, they arrive at an enormous size.

Leguat assures us, that he saw one in Java that was fifty feet long. Carli mentions their growing to above forty feet; and we have now the skin of one in the Museum, that measures thirty-two. Mr Wentwort, who had large concerns in the Berbices, in America, assures me, that in that country, they grow to an enormous length. He one day sent out a soldier, with an Indian, to kill wild fowl for the table; and they accordingly went some miles from the fort; in pursuing their game, the Indian, who generally marched before, beginning to tire, went to rest himself upon the fallen trunk of a tree, as he supposed it to be; but when he was just going to sit down, the enormous monster began to move, and the poor savage perceiving that he had approached a Liboya, the greatest of all the serpent kind, dropped down in an agony. The soldier, who perceived, at some distance, what had happened, levelled at the serpent's head, and, by a lucky aim, shot it dead: however, he continued his fire until he was assured that the animal was killed; and then going up to rescue his companion, who was fallen motionless by its side, he, to his astonishment, found him dead likewise, being killed by the fright. Upon his return to the fort, and telling what had happened, Mr Wentworth ordered the animal to be brought up, when it was measured, and found to be thirty-six feet long. He had the skin stuffed, and then sent to Europe, as a present to the Prince of Orange, in whose cabinet it is now to be seen at the Hague; but the skin has shrunk, by drying, two or three feet.

In the East Indies they grow also to an enormous size; particularly in the island of Java, where, we are assured, that one of them will destroy and devour a buffalo. In a letter, printed in the German Ephemerides, we have an account of a combat between an enormous serpent and a buffalo, by a person who assures us that he was himself a spectator. The serpent had, for some time, been waiting near the brink of a pool, in expectation of its prey; when a buffalo was the first that offered. Having darted upon the affrighted animal, it instantly began to wrap it round with its voluminous twistings; and, at every twist, the bones of the buffalo were heard to crack almost as loud as the report of a cannon. It was in vain that the poor animal struggled and bellowed; its enormous enemy entwined it too closely to get free; till, at length, all its bones being mashed to pieces, like those of a malefactor on the wheel, and the whole body reduced to one uniform mass, the serpent untwined its folds to swallow its prey at leisure. To prepare for this, and in order to make the body slip down the throat more glibly, it was seen to lick the whole body over, and thus cover it with its mucus. It then began to swallow it at that end that offered least resistance; while its length of body was dilated to receive its prey, and thus took in at once a morsel that was three times its own thickness. We are assured by travellers, that these animals are often found with the body of a stag in their gullet, while the horns, which they are unable to swallow, keep sticking out at their mouths.

But it is happy for mankind that the rapacity of these frightful creatures is often their punishment; for whenever any of the serpent kind have gorged themselves in this manner, whenever their body is seen particularly distended with food, they then become torpid, and may be approached and destroyed with safety. Patient of hunger to a surprising degree, whenever they seize and swallow their prey, they seem, like surfeited gluttons, unwieldly, stupid, helpless, and sleepy: they, at that time seek some retreat, where they may lurk for several days together, and digest their meal in safety: the smallest effort, at that time, is capable of destroying them; they can scarcely make any resistance; and they are equally unqualified for flight or opposition: that is the happy opportunity of attacking them with success; at that time the naked Indian himself does not fear to assail them. But it is otherwise when this sleepy interval of digestion is over: they then issue, with famished appetites, from their retreats, and with accumulated terrors, while every animal of the forest flies before them.

Carli describes the Long Serpent of Congo making its track through the tall grass, like mowers in a summer's day. He could not, without terror, behold whole lines of grass lying levelled under the sweep of its tail. In this manner it moved forward with great rapidity, until it found a proper situation frequented by its prey: there it continued to lurk, in patient expectation, and would have remained for weeks together, had it not been disturbed by the natives.

Other creatures have a choice in their provision; but the serpent indiscriminately preys upon all; the buffalo, the tiger, and the gazelle. One would think that the porcupine's quills might be sufficient to protect it; but whatever has life serves to appease the hun-

ger of these devouring creatures: porcupines, with all their quills, have frequently been found in their stomachs, when killed and opened; nay, they most frequently are seen to devour each other.

A life of savage hostility in the forest offers the imagination one of the most tremendous pictures in nature. In those burning countries, where the sun dries up every brook for hundreds of miles round; when what had the appearance of a great river in the rainy season, becomes, in summer, one dreary bed of sand —in those countries, I say, a lake that is never dry or a brook that is perennial, is considered by every animal as the greatest convenience of nature. As to food, the luxuriant landscape supplies that in sufficient abundance: it is the want of water that all animals endeavour to remove; and inwardly parched by the heat of the climate, traverse whole deserts to find out a spring. When they have discovered this, no dangers can deter them from attempting to slake their thirst. Thus the neighbourhood of a rivulet, in the heart of the tropical continents, is generally the place where all the hostile tribes of nature draw up for the engagement. On the banks of this little envied spot, thousands of animals of various kinds are seen venturing to quench their thirst, or preparing to seize their prey. The elephants are perceived, in a long line, marching from the darker parts of the forest; the buffaloes are there, depending upon numbers for security; the gazelles, relying solely upon their swiftness; the lion and tiger waiting a proper opportunity to seize; but chiefly the larger serpents are upon guard there, and defend the accesses of the lake. Not an hour passes without some dreadful combat; but the serpent, defended by its scales, and naturally capable of sustaining a multitude of wounds, is, of all others, the most formidable. It is the most wakeful also; for the whole tribe sleep with their eyes open, and are, consequently, for ever upon the watch: so that, till their rapacity is satisfied, few other animals will venture to approach their station.

But though these animals are, of all others, the most voracious, and though the morsel which they swallow without chewing is greater than what any other creature, either by land or water, the whale itself not excepted, can devour, yet no animals upon earth bear abstinence so long as they. A single meal, with many of the snake kind, seems to be the adventure of a season; it is an occurrence for which they have been for weeks, nay, sometimes for months, in patient expectation of. When they have seized their prey, their industry, for several weeks, is entirely discontinued; the fortunate capture of an hour often satisfies them for the remaining period of their annual activity. As their blood is colder than that of most other terrestrial animals, and as it circulates but slowly through their bodies, so their powers of digestion are but feeble. Their prey continues for a long time, partly in the stomach, partly in the gullet, and a part is often seen hanging out of the mouth. In this manner, it digests by degrees; and in proportion as the part below is dissolved, the part above is taken in. It is not therefore, till this tedious operation is entirely performed that the serpent renews its appetite and its activity. But should any accident prevent it from issuing once more from its cell, it still can continue to bear famine for weeks, months, nay, for years together. Vipers are often kept in boxes for six or eight months without any food whatever; and there are little serpents sometimes sent over to Europe from Grand Cairo, the name of which I have not been able to learn, that live, for several years, in glasses, and never eat at all, nor even stain the glass with their excrements. Thus the serpent tribe unite, in themselves, two very opposite qualities: wonderful abstinence, and yet incredible rapacity.

If, leaving the consideration of their appetites, we come to compare serpents, as to their voices, some are found silent, some have a peculiar cry; but hissing is the sound which they most commonly sent forth, either as a call to their kind, or as a threat to their enemies. In the countries where they abound, they are generally silent in the middle of the day, when they are obliged to retire from the heat of the climate; but as the cool of the evening approaches, they are then heard issuing from their cells with continued hissings; and such is the variety of their notes, that some have assured me they very much resemble the music of an English grove. This some will hardly credit—at any rate, such notes, however pleasing, can give but very little delight, when we call to mind the malignity of the minstrel. If considered, indeed, as they answer the animal's own occasions, they will be found well adapted to its nature, and fully answering the purposes of terrifying such as would venture to offend it.

With respect to motion, some serpents, particularly those of the viper kind, move slowly; while others, such as the Ammodytes, dart with amazing swiftness. The motion in all is similar; but the strength of body in some gives a very different appearance. The viper, that is but a slow feeble-bodied animal, makes way in a heavy undulating manner; advancing its head, then drawing up its tail behind, and bending the body into a bow; then, from the spot where the head and tail were united, advancing the head forward as before. This, which is the motion of all

serpents, is very different from that of the earth-worm, or the naked snail. The serpent, as was said above, has a back-bone with numerous joints, and this bone the animal has a power of bending in every direction, but without being able to shorten or lengthen it at pleasure. The earth-worm, on the other hand, has no back-bone; but its body is composed of rings, which, like a barber's puff, it can lengthen or shorten as it finds necessary. The earth-worm, therefore, in order to move forward, lengthens the body; then, by the fore part clings to the ground, where it has reached, and then contracts and brings up its rear: then, when the body is thus shortened, the fore part is lengthened again for another progression; and so on. The serpent, instead of shortening the body, bends it into an arch; and this is the principal difference between serpentine and vermicular progression.

I have instanced this motion in the viper, as most easily discerned; but there are many serpents that dart with such amazing swiftness, that they appear rather to leap than crawl. It is most probable, however, that no serpent can dart upon even ground farther than its own length at one effort. Our fears, indeed, may increase the force of their speed, which is sometimes found so fatal. We are told by some, that they will dart to a very great distance; but this my inquiries have never been able to ascertain. The manner of progression in the swiftest serpent we know, which is the jacalus, is by instantly coiling itself upon its tail, and darting from thence to its full extent; then carrying the tail as quick as lightning to the head, coiling and darting again; and by this means proceeding with extreme rapidity, without ever quitting the ground. Indeed, if we consider the length and the weakness of the back-bone in all these animals; if we regard the make of their vertebræ, in which we shall find the junctures all formed to give play, and none to give power; we cannot be of opinion that they have a faculty of springing from the ground, as they entirely want a *fulcrum*, if I may so express it, from whence to take their spring; the whole body being composed of unsupported muscles and joints that are yielding. It must be confessed, that they dart down from trees upon their prey; but their weight alone is sufficient for that purpose without much effort of their own.

Though all serpents are amphibious, some are much fonder of the water than others; and, though destitute of fins or gills, remain at the bottom, or swim along the surface with great ease. From their internal structure, just sketched above, we see how well adapted they are for either element; and how capable their blood is of circulating at the bottom, as freely as in the frog or the tortoise. They can, however, endure to live in fresh-water only; for salt is an effectual bane to the whole tribe. The greatest serpents are most usually found in fresh-water, either choosing it as their favourite element, or finding their prey in such places in the greatest abundance. But that all will live and swim in liquids appears from the experiment of Rhedi; who put a serpent into a large glass vessel of wine, where it lived swimming about six hours; though, when it was by force, immersed and kept under that liquid, it lived only one hour and a half. He put another in common water, where it lived three days; but when it was kept under water, it lived only about twelve hours.[1] Their motion there, however, is perfectly the reverse of what it is upon land; for, in order to support themselves upon an element lighter than their bodies, they are obliged to increase their surface in a very artificial manner. On earth their windings are perpendicular to the surface; in water they are parallel to it; in other words, if I should wave my hand up and down, it will give an idea of the animal's progress on land; if I should wave it to the right and left, it will give some idea of its progress on the water.

Some serpents have a most horrible fœtor attending them, which is alone capable of intimidating the brave. This proceeds from two glands near the vent, like those in the weasel or polecat; and, like those animals, in proportion as they are excited by rage, or by fear, the scent grows stronger. It would seem, however, that such serpents as are most venomous, are least offensive in this particular; since the rattlesnake and the viper have no smell whatever: nay, we are told that at Calicut and Cranganon, in the East Indies, there are some very noxious serpents who are so far from being disagreeable, that their excrements are sought after, and kept as the most pleasing perfume. The Esculapian Serpent is also of this number.

Some serpents bring forth their young alive, as the viper; some bring forth eggs, which are hatched by the heat of their situation: as the common black snake, and the majority of the serpent tribe. When a reader, ignorant of anatomy, is told, that some of those animals produce their young alive, and that some produce eggs only, he is apt to suppose a very great difference in the internal conformation, which makes such a variety in the manner of bringing forth. But this is not the case: these animals are internally alike, in whatever manner they produce their young; and the variety in their bringing forth is rather a slight, than a real discrimination. The only difference is, that the viper hatches her eggs, and brings them to maturity within her body;

[1] Rhedi, Exper. p. 170.

the snake is more premature in her productions, and sends her eggs into the light some time before the young ones are capable of leaving the shell. Thus, if either are opened, the eggs will be found in the womb, covered with their membranous shell, and adhering to each other like large beads on a string. In the eggs of both, young ones will be found, though at different stages of maturity: those of the viper will crawl and bite the moment the shell that incloses them is broke open; those of the snake are not yet arrived at their perfect form.

Father Labat took a serpent of the viper kind, that was nine feet long, and ordered it to be opened in his presence. He then saw the manner in which the eggs of these animals lie in the womb. In this creature there were six eggs, each of the size of a goose egg, but longer, more pointed, and covered with a membranous skin, by which also they were united to each other. Each of these eggs contained from thirteen to fifteen young ones, about six inches long, and as thick as a goose-quill. Though the female from whence they were taken was spotted, the young seemed to have a variety of colours very different from the parent; and this led the traveller to suppose that the colour was no characteristic mark among serpents. These little mischievous animals were no sooner let loose from the shell than they crept about, and put themselves into a threatening posture, coiling themselves up, and biting the stick with which he was destroying them. In this manner he killed seventy-four young ones; those that were contained in one of the eggs escaped at the place where the female was killed, by the bursting of the egg, and their getting among the bushes.

The last distinction that I shall mention, but the most material among serpents, is, that some are venomous, and some inoffensive. If we consider the poison of serpents as it relates to man, there is no doubt but that it is a scourge and an affliction. The various calamities that the poison of serpents is capable of producing, are not only inflicted by the animal itself, but by men, more mischievous than even serpents, who prepare their venom to destroy each other. With this the savages poison their arms, and also prepare their revengeful potions. The ancients were known to preserve it for the purposes of suicide; and even among semi-barbarous countries at this day, the venom of snakes is used as a philtre.

But, though the poison be justly terrible to us, it has been given to very good purposes for the animal's own proper support and defence. Without this, serpents, of all other animals, would be the most exposed and defenceless; without feet for escaping a pursuit; without teeth capable of inflicting a dangerous wound, or without strength for resistance; incapable, from their size, of finding security in very small retreats, like the earth-worm, and disgusting all from their deformity, nothing was left for them but a speedy extirpation. But furnished as they are with powerful poison, every rank of animals approach them with dread, and never seize them but at an advantage. Nor is this all the advantage they derive from it. The malignity of a few serves for the protection of all. Though not above a tenth of their number are actually venomous, yet the similitude they all bear to each other excites a general terror of the whole tribe; and the uncertainty of their enemies in which the poison chiefly resides, makes even the most harmless formidable.—Thus providence seems to have acted with double precaution; it has given some of them poison, for the general defence of a tribe naturally feeble; but it has thinned the numbers of those which are venomous, lest they should become too powerful for the rest of animated nature.

From these noxious qualities in the serpent kind, it is no wonder that not only man, but the beasts and birds, carry on an unceasing war against them. The ichneumon of the Indians, and the peccary of America, destroy them in great numbers. These animals have the art of seizing them near the head; and it is said that they can skin them with great dexterity. The vulture and the eagle also prey upon them in great abundance; and often sousing down from the clouds, drop upon a long serpent, which they snatch up struggling and writhing in the air. Dogs are also bred up to oppose them. Father Feuille tells us, that being in the woods of Martinico, he was attacked by a large serpent, which he could not easily avoid, when his dog immediately came to his relief, and seized the assailant with great courage. The serpent entwined him, and pressed him so violently, that the blood came out of his mouth, and yet the dog never ceased till he had torn it to pieces. The dog was not sensible of his wounds during the fight; but soon after his head swelled prodigiously, and he lay on the ground as dead. But his master having found hard by a banana-tree, he applied its juice, mixed with treacle, to the wounds, which recovered the dog, and quickly healed his sores.

But it is in man that these venomous creatures find the most dangerous enemy. The Psylli of old were famous for charming and destroying serpents. Some moderns pretend to the same art. Casaubon says, that he knew a man who could at any time summon a hundred serpents together, and draw them into the fire. Upon a certain occasion, when one of them, bigger than the rest, would not be brought in, he only repeated his charm, and it came forward like the rest, to submit

to the flames. Philostratus describes particularly how the Indians charm serpents. "They take a scarlet robe, embroidered with golden letters, and spread it before a serpent's hole. The golden letters have a fascinating power; and, by looking steadfastly, the serpent's eyes are overcome and laid asleep." These, and many other feats have been often practised upon these animals by artful men, who had first prepared the serpents for their exercise, and then exhibited them as adventitiously assembled at their call. In India there is nothing so common as dancing serpents, which are carried about in a broad flat vessel, somewhat resembling a sieve. These erect and put themselves in motion at the word of command. When their keeper sings a slow tune, they seem by their heads to keep time; when he sings a quicker measure, they appear to move more brisk and lively. All animals have a certain degree of docility; and we find that serpents themselves can be brought to move and approach at the voice of their master. From this trick, successfully practised before the ignorant, it is most probable has arisen all the boasted pretensions which some have made to charming of serpents; an art to which the native Americans pretend at this very day. One of Linnæus's pupils, we are told, purchased the secret from an Indian, and then discovered it to his master; but, like all secrets of the kind, it is probable this ended in a few unmeaning words of no efficacy.[1]

Though the generality of mankind regard this formidable race with horror, yet there have been some nations, and there are some at this day, that consider them with veneration and regard. The adoration paid by the ancient Egyptians to a serpent is well known: many of the nations at present along the western coast of Africa retain the same unaccountable veneration. Upon the Gold and Slave coasts, a stranger, upon entering the cottages of the natives, is often surprised to see the roof swarming with serpents, that cling there without molesting, and unmolested by the natives. But his surprise will increase upon going farther southward to the kingdom of Widah, when he finds that a serpent is the god of the country. This animal, which travellers describe as a huge overgrown creature, has its habitation, its temple, and its priests. These impress the vulgar with an opinion of its virtues; and numbers are daily seen to offer not only their goods, their provisions, and their prayers, at the shrine of

[1] The *incantation of serpents* is one of the most curious and interesting facts in natural history. This wonderful art, which disarms the fury, and soothes the wrath of the deadliest snake, and renders it obedient to the charmer's voice, is not an invention of modern times; for we discover manifest traces of it in the remotest antiquity. It is asserted, that Orpheus, who probably flourished soon after letters were introduced into Greece, knew how to still the hissing of the approaching snake, and to extinguish the poison of the creeping serpent. The Argonauts are said to have subdued by the power of song, the terrible dragon that guarded the golden fleece; and Ovid ascribes the same effect to the soporific influence of certain herbs, and magic sentences. It was the custom of others to fascinate the serpent, by touching it with the hand. Of this method Virgil takes notice, in the seventh book of the Ænead. But it seems to have been the general persuasion of the ancients, that the principal power of the charmer lay in the sweetness of the music. Pliny says, accordingly, that serpents were drawn from their lurking-places by the power of music. Seneca held the same opinion.

The wonderful effect which music produces on the serpent tribes is confirmed by the testimony of several respectable moderns. Adders swell at the sound of a flute, raising themselves up on the one half of their body, turning themselves round, beating proper time and following the instrument. Their head, naturally round and long like an eel, becomes broad and flat like a fan. The tame serpents, many of which the Orientals keep in their houses, are known to leave their holes in hot weather, at the sound of a musical instrument, and to run upon the performer. Dr Shaw had an opportunity of seeing a number of serpents keep exact time with the dervishes in their circulating dances, running over their heads and arms, turning when they turned, and stopping when they stopped.

The rattle snake acknowledges the power of music as much as any of his family; of which the following instance is a decisive proof. When Chateaubriand was in Canada, a snake of this species entered their encampment; a young Canadian, one of the party who could play on the flute, to divert his associates, advanced against the serpent with his new species of weapon. "On the approach of his enemy, the haughty reptile curled himself into a spiral line, flattened his head, inflated his cheeks, contracted his lips, displayed his envenomed fangs, and his bloody throat; his double tongue glowed like two flames of fire; his eyes were burning coals; his body, swoln with rage, rose and fell like the bellows of a forge; his dilated skin assumed a dull and scaly appearance, and his tail, which sounded the denunciation of death, vibrated with so great rapidity, as to resemble a light vapour. The Canadian now began to play upon his flute; the serpent started with surprise, and drew back his head. In proportion as he was struck with the magic effect, his eyes lost their fierceness, the oscillations of his tail became slower, and the sound which it emitted became weaker, and gradually died away. Less perpendicular upon their spiral line, the rings of the fascinated serpent were by degrees expanded, and sunk one after another upon the ground in concentric circles. The shades of azure green, white, and gold, recovered their brilliancy on his quivering skin, and slightly turning his head, he remained motionless in the attitude of attention and pleasure. At this moment the Canadian advanced a few steps, producing with his flute sweet and simple notes. The reptile inclining his variegated neck, opened a passage with his head through the high grass, and began to creep after the musician, stopping when he stopped, and beginning to follow him again as soon as he moved froward." In this manner he was led out of the camp, attended by a great number of spectators, both savages and Europeans, who could scarcely believe their eyes, when they beheld this wonderful effect of harmony. The assembly unanimously decreed, that the serpent which had so highly entertained them, should be permitted to escape.—*Natural History of the Bible.*

their hideous deity, but also their wives and daughters.—These the priests readily accept of, and after some days of penance, return them to their suppliants, much benefited by the serpent's supposed embraces. Such a complicated picture of ignorance and imposture gives no very favourable impressions of our fellow-creatures; but we may say, in defence of human nature, that the most frightful of reptiles is worshipped by the most uncultivated and barbarous of mankind.

From this general picture of the serpent tribe, one great distinction obviously presents itself; namely, into those that are venomous, and those that are wholly destitute of poison. To the first belong the viper, the rattle-snake, the cobra di capello, and all their affinities; to the other, the common black snake, the liboya, the boiguacu, the amphisbæna, and various others, that, though destitute of venom, do not cease to be formidable. I will, therefore, give their history separately, beginning with the venomous class, as they have the strongest claims to our notice and attention.

CHAP. II.

OF VENOMOUS SERPENTS IN GENERAL.

The poison of serpents has been for ages one of the greatest objects of human consideration. To us, who seldom feel the vengeful wound, it is merely a subject of curiosity; but to those placed in the midst of the serpent tribe, who are every day exposed to some new disaster, it becomes a matter of the most serious importance. To remedy the bite of a serpent is considered, among our physicians, as one of the slightest operations in medicine: but among the physicians of the East, the antidotes for this calamity make up the bulk of their dispensaries. In our colder climates, the venom does not appear with that instantaneous operation which it exhibits in the warmer regions; for either its powers are less exquisite, or our fluids are not carried round in such rapid circulation.

In all countries, however, the poison of the serpent is sufficiently formidable to deserve notice, and to excite our attention to its nature and effects. It will, therefore, in the first place, be proper to describe its seat in the animal, as also the instrument by which the wound is made, and the poison injected. In all this venomous class of reptiles, whether the viper, the rattle-snake, or the cobra di capello, there are two large teeth or fangs that issue from the upper jaw, and that hang out beyond the lower. The rest of the snake tribe are destitute of these; and it is most probable that wherever these fangs are wanting, the animal is harmless; on the contrary, wherever they are found it is to be avoided as the most pestilent enemy. These are the instruments that seem to place the true distinction between animals of the serpent kind; the wounds which these fangs inflict produce the most dangerous symptoms; the wounds inflicted by the teeth only are attended with nothing more than the ordinary consequences attending the bite of any other animal. Our first great attention, therefore, upon seeing a serpent, should be directed to the teeth. If it has the fang teeth, it is to be placed among the venomous class; if it wants them, it may be set down as inoffensive. I am not ignorant that many serpents are said to be dangerous whose jaws are unfurnished with fangs; but it is most probable that our terrors only have furnished these animals with venom; for of all the tribe whose teeth are thus formed, not one will be found to have a bag for containing poison, nor a conduit for injecting it into the wound. The Black Snake, the Liboya, the Blind Worm, and a hundred others that might be mentioned, have their teeth of an equal size, fixed into the jaws, and with no other apparatus for inflicting a dangerous wound than a dog or a lizard: but it is otherwise with the venomous tribe we are now describing; these are well furnished, not only with an elaboratory where the poison is formed, but a canal by which it is conducted to the jaw, a bag under the tooth for keeping it ready for every occasion, and also an aperture in the tooth itself for injecting it into the wound. To be more particular: the glands that serve to fabricate this venomous fluid are situated on each side of the head behind the eyes, and have their canals leading from thence to the bottom of the fangs in the upper jaw, where they enter into a kind of bladder, from whence the fangs on each side are seen to grow. The venom contained in this bladder is a yellowish thick tasteless liquor, which injected into the blood is death, yet which may be swallowed without any danger.

The fangs that give the wound come next under observation; they are large in proportion to the size of the animal that bears them; crooked, yet sharp enough to inflict a ready wound. They grow one on each side, and sometimes two, from two movable bones in the upper jaw, which by sliding backward or forward, have a power of erecting or depressing the teeth at pleasure. In these bones are also fixed many teeth, but no way venomous, and only serving to take and hold the animal's prey. Besides this apt disposition of the fangs, they are hollow within and have an opening towards the point, like the slit of a pen, through which, when the fang is pressed

down upon the bladder where it grows, there is seen to issue a part of the venom that lay below. To describe this operation at once: when the serpent is irritated to give a venomous wound, it opens its formidable jaws to the widest extent; the movable bones of the upper jaw slide forward; the fangs that lay before inclining are thus erected; they are struck with force into the flesh of the obnoxious person; by meeting resistance at the points, they press upon the bladders of venom from whence they grow; the venom issues up through the hollow of the tooth, and is pressed out through its slit into the wound, which by this time the tooth has made in the skin. Thus from a slight puncture, and the infusion of a drop of venom scarcely larger than the head of a pin, the part is quickly inflamed, and, without a proper antidote, the whole frame contaminated.

The appearance which this venom produces are different, according to the serpent that wounds, or the season, or the strength of the animal that strikes the blow. If a viper inflicts the wound, and the remedy be neglected, the symptoms are not without danger. It first causes an acute pain in the place affected, attended with a swelling, first red, and afterwards livid. This by degrees spreads to the neighbouring parts; great faintness, and a quick, though low and interrupted, pulse ensues; to this succeed great sickness at the stomach, bilious and convulsive vomitings, cold sweats, pains about the navel, and death itself. But the violence of these symptoms depends much on the season of the year, the difference of the climate, the size or rage of the animal, and the depth and situation of the wound. These symptoms are much more violent, and succeed each other more rapidly, after the bite of a rattle-snake; but when the person is bit by the cobra di capello, he dies in an hour, his whole frame being dissolved into a putrid mass of corruption.

Nothing surely can more justly excite our wonder, than that so small a quantity of venom should produce such powerful and deadly effects. If the venom itself be examined through a microscope, it will be found to shoot into little crystals, that, to an imagination already impressed with its potency, look like so many darts fit for entering the blood-vessels, and wounding their tender coats. But all these darts are wholly of our own making: the softest, mildest fluid whatever, possessed of any consistency, will form crystals under the eye of the microscope, and put on an appearance exactly like the venom of the viper. In fact, this venom has no acrid taste whatever; and to all experiments that our senses can make upon it, appears a slimy insipid fluid. Charas, who often tasted it, assures us of the fact; and asserts, that it may be taken inwardly without any sensible effects, or any prejudice to the constitution. But the famous experiments that were tried by Rhedi and others in the presence of the Great Duke of Tuscany and his court, put this beyond any doubt whatsoever. By these it appeared, that the serpent having once bitten exhausted for that time the greatest part of its poison; and though the wound caused by its biting a second time was attended with some malignant symptoms, yet they were much milder than before. It appeared that the serpent biting upon a sponge, or a piece of soft bread, and then biting a dog immediately after, did not inflict a wound more dangerous than the prick of a needle. It appeared that the venom being collected, and a needle dipped therein, this produced almost as painful effects as the tooth of the animal itself. But what caused the greatest surprise in the court was, the seeming rashness of one Tozzi, a viper-catcher; who while the philosophers were giving elaborate lectures on the danger of the poison when taken internally, boldly desired a large quantity of it might be put together; and then, with the utmost confidence, drank it off before them all. The court was struck with astonishment, and expected that the man would instantly fall dead; but they soon perceived their mistake, and found that taken in this manner, the poison was as harmless as water; so true is that famous passage of Lucan,

> Noxia serpentum est admixto sanguine pestis:
> Morsu virus habent, et fatum in dente minantur:
> Pocula morte carent.

What then shall we say to the speedy effect of so seemingly harmless a liquid taken into the circulation? Let us first observe, that milk is one of the most mild and nourishing of all fluids, and seemingly the most friendly to the human constitution; yet if milk be injected into a vein, it will quickly become fatal, and kill with more certain destruction than even the venom of the viper. From hence then we may infer, that the introducing not only the serpentine venom, but also a quantity of any other mixture, into the circulation, will be fatal; and that, consequently, serpents kill as well by their power of injecting the wound as by the potency of their poison. Some indeed may inject a more acrimonious mixture, and this may produce more speedy effects; but any mixture thus injected would be dangerous, and many would be fatal.

Ray gives us an instance of the potency of the serpent-poison; which, though it has all the air of a fable, I cannot help transcribing. "A gentleman who went over to the East Indies, while he was one day sitting among some friends, was accosted by an Indian juggler, who offered to show him some experiments respecting the venom of serpents; an ex-

hibition usual enough in that country. Having first, therefore, produced a large serpent, he assured the company that it was harmless; and to convince them of what he said, he tied up his arm, as is usual with those who are going to be bled, and whipped the serpent till it was provoked to bite him. Having drawn in this manner about half a spoonful of blood from his arm, he put the congealed clot upon his thigh. He then took out a much smaller serpent, which was no other than the cobra di capello; and having tied up his neck, he procured about half a drop of its venom, which he sprinkled on the clot of blood on his thigh, which instantly began to ferment and bubble, and soon changed colour from a red into a yellow."

This he pretended was caused by the extreme malignity of that animal's venom: however, I have no doubt that the whole is either a fable, or a trick of the Indian; who, while he seemed to mix the serpent's venom, actually infused some stronger ingredient, some mineral acid, into the mass of blood, which was capable of working such a change. It cannot be supposed that any animal poison could act so powerfully upon the blood already drawn and coagulated; for a poison that could operate thus instantaneously upon cold blood, could not fail of soon destroying the animal itself.

Be this as it will, the effects of serpent-poison are but too well known, though the manner of operation be not so clear. As none of this malignant tribe grow to a great size, the longest of them not exceeding nine feet, they seldom seek the combat with larger animals, or offend others till they are first offended. Did they exert their malignity in proportion to their power, they could easily drive the ranks of Nature before them; but they seem unconscious of their own superiority, and rather fly than offer to meet the meanest opposer. Their food chiefly consists of small prey, such as birds, moles, toads, and lizards; so that they never attack the more formidable animals, that would seldom die unrevenged. They lurk therefore in the clefts of rocks, or among stony places; they twine round the branches of trees, or sun themselves in the long grass at the bottom. There they only seek repose and safety. If some unwary traveller invades their retreats, their first effort is to fly; but when either pursued or accidentally trod upon, they then make a fierce and fatal resistance. For this purpose they raise themselves according to their strength upon their tail, erect the head, seize the limb that presses them, the wound is given, and the head withdrawn in a moment. It is not therefore without reason, that the Asiatics, who live in regions where serpents greatly abound, wear boots and long clothes, which very well protect their lower parts from the accidental resentment of their reptile annoyers.

In the eastern and western Indies, the numbers of noxious serpents are various; in this country we are acquainted only with one.[1] The viper is the only animal in Great Britain from whose bite we have any thing to fear. In the tropical climates, the rattlesnake, the whip-snake, and the cobra di capello, are the most formidable, though by no means the most common, From the general notoriety of those particular serpents, and the universal terror which they occasion, it would seem that few others are possessed of such powerful malignity.

Vipers are found in many parts of this island; but the dry, stony, and particularly the chalky countries, abound with them.[2] This animal

---

[1] It is a curious fact, that since the introduction of sheep farming into the Highlands of Scotland, the number of vipers has greatly diminished there. This is owing to the flocks of sheep trampling them to death as they go along. Formerly the viper used to be very destructive to cattle, by biting them in the udder as they lay down: from this the sheep are protected by their wool.

[2] *Common Viper* or *Adder.*—The *Common Viper* is

happily the sole British representative of any of the poisonous groups of Serpents, and indeed the only poisonous reptile indigenous to this country. It is far more numerous in Scotland than the Common Snake, and is found in abundance in all parts of England and Wales, frequenting heaths, dry woods, and banks. In Ireland it has never been seen; and it may, almost with certainty, be stated that it does not exist there. On the continent of Europe it is extensively distributed, being found from the northern parts of Russia to the south of Italy and Spain. It is everywhere deservedly feared on account of its venom, which, although less virulent than that of many other species, is yet sufficiently so to produce severe symptoms, and sometimes, in the warmer climates, even fatal results. In this country I have never seen a case which terminated in death, nor have I been able to trace to an authentic source any of the numerous reports of such a termination, which have at various times been confidently promulgated. At the same time the symptoms are frequently so threatening, that I cannot but conclude that in very hot weather, and when not only the reptile is in full activity and power, but the constitution of the victim in a state of great irritability and diminished power, a bite from the Common Viper would very probably prove fatal. The remedies usually employed are the external application of oil, and the internal administration of ammonia.

The poisonous fluid is perfectly innocuous when swallowed. Dr Mead, and others, have made this experiment, and never experienced the slightest ill effects from it. It is, however, clear that there would be danger in swallowing it, were any part of the mouth, the throat, or the œsophagus, in a state of ulceration, or having an abraded surface.

It will not perhaps be wholly uninteresting to describe briefly the very beautiful apparatus by which the poison wounds are inflicted, which render these, and so many other serpents, so formidable. On each side of

seldom grows to a greater length than two feet; though sometimes they are found above three. The ground colour of their bodies is a dirty yellow; that of the female is deeper. The back is marked the whole length with a series of rhomboid black spots, touching each other at the points; the sides with triangular ones; the belly entirely black. It is chiefly distinguished from the common black snake by the colour, which in the latter is more beautifully mottled, as well as by the head, which is thicker than the body; but particularly by the tail, which in the viper, though it ends in a point, does not run tapering to so great a length as in the other. When, therefore, other distinctions fail, the difference of the tail can be discerned at a single glance.

The viper differs from most other serpents in being much slower, as also in excluding its young completely formed, and bringing them

---

the upper jaw, instead of the outer row of teeth which are found, in nonvenomous serpents, there exist two or three, or more, long, curved, and tubular teeth, the first of which is larger than the others, and is attached to a small movable bone, articulated to the maxillary bone, and moved by a muscular apparatus, by which the animal has the power of erecting it. In a state of rest the fang reclines backwards along the margin of the jaw, and is covered by a fold of skin; but when about to be called into use, it is erected by means of a small muscle, and brought to stand perpendicular to the bone. The tooth itself is as it were perforated by a tube, the mode of formation of which was not understood until it was demonstrated by Mr Smith in the Philosophical Transactions for 1818. This tube, although completely enclosed, excepting at its basal and apical orifices, must be considered as formed merely by the closing round of a groove in the external part of the tooth itself, and hence not in any way connected with the inner cavity of the tooth, in which exists the pulp upon which the substance of the tooth is formed. The base of the tooth, and consequently the basal orifice of the tube just described, is embedded in a sac, into which the poison is poured from the ducts of the glandular structure by which it is secreted, and which is believed to represent the parotid gland of the higher vertebrata. The poisonous fluid itself is indorous, tasteless, and of a yellow colour. It is secreted in greater quantity, and its qualities are more virulent in a high temperature than in cold. Its secretion may be greatly increased by local irritation; as is evidenced by the following fact. Some years since I was dissecting very carefully and minutely the poison apparatus of a large rattlesnake, which had been dead for some hours; the head had been taken off immediately after death; yet as I continued my dissection the yellow poison continued to be secreted so fast as to require to be occasionally dried off with a bit of rag or sponge; I believe that there could not have been less altogether than six or eight drops at the least.

When the animal inflicts the wound, the pressure on the tooth forces a small drop of the poison through the tube; it passes through the external orifice, which is situated on the concave side of the curved tooth, and is in the form of a slit. The manner in which the blow is inflicted is as follows. The animal generally throws itself in the first place into a coil more or less close, and the anterior part of the body is raised. The neck is bent somewhat abruptly backwards, and the head fixed almost horizontally. In an instant the head is, as it were, launched by a sudden effort towards the object of its anger, and the erected tooth struck into it, and withdrawn with the velocity of thought. It is found by experiment that the effect of subsequent wounds is greatly diminished either by the diminution of the quantity of venom, or by some deterioration of its strength; so that if a venomous serpent be made repeatedly to inflict wounds, without allowing sufficiently long intervals for it to recover its powers, each successive bite becomes less and less effective. A gentleman of my acquaintance had some years since received a living rattlesnake from America. Intending to try the effects of its bite upon some rats, he introduced one of these animals into the cage with the serpent; it immediately struck the rat, which died in two minutes. Another rat was then placed in the cage; it ran to the part of the cage furthest from the serpent, uttering cries of distress. The snake did not immediately attack it; but after about half an hour, and on being irritated, it struck the rat, which did not exhibit any symptoms of being poisoned for several minutes, and died at twenty minutes after the bite. A third, and remarkably large rat, was then introduced into the cage. It exhibited no signs of terror at its dangerous companion, which, on its part, appeared to take no notice of the rat. After watching for the rest of the evening, my friend retired, leaving the serpent and the rat together; and on rising early the next morning to ascertain the fate of his two heterogeneous prisoners, he found the snake dead, and the muscular part of its back eaten by the rat. I do not remember at what time of the year this circumstance took place, but I believe it was not during very hot weather.

Although there is no reason to believe that the viper employs this powerful means of destruction for the purpose of disabling its prey before it is finally seized; but, on the contrary, all the observations which have been made upon its mode of feeding, tend to show that, like the snake, it seizes its prey at once, and immediately begins to swallow it; yet it is not at all improbable, considering how instantaneously the poison begins to affect small animals, that even in the act of seizing a mouse or bird, or any other victim, it may instil a sufficient quantity of venom into its system to paralyze and presently destroy it. Still the action by which it takes its prey is very different from that which it employs in its defensive attack, and resembles that employed by the innocuous tribes. Its favourite food consists of the smaller mammalia, field-mice, shrews, and similar little animals, of frogs also, though less commonly, and occasionally of birds. It does not always confine its voracity within the limits of its powers of deglutition; for I have in my possession a specimen of a small viper which was taken on Poole Heath in Dorsetshire, in a dying state, in the act of attempting to swallow a mouse which was too large for it, the skin of the neck being so distended as to have burst in several places.

The viper, like the other reptilia, seeks a secret and secure place in which to hibernate during the cold months of the year. Here several are found entwined together, and in a very torpid condition; and if at this period a viper be made to wound an animal with its poison-fang, no injury is likely to result from it; the poison either does not exist at all, or it is inert.

It frequents dry sandy heaths and waste places, not requiring, like the snake, the neighbourhood of water, nor swimming so readily as that species. In many parts of the country it is even more common than the snake.

The name Adder, by which it is known in many parts of England and Scotland, is anciently written *nedre*, and afterwards *eddre*, the initial *n* being dropped. It is from the Anglo Saxon *nædre*,—neither, lower,—from its creeping position, and the name was applied to all the Serpent tribe. The word Viper, Latin *Vipera*, is derived from its viviparous habit.—*Bell's British Reptiles.*

forth alive. The kindness of Providence seems exerted, not only in diminishing the speed, but also the fertility, of this dangerous creature. They copulate in May, and are supposed to be about three months before they bring forth, and have seldom above eleven eggs at a time. These are of the size of a blackbird's egg, and chained together in the womb like a string of beads. Each egg contains from one to four young ones; so that the whole of a brood may amount to about twenty or thirty. They continue in the womb till they come to such perfection as to be able to burst from their shell; and they are said by their own efforts to creep from their confinement into the open air, where they continue for several days without taking any food whatsoever. "We have been assured," says Mr Pennant, "by intelligent people, of the truth of a fact, that the young of the viper, when terrified, will run down the throat of the parent and seek shelter in its belly, in the same manner as the young of the opossum retire into the ventral pouch of the old ones. From this," continues he, "some have imagined, that the viper is so unnatural as to devour its own young; but this deserves no credit, as these animals live upon frogs, toads, lizards, and young birds, which they often swallow whole, though the morsel is often three times as thick as their own body."

The viper is capable of supporting very long abstinence, it being known that some have been kept in a box six months without food; yet during the whole time they did not abate of their vivacity. They feed only a small part of the year, but never during their confinement; for if mice, their favourite diet, should at that time be thrown into their box, though they will kill, yet they will never eat them. When at liberty, they remain torpid throughout the winter; yet, when confined, have never been observed to take their annual repose. Their poison, however, decreases in proportion to the length of their confinement; and it is thought that the virtues of the animal's flesh, are, by the same restraints, considerably lessened.

They are usually taken with wooden tongs, by the end of the tail, which may be done without danger; for, while held in that position, they are unable to wind themselves up to hurt their enemy: yet, notwithstanding this precaution, the viper-catchers are frequently bit by them; but, by the application of salad oil, the bite is effectually cured.

One William Oliver, a viper-catcher at Bath, was the first who discovered this admirable remedy. On the first of June, 1735, in the presence of a great number of persons, he suffered himself to be bit by an old black viper, (brought by one of the company,) upon the wrist and joint of the thumb of the right hand, so that drops of blood came out of the wounds: he immediately felt a violent pain, both at the top of his thumb and up his arm, even before the viper was loosened from his hand; soon after he felt a pain, resembling that of burning, trickle up his arm; in a few minutes his eyes began to look red and fiery, and to water much; in less than an hour he perceived the venom seize his heart, with a pricking pain, which was attended with faintness, shortness of breath, and cold sweats; in a few minutes after this, his belly began to swell, with great gripings, and pains in his back, which were attended with vomitings and purgings: during the violence of these symptoms, his sight was gone for several minutes, but he could hear all the while. He said, that in his former experiments he had never deferred making use of his remedy longer than he perceived the effects of the venom reaching his heart; but this time, being willing to satisfy the company thoroughly, and trusting to the speedy effects of his remedy, which was nothing more than olive-oil, he forbore to apply any thing till he found himself exceeding ill and quite giddy. About an hour and a quarter after the first of his being bit, a chafing dish of glowing charcoal was brought in, and his naked arm was held over it, as near as he could bear, while his wife rubbed in the oil with her hand, turning his arm continually round, as if she would have roasted it over the coals: he said the poison soon abated, but the swelling did not diminish much. Most violent purgings and vomitings soon ensued; and his pulse became so low, and so often interrupted, that it was thought proper to order him a repetition of cordial potions: he said he was not sensible of any great relief from these; but that a glass or two of olive-oil drank down, seemed to give him ease. Continuing in this dangerous condition, he was put to bed, where his arm was again bathed over a pan of charcoal, and rubbed with salad oil, heated in a ladle over the charcoal, by Dr Mortimer's direction, who was the physician that drew up the account. From this last operation he declared that he found immediate ease, as though by some charm: he soon after fell into a profound sleep, and, after about nine hours' sound rest, awaked about six the next morning, and found himself very well; but in the afternoon, on drinking some rum and strong beer, so as to be almost intoxicated, the swelling returned, with much pain and cold sweats, which abated soon, on bathing the arm, as before, and wrapping it up in brown paper soaked in the oil.[1]

[1] The treatment for the bite of the viper has been very well indicated by Celsus in his treatise of medicine, and it merits some attention, especially as naturalists are frequently exposed to accidents from this reptile. The first precaution to be observed in a case of this kind, is, when

Such are the effects of the viper's bite; yet its flesh has long been celebrated as a noble medicine. A broth, made by boiling one viper in a quart of water till it comes to a pint, is the usual method in which it is given at present; and it is said to be a very powerful restorative in battered constitutions; the salt of vipers is also thought to exceed any other animal salt whatever, in giving vigour to the languid circulation, and prompting to venery.

The Rattle-snake is bred in America, and in no part of the old world. Some are as thick as a man's leg, and six feet in length; but the most usual size is from four to five feet long. In most particulars it resembles the viper; like that animal having a large head and a small neck, being of a dusky colour, and furnished with fangs that inflict the most terrible wounds. It differs, however, in having a large scale, which hangs like a pent-house over each eye. The eye also is furnished with a nictitating membrane, that preserves it from dust; and its scales are of a considerable degree of hardness. They are of an orange, tawny, and blackish colour on the back; and of an ash-colour on the belly, inclining to lead. The male may be readily distinguished from the female, by a black velvet spot on the head, and by the head being smaller and longer. But that which, besides their superior malignity, distinguishes them from all other animals, is their rattle, an instrument lodged in their tail, by which they make such a loud rattling noise, when they move, that their approach may readily be perceived, and the danger avoided. This rattle, which is placed in the tail, somewhat resembles, when taken out of the body, the curb-chain of a bridle: it is composed of several thin, hard, hollow bones, linked to each other, and rattling upon the slightest motion. It is supposed by some that the snake acquires an additional bone every year; and that, from hence, its age may be precisely known: however this may be, certain it is, that the young snakes, of a year or two old, have no rattles at all: while many old ones have been killed, that had from eleven to thirteen joints each. They shake and make a noise with these rattles with prodigious quickness, when they are disturbed: however, the peccary and the vulture are no way terrified at the sound, but hasten, at the signal, to seize the snake, as their most favourite prey.

It is very different with almost every other animal. The certain death which ensues from this terrible creature's bite, makes a solitude wherever it is heard. It moves along with the most majestic rapidity;[1] neither seeking to offend the larger animals, nor fearing their insults. If unprovoked, it never meddles with any thing but its natural prey; but when accidentally trod upon, or pursued to be

---

the disposition of the parts will permit, to fix a ligature above the wounded place, and not to tighten it too much, for fear of giving rise to mortification. Immediately after, a cupping-glass is applied on the wound, the parts adjacent being first scarified, and this mode, highly praised by Celsus, has very recently been attended with happy results in the hands of Messrs Mangili, Barry, and Bouillaud. This method, from analogy, affords an additional recommendation to employ the plan of suction, which has received the further confirmation of professional experiments tried by a number of physiologists and physicians. When the cupping-glass has performed its office, the lips of the wound, already scarified, should be cauterized deeply and extensively. This should be done with a red-hot iron, chlorine of antimony, or concreted potassium. A variety of different substances, taken internally, has been lauded from time to time as efficacious against the bite of the viper. Sudorifics have been especially recommended, and among them the flesh of the lizard, of the coluber, and the viper itself, have been preferred, in consequence of the great quantity of ammonia which it has been ascertained to contain. An alexipharmic virtue of the same kind has been also attributed to theriaca and other analogous electuaries.

The *Chersæa* (*Swedish viper*, Shaw) is common in the environs of Upsal, in Sweden: also in Smaland, Scania, and Pomerania, where it retires into thickets, under hedges, and to the foot of tufted trees. It is sometimes seen in Prussia, Poland, Denmark, and in the Pyrenees. In Sweden it is known under the name of *æsping*, which seems evidently a corruption of *aspic*, and it has been sometimes called the *red viper*. It is erroneously located by Linnæus, Wolf, and Laurenti, in the genus coluber. Its resemblance to the common viper is very striking. The chersæa of Sweden is a small reptile, about six inches long, and as thick as one's little finger. That of Switzerland and France differs from it much both in size and number of plates. Herpetologists, however, admit the identity of these animals, and make but one species of them. Be this as it may, the Swedish viper is a reptile of the most dangerous kind. Its bite is often mortal, and its deleterious effects are manifested with greater rapidity than those which follow from the bite of the common viper.

The *Ammodytes* is a native of all the south of Europe. It is found in Dauphine, and in the neighbourhood of Lyons in France, and in the east of Europe, in the mountains of Illyria. It habitually frequents the rocks which border on the Danube, the neighbourhood of the city of Gorice and the Japidian mountains. This reptile passes the winter concealed in clefts and crevices of rocks, from which it issues forth when the warmer rays of the sun announce the return of spring. Then it casts its skin, and the time of reproduction begins. Its habitual food differs in nothing from that of the common viper, and its bite is not less dangerous.

The *Cerastes* has received its name from the Greek word *κέρας*, in consequence of the eminences which surround its eyes, and which, from the most ancient times, have been erroneously compared to the horns of mammiferous animals. Shunning humid and marshy situations, it is found only in the burning and arid sands of Egypt, Arabia, and Syria—sands in which it remains concealed during the entire day, and notwithstanding its great agility, it waits patiently until some victim presents itself to its insatiable voracity. It sometimes in this way gets possession of the jerboa, whose hole, according to Bruce, is very often contiguous to its own.

[1] This is an error: the movements of the rattle-snake are extremely sluggish.

destroyed, it then makes a dreadful and desperate defence. It erects itself upon its tail, throws back its head, and inflicts its wound in a moment; then parts and inflicts a second wound: after which, we are told by some, that it remains torpid and inactive, without even attempting to escape.

The very instant the wound is inflicted, though small in itself, it appears more painful than the sting of a bee. This pain, which is so suddenly felt, far from abating, grows every moment more excruciating and dangerous: the limb swells; the venom reaches the head, which is soon of a monstrous size; the eyes are red and fiery; the heart beats quick, with frequent interruptions; the pain becomes insupportable, and some expire under it in five or six hours; but others, who are of stronger constitutions, survive the agony for a few hours longer, only to sink under a general mortification, which ensues, and corrupts the whole body.[1]

As a gentleman in Virginia was walking in the fields for his amusement, he accidently trod upon a rattle-snake, that had been lurking in a stony place; which, enraged by the pressure, reared up, bit his hand, and shook its rattles. The gentleman readily perceived that he was in the most dreadful danger; but, unwilling to die unrevenged, he killed the snake, and carrying it home in his hand, threw it on the ground before his family, crying out, "I am killed, and there is my murderer." In such an extremity, the speediest remedies were the best. His arm, which was beginning to swell, was tied up near the shoulder, the wound was anointed with oil, and every precaution taken to stop the infection. By the help of a very strong constitution he recovered; but not without feeling the most various and dreadful symptoms for several weeks together. His arm, below the ligature, appeared of several colours, with a writhing among the muscles, that, to his

[1] *Death by the bite of a Rattle-snake.*—At the meeting of the Academy of Sciences of France on the 9th of April, 1827, some documents were presented by M. Dumerel, connected with the death of Mr Drake by the bite of a rattle-snake, forming part of a collection of reptiles which that person had exhibited at London, and had taken to France for the same purpose. These documents were transmitted to the Academy by the Minister of the Interior; and seem to have excited fears in some of the members, lest, the climate of France being favourable, some of these dangerous reptiles might escape and propagate.

From these documents it appears, that Mr Drake arrived at an inn in Rouen on the 8th of February, with three live rattle-snakes and some young crocodiles, and that, notwithstanding his care to preserve them from cold on the road, he saw with grief on his arrival that the finest of the three was dead. The dead animal was removed from the cage, and the cage itself, with the other two, were taken into the dining-room, and placed near the stove. Here Mr Drake endeavoured to rouse them with a stick; but, perceiving that one of the two gave no signs of animation, he opened the cage, took the serpent by the head and tail, and approaching a window to ascertain by handling if life was extinct, the animal turned its head half round, and fixed one of its fangs in the posterior external part of the left hand. Mr Drake shrieked, pronounced some words in English, according to the report, and was replacing the serpent in the cage, when it again bit him on the palm of the same hand. Mr Drake now ran out into the court calling eagerly for a surgeon: and, not finding water readily, rubbed his hand upon some ice, which he found at the door. Two minutes after, having procured a cord, he himself made a ligature on the arm above the hand. Notwithstanding these precautions, his agitation from the fear of the consequences continued to increase till the arrival of Dr Pihorel. The presence of this gentleman somewhat composed the feelings of Mr Drake; and he saw with eager joy the chafing-dish and irons arrive, with which the wounds were to be cauterized. This operation was instantly performed, and the patient took internally half a glassful of olive oil. Drake seemed now to have resumed his tranquillity. But in a few minutes more symptoms made their appearance which rendered the case hopeless, and he died in eight hours and three quarters after the bites.

The body was afterwards opened. The internal organs appeared healthy; the brain and spinal cord were unaltered. The membrane which covered these parts, however, was observed to have a reddish tinge. The veins presented no trace of inflammation; and the only appearance of derangement in the system, consisted in the veins of the affected side having the blood curdled or clotted.

In a curious memoir on the habits of the rattle-snake, read by M. Audubon at the Wernerian Society, that gentleman mentioned a circumstance which tends to show that the poisonous fangs of this reptile, even when withdrawn from the animal, retain their virulence for years. A person had been bitten by a rattle-snake in the wood, through a strong boot. He died without the cause of his death being properly investigated. The boots descended to his son, who, after putting them on, was taken suddenly ill, and also died. The effects of this last were brought to sale; and a younger brother fancying the boots, or willing to preserve some memorial of his father and brother, was the purchaser. He used them only once, when he also fell ill and died. The medical men, whom such an occurrence had led to investigate its cause, at last ripped up the fatal boot, and found, firmly fixed in the substance of the leather, the fang of the rattle-snake, which had thus caused the death of three individuals. Rattle-snakes, M. Audubon further observed, are often found coiled up and torpid when the temperature is low; and he himself once narrowly escaped from perhaps a serious accident, in trusting to their continued torpidity. He had found an excellent specimen coiled up and torpid, which he put in his knapsack along with some wild ducks which he had shot. The motion and heat of his body, together with the additional heat afforded by a sportsman's fire at a repast in the woods, had, however, revived the animal; and the motions of his knapsack, observed from the outside, indicated life within. M. Audubon at first thought that some of his ducks, imperfectly killed, had found their situation irksome, and were testifying their impatience; but the recollection of the rattle-snake flashing at once on his mind, he threw off his bag, duck, and reptile, altogether. The removal of the animal to a colder temperature brought on again its torpidity. He carried the snake home; and the identical specimen, if we rightly understood him, is now in the Museum of the Lyceum of Natural History of New York.—*Brewster's Jour.*

terrified imagination, appeared like the motions of the animal that wounded him. A fever ensued; the loss of his hair, giddiness, drought, weakness, and nervous faintings; till, by slow degrees, a very strong habit overpowered the latent malignity of the poison.

Several remedies have been tried to alleviate this calamity. A decoction of the Virginian snake-root is considered as the most effectual; and at the same time the head of the animal, bruised and laid upon the part affected, is thought to assist the cure. In general, however, it is found to be fatal: and the Indians, sensible of this, take care to dip their arrows in the poison under the rattle-snake's fangs, when they desire to take a signal revenge of their enemies.

Thus much concerning this animal is agreed upon by every naturalist: there are other circumstances in its history, which are not so well ascertained. And first, its motion, which some describe as the swiftest imaginable; asserting, that its Indian name of *Ecacoalt*, which signifies the wind-serpent, implies its agility: others, on the contrary, assert that it is the slowest and the most sluggish of all serpents; and that it seldom moves from one place. In this opposition of opinions, there are others, who assert, that on even ground it moves but slowly; but then, among rocks, that it goes at a great rate. If we may argue from analogy, the opinion of those who contend for its slow motion, seems the most probable; as the viper, which it so very much resembles, is remarkable among serpents for its inactivity.

It is said also by some, that the rattle-snake has a power of charming its prey into his mouth; and this is as strongly contradicted by others. The inhabitants of Pennsylvania are said to have opportunities of observing this strange fascination every day. The snake is often seen basking at the foot of a tree, where birds and squirrels make their residence. There, coiled upon its tail, its jaws extended, and its eyes shining like fire, the rattle snake levels its dreadful glare upon one of the little animals above. The bird or the squirrel, whichever it may be, too plainly perceives the mischief meditating against it; and hops from branch to branch, with a timorous plaintive sound, wishing to avoid, yet incapable of breaking through the fascination: thus it continues for some time its feeble efforts and complaints, but is still seen approaching lower and lower towards the bottom branches of the tree, until, at last, as if overcome by the potency of its fears, it jumps down from the tree directly into the throat of its frightful destroyer.[1]

In order to ascertain the truth of this story, a mouse was put into a large iron cage, where a rattle-snake was kept, and the effects carefully observed. The mouse remained motionless at one end of the cage; while the snake, at the other, continued fixed, with its eye glaring full on the little animal, and its jaws opened to their widest extent: the mouse for some time seemed eager to escape; but every effort only served to increase its terrors, and to draw it still nearer the enemy; till, after several ineffectual attempts to break the fascination, it was seen to run into the jaws of the rattle-snake, where it was instantly killed.

To these accounts the incredulous oppose the improbability of the fact: they assert, that such a power ascribed to serpents, is only the remnant of a vulgar error, by which it was supposed that serpents could be charmed, and had also a power of charming. They aver, that animals are so far from running down the throat of a rattle-snake in captivity, that the snake will eat nothing in that state, but actually dies for want of subsistence.

A serpent, called the Whip-snake, is still more venomous than the former. This animal, which is a native of the East, is about five feet long, yet not much thicker than the thong of a coachman's whip. It is exceedingly venomous; and its bite is said to kill in about six hours. One of the Jesuit missionaries, happening to enter into an Indian pagoda, saw what he took to be a whipcord lying on the floor, and stooped to take it up; but, upon handling it, what was his surprise to find that it was animated, and no other than the whip-snake, of which he had heard such formidable accounts: fortune, however, seemed favourable to him, for he grasped it by the head, so that it had no power to bite him, and only twisted its folds up his arm. In this manner he held it, till it was killed by those who came to his assistance.

To this formidable class might be added the Asp, whose bite, however, is not attended with those drowsy symptoms which the ancients ascribed to it. The Jaculus of Jamaica also is one of the swiftest of the serpent kind. The Hæmorrhois, so called from the *hæmorrhages* which its bite is said to produce; the Seps,[2] whose

[1] The power said to be possessed by the Rattle-snake of fascinating its prey, has been the theme of many an astonishing tale, and the possession of this faculty is still believed by many. There is no doubt that the smaller animals on which the reptile subsists are alarmed in the presence of their known enemy, and that fear may cause them to lose their self-possession, and thus they are more readily seized by their cunning opponent.

[2] *The Seps.*—This word, which comes from a Greek word, signifying *to corrupt*, was used by the ancients to designate an animal which some considered a lizard and others a serpent.

The Seps is no longer considered to be a lizard, neither is it quite a serpent. Its lengthened body gives, at

wound is very venomous, and causes the part affected to corrupt in a very short time; the Coral Serpent, which is red, and whose bite is said to be fatal. But of all others, the Cobra di Capello, or Hooded Serpent, inflicts the most deadly and incurable wounds.[1] Of this formidable creature there are five or six different kinds; but they are all equally dangerous, and their bite followed by speedy and certain death. It is from three to eight feet long, with two large fangs hanging out of the upper jaw. It has a broad neck, and a mark

first sight, a striking resemblance to the Blind-worm, but on closer examination it is found to possess two pair of such very short paws, that they cannot possibly reach the ground.

This animal belongs to the family of the *Scinoides*, which are all distinguished by the extreme smallness of their members, and of which some species present very remarkable peculiarities. Some Seps are only provided with one toe on each foot; the bipeds possess only one pair of paws, situated at the hinder part of their body; the foremost paws only are observable in the *bimanus*.

One species inhabits the southern part of France, but is rare; in the north it is entirely unknown. In Italy, where it is more common, it is known by the name of *Cicella* or *Ciciqua*. The scales of its belly are separated from those of its back by three lines. This reptile is not dangerous, for nature has not bestowed upon it any venom, and even if it possessed any, its mouth is too small for it to bite a man, or any other large animal.

[1] The *naja* or *cobra di capello* is equally remarkable

for the elegance of its form, the strength of its body, and the danger which accompanies its bite. It has received the name of spectacle snake, in consequence of a black mark which more or less exactly represents spectacles on the extensible portion of its neck. When the animal is in a state of repose, the neck has no greater a diameter than the head, but under the influence of passion, the skin of this part extends in the form of a coif or hood. This serpent inhabits Coromandel, and is not found in Peru or Mexico, as many modern naturalists have erroneously stated, after Seba. It is very formidable from its envenomed bite, which is as dangerous as that of any other species of reptiles. When surprised by some imprudent traveller, it slowly raises its head, swells its neck, and advances against its aggressor in undulating movements executed solely by the tail.

In the sixth volume of the "Asiatic Researches," Mr Boaz, after having examined with care the ancient curative processes for the bite of venomous serpents, recommends in the last place as a specific in the dreadful malady caused by the poison of the cobra di capello, nitrate of silver, which was a remedy long since proposed by Fontana in the case of the viper. In the second volume of the same collection, Mr J. Williams has inserted a paper on the caustic volatile alkali against the deleterious effects of the bite of different serpents, and particularly that of the cobra di capello. It seems that this medicament should be applied both externally on the wound, and at the same time administered internally. A remedy much boasted of by some of the ancient missionaries, who had travelled in the East Indies, and who pretended to cure the bite of the naja, as well as that of other venomous animals, has been proved useless by the experiments of the learned Redi. This is a calculous concretion, which according to them is formed near the head, or in the body of the serpent in question, and which is named serpent or cobra-stone. This account of the origin of this pretended stone is assuredly false, and it is nothing but a factitious medicament composed by some charlatan. It appears to be nothing but a blackish or greenish argillaceous earth, which has the property of absorbing with great facility the humours which are formed at the surface of any wound whatever. But in India it is believed to imbibe quickly the poison discharged recently into the body of an animal bitten by the naja.

The name of *aspic* has been given amongst all civilized nations to a serpent rendered ever memorable by the death of Cleopatra, whose beauty, glory, honours, and deplorable end, have occupied the historians and poets of all nations. It has been only since the expedition of the French to Egypt that the true species of the aspic has been ascertained. During the period of that expedition, the French philosophers attached to the army observed a species of ophidian, regarded as harmless by Linnæus and most herpetologists, but considered as extremely venomous by the traveller, Forskal. This serpent is called *haje* by the inhabitants, and recent travellers have incontestably proved that it is the true aspic of the ancients, which never inhabited Europe; for the reptile which some years since infested the forest of Fontainbleau, and was called by this name, was nothing but a variety of the common viper, and the *æsping* of the Swedes is quite another species from the one in question.

Forskal informs us that when the haje is provoked, it swells and extends its neck greatly, and then springs with a single bound upon its enemy. This habit of rearing up when it is approached, caused the ancient inhabitants of the countries watered by the Nile, to believe that this serpent guarded the fields which it inhabited. They made it in consequence the emblem of the protecting divinity of the world. They sculptured it on the two sides of a globe, on the portico of all their temples. It is often exhibited by the jugglers at Cairo, apparently metamorphosed into a rod or wand, which is done by pressing its nape with the finger, and thus causing a sort of catalepsy. They take care, however, to remove the fangs, which might cause very serious accidents.

The poison of the haje is excessively violent, and far more deleterious than that of the European viper, which it resembles in its yellowish tint, and its transparence. Forskal relates, that having taken a very small drop of it, and introduced it into a slight incision made in the thigh of a pigeon, he saw this unfortunate bird perish in a quarter of an hour in convulsions and vomitings. The modes adopted against the bite of the haje are the same, for the most part, as those used in the case of that of the viper, particularly cauterization by fire, alcholized potassum, &c., and the administration of sudorifics internally.—*Supplement to the English edition of Cuvier by Edward Griffith and others.*

Serpents in South Africa.—The late excellent Mr Thomas Pringle, whose residence in South Africa, though unproductive to himself in a pecuniary sense, was fertile in observation, and has added largely to our knowledge of that portion of the globe, gives the following account of the *Venomous Serpents* to be found there:—

"The serpents of South Africa (he says) commonly accounted the most dangerous, are the Cobra-Capello (or hooded snake), the Puff-Adder, and the Berg-Adder (or mountain snake). The first of these is exceedingly fierce and active, and sometimes, it is said, attains the formidable length of ten feet; I have, however, never

of dark brown on the forehead; which, when viewed frontwise, looks like a pair of spectacles; but behind, like the head of a cat. The eyes are fierce, and full of fire; the head is small, and the nose flat, though covered with very large scales, of a yellowish ash-colour; the skin is white, and the large tumour on the neck is flat, and covered with oblong,

met with any of much more than half that size. The cobra has been known to spring at a man on horseback, and to dart himself with such force as to overshoot his aim. The puff-adder, on the other hand, is a heavy and sluggish animal, very thick in proportion to its length, and incapable, when attacked in front, of projecting itself upon its enemy. To make amends, however, it possesses the faculty of throwing itself backward with perilous and unexpected effect; but its disposition is inert, and unless accidentally trod upon or otherwise provoked, it will seldom attack mankind. The berg-adder, though much smaller in size than either of the preceding, is generally considered not less deadly, and it is the more dangerous from its being less easily discovered and avoided.

"During a residence of six years in the interior of the Cape Colony, and in the course of various journeys through the interior (extending to upwards of three thousand miles), I have met with a considerable number of snakes; yet I do not recollect of ever being exposed, except in one instance, to any imminent hazard of being bit by any of them. On the occasion referred to I was superintending some Hottentots, whom I had employed to clear away a patch of thicket from a spot selected for cultivation, when one of the men, suddenly recoiling with signs of great alarm, exclaimed, that there was a cobra-capello in the bush. Not being at that time fully aware of the dangerous character of this species of snake, I approached to look at him. The Hottentots called out to me to take care, for he was going to spring. Before they had well spoken, or I had caught a view of the reptile, I heard him hiss fiercely, and then dart himself towards me amidst the underwood. At the same instant, instinctively springing backward to avoid him, I fell over a steep bank into the dry stony bed of a torrent; by which I suffered some severe bruises, but fortunately escaped the more formidable danger to which I had too incautiously exposed myself. The Hottentots then assailed the snake with sticks and stones, and forced him (though not before he had made another spring and missed one of them still more narrowly then myself) to take refuge up a mimosa tree. Here he became a safe and easy mark to their missiles, and was speedily beaten down, with a broken back, and consequently rendered incapable of farther mischief. The Hottentots having cut off his head, carefully buried it in the ground, a practice which they never omit on such occasions, and which arises from their apprehension of some one incautiously treading on the head of the dead snake, and sustaining injury from its fangs; for they believe that the deathful virus, far from being extinguished with life, retains its fatal energy for weeks, and even months afterwards. This snake measured nearly six feet in length, and was the largest cobra I have met with.

"My little Hottentot corporal, Piet (or Peter) Spandilly, who assisted in killing this cobra, had a still narrower escape from a small but venomous snake, of which I have forgotten the colonial appellation. Piet and his men (six soldiers of the Cape Corps, placed at that time under my direction for the protection of our remote settlement against the Caffres) slept in a tent adjoining to mine, pitched in a grove of mimosas on the brink of the Bavian's river; and one morning when he rose from his couch of dry grass, Piet felt some living creature moving about his thigh in the inside of his leathern trousers. Thinking it was only one of the harmless lizards which swarm in every part of South Africa, he did not at first much mind it, but came out to the open air, laughing, and shaking his limb to dislodge the vermin. But when a black wriggling snake came tumbling down about his naked ancles, poor Spandilly, uttering a cry of horror, kicked the reptile off, springing at the same moment nearly his own height from the ground; and, though he had in reality sustained no injury, could scarcely for some time be persuaded that he was not 'a gone man.'

"It is, in fact, from apprehensions of danger, or the instinct of self-defence, far more than from any peculiar fierceness or innate malignity, that the serpent race ever assail man or any of the larger animals. They turn, of course, against the foot that tramples or the hand that threatens them; but happily nature has not armed them, in addition to their formidable powers of destruction, with the disposition of exerting these powers from motives of mere wanton cruelty, or for purposes unconnected with their own subsistence or security. Were it otherwise, countries like the Cape would be altogether uninhabitable. As it is, the annoyance experienced from the numerous poisonous snakes is not such as, on the whole, to affect in any considerable degree the comfort of those accustomed to them.

"Conversing on this subject one day with my friend Captain Harding, who had been for many years a resident and magistrate in the interior, I inquired whether he had ever, in the course of his campaigns on the Caffre and Bushman frontiers, and when necessarily obliged to sleep in the desert or jungle in the open air, suffered injury or incurred danger from serpents—he replied, that the only occasion he recollected of incurring any great hazard of this sort, was the following:—

"'Being upon a military expedition across the frontier,' said he, 'I had slept one night, as usual, wrapt in my cloak, beneath a tree. On awaking at daybreak, the first object I perceived on raising my head from the saddle, which served for my pillow, was the tail of an enormous puff-adder lying across my breast, the head of the reptile being muffled under the folds of the cloak close to my body, whether it had betaken itself, apparently for warmth, during the chillness of the night. There was extreme hazard that if I alarmed it by moving, it might bite me in a vital part;—seizing it therefore softly by the tail, I pulled it out with a sudden jerk, and threw it violently to a distance. By this means I escaped without injury: but had I happened to have unwittingly offended this uninvited bedfellow before I was aware of his presence, I might in all probability have fatally atoned for my heedlessness.'

"It is not very unusual for snakes of various sorts to be found in the houses at the Cape, nor does it, in ordinary cases, excite any violent alarm when such inmates are discovered. They make their way both through the roofs and under the walls, in search of food and shelter, and especially in pursuit of mice, which many of them chiefly subsist upon. During my residence in the interior, however, I recollect only two instances of their being found in my own cabin. On one of these occasions I had sent a servant girl (a bare-legged Hottentot) to bring me some article from a neighbouring hut. It was after night-fall; and on returning with it, she cried out before entering the cabin—'Oh, Mynheer; Mynheer! what shall I do? A snake has twined itself round my ancles, and if I open the door he will come into the house.' 'Never mind,' I replied, 'open the door, and let him come if he dare.' She obeyed, and in glided the snake, luckily without having harmed the poor girl. I stood prepared, and instantly smote him dead; and afterwards found him to be one of the very venomous sort called *Nachtslang*.

smooth scales. The bite of this animal is said to be incurable, the patient dying in about an hour after the wound; the whole frame being dissolved into one putrid mass of corruption.

To remedy the bite of all these animals, perhaps salad oil would be very efficacious; however, the Indians make use of a composition, which is called in Europe, *Petro de Cobra*, or the *Serpent-stone;* and which applied to the

---

"People get used to these things, and even Europeans by degrees come to regard them with much indifference. Just before leaving the colony, I spent a week or two with my friend Major Pigot, at his residence near Graham's Town; and going one day to take a book from some shelves in the drawing-room, I found a beautiful yellow snake, about five feet long, lying asleep upon the uppermost range of books. It lay so still that I at first thought it was a stuffed specimen; but perceiving a slight movement in its tail, I lent him such a thwack with a quarto volume as broke the poor fellow's back, and enabled me to demolish him at my leisure. I afterwards learned that another snake had been killed a few days previously in the very same spot, and a third in Major P.'s dressing-room. They had all entered through a loop hole which had casually been left open, and apparently had no other object in coming there (mousing apart) than literary seclusion.

"Such as these are no very uncommon occurrences, and as such pass even for subjects of jocularity amidst the adventures of a wild country. Instances, however, both frightful and revolting, sometimes occur.

"It is well known that the Bushmen, a tribe of wild Hottentots who inhabit the mountains and deserts of South Africa, imbue the points of their arrows in a strong and subtle poison, and that the venom of the most dangerous serpents to be found in that country forms a principal ingredient in its composition. The boldness and dexterity displayed by these wild huntsmen, and by many also of the colonial Hottentots, in searching out and seizing alive the formidable cobra-capello and puff-adder, are truly astonishing. Still more surprising is it to witness the snake-hunter extracting from the yet living and writhing reptile, held fast by his naked foot planted on its neck, the little bag containing the secreted venom, which the rage of the animal injects into the wound made by its fangs at the moment it strikes its victim,—to see him take this, and fearlessly drink its contents, as school-boys in England would suck the blob of the honey-bee! The swallowing of this venom, they conceive, renders them in time proof against its deleterious effects, when it is brought into immediate contact with the blood, whether by the bite of a snake or the barb of an arrow.

"Several of the most respectable Dutch colonists assured me, as a fact which had come within their own knowledge, that there are to be found among the wandering Bushmen persons whom they term *slang meesters* (snake masters), who actually possess the power of charming the fiercest serpents, and of readily curing their bite; and who pretend that they can communicate to others their mysterious powers and invulnerability, by putting them through a regular course of *poison-eating*.

"The more usual object, however, of the Bushman in catching serpents (exclusive of their value to him as an article of food), is to procure poison for his arrows. The animal venom, too thin and volatile to preserve its efficacy long unimpaired when used alone, is skilfully concocted into a black glutinous consistency, by the admixture of powerful vegetable and mineral poisons; the former being generally the juice of the root of a species of amaryllis, called by the boors, from this circumstance, the *gift-bol*, or poison-bulb; the latter, a bituminous or unctuous substance which is said to exude from certain rocks and caverns. With this deadly mixture the dwarfish and despised African anoints the desperate weapons with which he resists (though unavailingly) the aggressions of the colonists, and sometimes cruelly revenges the injuries they have inflicted."

To the above interesting account, by Mr Pringle, of the Serpents of South Africa, we may here add Mr Waterton's observations on the *Snakes of South America*, or, more properly, *Demerara*.

"Snakes," says that eccentric and enterprising naturalist, "are frequently met with in the woods betwixt the sea-coast and the rock Saba, chiefly near the creeks and on the banks of the river. They are large, beautiful, and formidable. The rattle-snake seems partial to a tract of ground known by the name of Canal, No. 3; there the effects of his poison will be long remembered.

"The *camoudi* has been killed from thirty to forty feet long; though not venomous, his size renders him destructive to the passing animals. The Spaniards in the Oroonoque positively affirm that he grows to the length of seventy or eighty feet, and that he will destroy the strongest and largest bull. His name seems to confirm this: there he is called 'matatoro,' which literally means 'bull killer.' Thus he may be ranked amongst the deadly snakes; for it comes nearly to the same thing in the end, whether the victim dies by poison from the fangs which corrupts his blood and makes it stink horribly, or whether his body be crushed to mummy, and swallowed by this hideous beast.

"The *whip-snake*, of a beautiful changing green, and the coral, with alternate broad traverse bars of black and red, glides from bush to bush, and may be handled with safety; they are harmless little creatures.

"The *labarri snake* is speckled, of a dirty brown colour, and can scarcely be distinguished from the ground or stump on which he is coiled up; he grows to the length of about eight feet, and his bite often proves fatal in a few minutes.

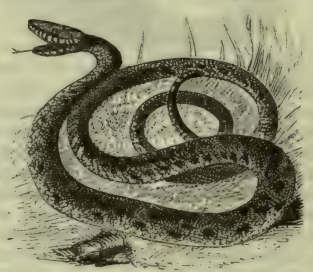
"Unrivalled in his display of every lovely colour of the rainbow, and unmatched in the effects of his deadly poison, the *counacouchi* glides undaunted on, sole monarch of these forests; he is commonly known by the name of the bush-master. Both man and beast fly before him, and allow him to pursue an undisputed path. He sometimes grows to the length of fourteen feet.

"A few small *caimen*, from two to twelve feet long, may be observed now and then in passing up and down the river; they just keep their heads above water, and a stranger would not know them from a rotten stump.

"Snakes in these wilds are certainly an annoyance, though, perhaps, more in imagination than reality, for you must recollect that the serpent is never the first to offend; his poisonous fang was not given him for conquest; he never inflicts a wound with it but to defend existence. Provided you walk cautiously, and do not absolutely touch him, you may pass in safety close by him. As he is often coiled up on the ground, and amongst the branches of the trees above you, a degree of circumspection is necessary, lest you unwarily disturb him. One morning I had been following a new species of parouquet, and the day being rainy, I had taken an umbrella to keep the gun dry, and had left it under a tree; whilst searching about for it I observed a young *coulacanara*, ten feet long, moving slowly onwards in a path where timber had formerly been dragged along; I saw he was not thick enough to break my arm in case he got twisted round it. There was not a moment to be lost. I laid hold of his tail with the left hand, one knee being on the ground; with the right I took off my hat,

wound, is said to draw out the venom. The composition of this stone, for it is an artificial substance, is kept a secret; and perhaps its effects in extracting the venom may be imaginary: nevertheless, it is certain that it has a power of sticking to the skin, and sucking a part of the blood from the wound. This it may do somewhat in the same manner as we see a tobacco-pipe stick to the lips of a man who is smoking; yet still we are ignorant of the manner; and the secret might probably be of some use in medicine. It were to be wished, therefore, that those who go to India would examine into this composition, and give us the result of their inquiries; but I fear that it is not to benefit mankind, that our travellers now go to India.

CHAP. III.



OF SERPENTS WITHOUT VENOM.

The class of serpents without poison may be distinguished from those that are venomous by their wanting the fang-teeth: their heads also are not so thick in proportion to their bodies; and, in general, they taper off to the tail more gradually in a point. But, notwithstanding their being destitute of venom, they do not cease to be formidable: some grow to a size by which they become the most powerful animals of the forest; and even the smallest and most harmless of this slender tribe find protection from the similitude of their form.

The fangs make the great distinction among serpents; and all this tribe are without them. Their teeth are short, numerous, and, in the smaller kinds, perfectly inoffensive: they lie in either jaw, as in frogs and fishes, their points bending backwards, the better to secure their prey. They want that artificial mechanism by which the poisonous tribe inflict such deadly wounds: they have no gland in the head for preparing venom: no conduits for conveying it to the teeth; no receptacles there: no hollow in the instrument that inflicts the wound. Their bite, when the teeth happen to be large enough to penetrate the skin (for, in general, they are too small for this purpose) is attended with no other symptoms than those of an ordinary puncture; and many of this tribe, as if sensible of their own impotence, cannot be provoked to bite, though never so rudely assaulted. They hiss, dart out their forky tongues, erect themselves on the tail, and call up all their terrors to intimidate their aggressors; but seem to consider their teeth as unnecessary instruments of defence, and never attempt to use them. Even among the largest of this kind the teeth are never employed, in the most desperate engagements. When a hare or a bird is caught, the teeth may serve to prevent such small game from escaping; but when a buffalo or a tiger is to be encountered, it is by the strong folds of the body, by the fierce verberations of the tail, that the enemy is destroyed: by thus twining round, and drawing the knot with convulsive energy, this enormous reptile breaks every bone in the animal's body, and then, at one morsel, devours its prey.

From hence we may distinguish the unvenomous tribe into two kinds: first, into those that are seldom found of any considerable magnitude, and that never offend animals larger or more powerful than themselves, but which find their chief protection in flight, or in the doubtfulness of their form; secondly, into such as grow to an enormous size, fear no enemy, but indiscriminately attack all other animals and devour them. Of the first kind is the Common Black Snake, the Blind Worm, the Esculapian Serpent, the Amphisbæna, and several others. Of the second, the Liboya, the Boiguacu, the Depona, and the Boiquatrara.

The *Black Snake* is the largest of English

serpents, sometimes exceeding four feet in length. The neck is slender; the middle of the body thick; the back and sides covered with small scales; the belly with oblong, narrow, transverse plaits; the colour of the back and sides are of a dusky brown; the middle of the back marked with two rows of small black spots, running from the head to the tail; the plaits on the belly are dusky; the scales on the sides are of a bluish white; the teeth are small and serrated, lying on each side of the jaws in two rows. The whole species is perfectly inoffensive; taking shelter in dunghills,

and held it as you would hold a shield for defence. The snake instantly turned and came on at me with his head about a yard from the ground, as if to ask me what business I had to take liberties with his tail. I let him come, hissing and open-mouthed, within two feet of my face, and then, with all the force I was master of, I drove my fist, shielded by my hat, full in his jaws. He was stunned and confounded by the blow, and ere he could recover himself, I had seized his throat with both hands in such a position that he could not bite me; I then allowed him to coil himself round my body, and marched off with him as my lawful prize. He pressed me hard, but not alarmingly so."—*Waterton's Wanderings.*

and among bushes in moist places; from whence they seldom remove, unless in the midst of the day in summer; when they are called out by the heat to bask themselves in the sun. If disturbed or attacked, they move away among the brambles with great swiftness; but if too closely pursued, they hiss and threaten, and thus render themselves formidable, though incapable of offending.[1]

The black snake preys upon frogs, insects, worms, mice, and young birds: and, considering the smallness of the neck, it is amazing how large an animal it will swallow. The black snake of Virginia, which is larger than ours, and generally grows to six feet long, takes a prey proportionable to its size; partridges, chickens, and young ducks. It is generally found in the neighbourhood of the henroost, and will devour the eggs even while the hen is sitting upon them: these it swallows whole; and often, after it has done the mischief, will coil itself round in the nest.

The whole of this tribe are oviparous, excluding eighty or a hundred eggs at a time, which are laid in dunghills or hot-beds; the heat of which, aided by that of the sun, brings them to maturity. During winter they lie torpid, in banks or hedges, and under old trees.

The *Blind Worm* is another harmless reptile, with a formidable appearance. The usual length of this species is eleven inches. The eyes are red; the head small; the neck still more slender; from that part the body grows suddenly, and continues of an equal bulk to the tail, which ends quite blunt: the colour of the back is cinereous, marked with very small lines, composed of minute black specks; the sides are of a reddish cast; the belly dusky, and marked like the back. The motion of this serpent is slow; from which, and from the smallness of the eyes, are derived its names; some calling it the slow, and some the blind worm. Like all the rest of the kind in our climates, they lie torpid during winter; and are sometimes found in vast numbers, twisted together. This animal, like the former, is perfectly innocent; however, like the viper, it brings forth its young alive. Gesner tells us, that one of these being struck on the forehead when it was pregnant, it immediately cast forth its young.

The Amphisbæna, or the Double Headed Serpent, is remarkable for moving along with either the head, or the tail foremost; and from thence it has been thought to have two heads.[2] This error took its rise from the thickness of the tail, which, at a distance, may be mistaken for another head. Upon a nearer view, however, the error is easily discovered, and the animal will be found formed according to the usual course of nature. It is as thick at one end as at the other; and the colour of the skin is like that of the earth, being rough, hard, and variously spotted. Some have affirmed that its bite is dangerous; but this must be a mistake, as it wants the fangs, and, consequently, the elaboratory that prepares the poison.

These animals are only formidable from their similitude to the viper tribe. In some

[1] This snake, though not poisonous, is sometimes bold enough to attack a man, but may be driven off by a smart stroke from a stick, or whatever weapon he may chance to have in his hand. When it overtakes a person who has endeavoured to escape, (not having had courage enough to oppose it,) it is said to wind itself round his legs in such a manner as to throw him down, and then to bite him several times in the leg, or whatever it can lay hold of, and run off again.

The black snake is very greedy of milk, and it is difficult to keep it out when once it is accustomed to get into a cellar where milk is kept. It has been seen taking milk out of the same dish with the children without biting them, though they often gave it blows with their spoons upon the head when it was too greedy.

These snakes are, however, found extremely useful in America in clearing houses of rats, which they pursue with wonderful agility, even to the very roofs of barns and out-houses; for which good services they are cherished by the generality of the Americans, who are at great pains to preserve and multiply the breed.

There are many species and varieties of this genus of serpents, which it would be tedious to enumerate.

[2] *Amphisbæna* literally signifies *double-walker*, and was applied to these animals because they can move both backwards and forwards. The amphisbænæ of modern naturalists all belong to America, and must therefore be different from the amphisbænæ of the ancients. They are not venomous. The *White Amphisbæna* is common in Brazil, and feeds chiefly on ants. Its length is about a foot and a half. All the amphisbænæ which are varied with brown and white are known under the name of *fuliginosa*. The following cut represents a *Punctated Amphisbæna*.

The tail of an amphisbæna is almost as bulky as the head; and as the eyes are extremely small, it is difficult at first sight to say at which end the head is situated.

countries, where such reptiles are common, they make the distinction so exactly, that, while they destroy serpents of one kind with great animosity, they take others into their houses, and even into their bosoms, with a kind of unaccountable affection. The Esculapian Serpent of Italy is among this number. It is there suffered to crawl about the chambers; and often gets into the beds where people lie. It is a yellow serpent, of about an ell long; and though innocent, yet will bite when exasperated. They are said to be great destroyers of mice; and this may be the reason why they are taken under human protection. The Boyuna of Ceylon is equally a favourite among the natives; and they consider the meeting it as a sign of good luck. The Surinam Serpent, which some improperly call the Ammodytes, is equally harmless and desirable among the savages of that part of the world. They consider themselves as extremely happy if this animal comes into their huts. The colours of this serpent are so many and beautiful, that they surpass all description; and these, perhaps, are the chief inducements to the savages to consider its visits as so very fortunate. A still greater favourite is the Prince of Serpents, a native of Japan, that has not its equal for beauty. The scales which cover the back are reddish, finely shaded, and marbled with large spots of irregular figures mixed with black. The fore part of the head is covered with large beautiful scales; the jaws bordered with yellow; the forehead marked with a black marbled streak; and the eyes handsome and lively. But, of all others, the Gerenda of the East Indies is the most honoured and esteemed. To this animal, which is finely spotted with various colours, the natives of Calicut pay divine honours; and while their deity lies coiled up, which is its usual posture, the people fall upon their faces before it with stupid adoration. The African Gerenda is larger, and worshipped in the same manner by the inhabitants of the coasts of Mosambique. The skin is not so finely spotted as the former; but it is variegated all over the body with very fine white, ash-coloured, and black spots. The brilliancy of colouring in these reptiles would only serve with us to increase our disgust; but in those countries where they are common, distinctions are made; and even in this horrid class there are some eyes that can discover beauty.

But in the larger tribe of serpents, there is nothing but danger to be apprehended. This formidable class, though without venom, have something frightful in their colour, as well as their size and form. They want that vivid hue with which the savages are so much pleased in the lesser kinds; they are all found of a dusky colour, with large teeth, which are more formidable than dangerous.

The first of this class is the great Liboya of Java and Brazil, which Legaut affirms, he has seen fifty feet long.[1] Nor is he singular

[1] The *Boa Constrictor*.—This is the largest of the serpent race, reaching generally to thirty feet in length. Its ground colour is yellowish gray, on which is distributed, along the back, a series of large, chine-like, reddish brown, and sometimes perfectly red variegations, with other smaller and more irregular marks and spots. They are readily distinguished from other serpents in the under surface of the tail, being covered with scuta or divided plates, like those on their belly, and in their body not being terminated by a rattle. There are three species, natives of Africa, India, the larger Indian islands, and South America, where they chiefly reside in most retired situations in woods and marshy retreats. In those cases where the boa attacks a large quadruped, such as an antelope, he entwines himself round his prey, and by his great muscular power crushes the principal bones, so that the dimensions of the victim are considerably reduced, and after a series of efforts which sometimes approach to strangulation, the monster makes an end of his meal. There are stories of the boa constrictor destroying even the buffalo and the tiger, by crushing them in this manner by the astonishing force of its muscles. We shall confine ourselves at present to a well-authenticated account of the voracious appetite of a serpent of this species, which was brought from Batavia, in the year 1817, on board a vessel which conveyed Lord Amherst and his suite to England. This serpent was of large dimensions, though not of the very largest. A living goat was placed in his cage. He viewed his prey for a few seconds, felt it with his tongue, and then, withdrawing his head, darted at the throat. But the goat, displaying a courage worthy of a better fate, received the monster on his horns. The serpent retreated, to return to the combat with more deadly certainty. He seized the goat by the leg, pulled it violently down, and twisted himself with astonishing rapidity round the body, throwing his principal weight upon the neck. The goat was so overpowered that he could not even struggle for escape. For some minutes after his victim was dead the serpent did not change his posture. At length he gradually slackened his grasp, and having entirely disengaged himself, he prepared to swallow the lifeless body. Feeling it about with his mouth, he began to draw the head into his throat; but the horns, which were four inches in length, rendered the gorging of the head a difficult task. In about two hours the whole body had disappeared. During the continuance of this extraordinary exertion the appearance of the serpent was hideous; he seemed to be suffering strangulation; his cheeks looked as if they were bursting; and the horns appeared ready to protrude through the monster's scales. After he had accomplished his task, the boa measured double his ordinary diameter. He did not move from his posture for several days, and no irritation could rouse him from his torpor.

The *Anaconda* is a name which, like that of the Boa Constrictor, has been popularly applied to all the larger and more powerful snakes. It appears to be of Ceylonese origin, and may therefore belong of right, as well as of usage, to the Indian species.

Happily the appetite of these gigantic snakes bears no proportion to their means of gratifying it, as a full meal is uniformly succeeded by a state of torpor, which frequently lasts for a month or six weeks, or, during the cold season, even for a longer period.

The term *Python* is bestowed on a genus approximating to the *Boa*, and which Cuvier conceives to contain all the pretended Boas of the ancient continent. Among

in this report, as many of the missionaries affirm the same; and we have the concurrent testimony of historians as a further proof. The largest animal of this kind which has been brought into Europe, is but thirty-six feet long; and it is probable that much greater have been seen and destroyed before they were thought worth sending so far to satisfy European curiosity. The most usual length, however, of the Liboya, is about twenty feet, and the thickness in proportion. The teeth are small in proportion to the body; nor are they used but when it seizes the smallest prey. It lies in wait for wild animals near the paths, and when it throws itself upon them, it wraps them round so closely as to break all the bones; then moistening the whole body over with its slaver, it makes it fit for deglutition, and swallows it whole.

The Boiguaca is supposed to be the next in magnitude, and has often been seen to swallow a goat whole. It is thickest in the middle of the body, and grows shorter and smaller towards the head and the tail: on the middle of the back there is a chain of small black spots running along the length of it; and on each side there are large, round, black spots, at some distance from each other, which are white in the centre; between these, near the belly, there are two rows of lesser black spots, which run parallel to the back. It has a double row of sharp teeth in each jaw, of a white colour, and shining like mother-of-pearl. The head is broad; and over the eyes it is raised into two prominences; near the extremity of the tail there are two claws, resembling those of birds.

These serpents lie hid in thickets, from whence they sally out unawares, and, raising themselves upright on their tails, will attack both men and beasts. They make a loud hissing noise when exasperated; and sometimes winding up trees, will dart down upon travellers, and twist themselves so closely round their bodies, as to despatch them in a very few minutes. Condamine, however, affirms that their bite is not dangerous; for though the teeth are so large as to inspire the beholder with terror, yet the wound they make is attended with no dangerous consequences whatever. Dellon affirms, that they generally haunt desert places; and though they are sometimes seen near great towns, or on the banks of rivers, yet it is generally after some great inundation: he never saw any but what were dead; and they appeared to him like the trunk of a great tree lying on the ground.

To this class of large serpents we may refer the Depona, a native of Mexico, with a very large head and great jaws. The mouth is armed with cutting crooked teeth, among which there are two longer than the rest, placed in the fore part of the upper jaw, but very different from the fangs of the viper. All round the mouth there is a broad scaly border; and the eyes are so large, that they give it a very terrible aspect. The forehead is covered with very large scales; on which are placed others that are smaller, curiously ranged: those on the back are grayish, and along it runs a double chain, whose ends are joined in the manner of a buckler. Each side of the belly is marbled with large square spots, of a chestnut colour, in the middle of which is a spot which is round and yellow. They avoid the sight of man; and, consequently, never do much harm.

Such are the most noted animals of the serpent tribe; but to recount all, would be a vain, as well as useless, endeavour. In those countries where they abound, their discriminations are so numerous, and their colours so various, that every thicket seems to produce a new animal. The same serpent is often found to bring forth animals of eight or ten different colours; and the naturalist who attempts to arrange them by that mark, will find that he has made distinctions which are entirely disowned by Nature: however, a very con-

---

the species of this genus is the Javan snake, which is as large as any boa. It inhabits the rice fields of Java, and feeds usually on birds, rats, &c. Its bite is not venomous. The following cut represents a Python, called

Peron's Python.

The *Bungai*, like the boa, have simple plates under the belly and under the tail. They inhabit the East Indies, where they are called Rock-Serpents. Their length is about seven feet. The following cut represents

a *Banded Bungarum.*

The *Hydras* have the posterior part of the body and tail very much compressed, and greatly raised in the verticle direction, which, giving them the faculty of swimming, constitutes them aquatic animals. They are

common in some latitudes of the Indian seas. The above is a figure of the *Spiral Hydra.*

siderable number might be added to enlarge the catalogue; but having supplied a general history, the mind turns away from a subject, where every object presents something formidable or lothesome to the imagination. Indeed, the whole tribe resemble each other so nearly, that the history of one may almost serve for every other. They are all terrible to the imagination, all frightful to behold in their fury, and have long been considered as a race of animals, between whom and man there is a natural antipathy.[1]

[1] *Supplemental Note on Reptiles.*—This department of animated beings, forming the third class of vertebrate animals, according to the arrangement of Cuvier, has occupied various situations in the classification of authors. Many of this species were known to the ancients. Pliny, in his *Historia Naturalis*, has given all the information, respecting those that were known during his time, which was, however, extremely limited, in comparison to what is our present stock of knowledge. The first of the moderns who increased our knowledge respecting the *Reptilia* was Aldrovandus, a Bohemian nobleman, and a professor of the university of Bologna: he published the first volume of his Natural History in folio, in the 1599, which was continued by his successors, and completed in fourteen volumes, in the year 1640. Gesner, a physician of Zurich, was the next who took up this subject; he published a work entitled a History of Animals, in three volumes folio, which appeared in 1620. To this work he added a treatise on Serpents. He was followed by Topsel, a British author, who published a History of Four-footed Beasts and Serpents in folio, 1718. These several works contain much curious information respecting reptiles, but so mixed up with fable, and the romance of travellers, that the accounts are not to be depended upon, and it is difficult to separate the pure matter from the dross. The animals of this class have in all ages furnished matter for fiction, from the dangerous qualities of many of the species, or the disgusting forms and frightful appearance of others. We are told that the march of the army of Attilius Regulus was arrested by the power of an African serpent, 120 feet long; and the Basilisk was said to possess the power of killing any person who looked at it, with a glance from its eyes.

But it was not until the publication of the *Synopsis Methodica Animalium, Quadrupedum et Serpentini generis*, in the year 1693, by Ray, that we had any distinct classification of reptiles which was worthy of attention. His arrangement consists of three orders; *first*, oviparous animals, with red blood, which respire by means of lungs, and which have a heart consisting of one ventricle. This order includes frogs, divided into aquatic and terrestrial, toads, and tortoises. *Second*, Lizards, and their congeners, including the saurians of Cuvier; and *third*, Serpents, or the ophidians of Cuvier.

The next systematic writer who followed Ray was Linnæus, who arranged this class of animals under the title of *Amphibia* in his *Systema Naturæ:* these he divided into three orders: namely, *Reptilia, Serpents,* and *Nantes,* which last most improperly included the cartilaginous fishes; these were removed to their proper station by Gmelin, who published an edition of the *Systema Naturæ*, with additions, in the year 1758. Linnæus was followed by Klein, who, in 1755, published his *Tentamen Erpetologiæ*, in which he arranged serpents into two orders; *first*, those whose heads are distinct from the body, with an elongated tail; and *second*, those with the head not distinctly developed from the body, and provided with an obtuse tail.

The next author was Laurentini, a physician of Vienna, who published his *Specimen Medicum exhibens Synopsin Reptilium emendatam*, in 1768, in which he divides them into three orders; namely, 1. *Leapers*, including frogs and their congeners; 2. *Walkers*, such as lizards; 3. *Serpents*. But this author entirely omitted tortoises in his classification.

The naturalist whose works are next worthy of notice, is Lacepede, who in 1798—1800, published his *Histoire Naturelle, Generale et Particulière des Quadrupedes ovipares et des Serpentes*, intended as a continuation of the *Histoire Naturelle* of Buffon. His classification differs but little from that of Linnæus, but contains a great mass of new and interesting matter, and he gives more accurate details, and more precise generic distinction than that author.

We now come to Brongniart, whose classification of reptiles far outstripped all those who preceded him. In 1799, he first made known his arrangements, which was published in 1805, under the title of *Essai d'une Classification Naturelle des Reptiles*. This has superseded all other arrangements, and has been followed by Cuvier in his *Regne Animal*. His orders are constructed upon their organization, such as generation and respiration, together with the exercise of the animal function, such as touch, digestion, and locomotion. Founded upon these, he divides the class Reptiles into four orders; viz. 1. *Chelonians*, in which the body is covered with a shield or plate, comprehending the turtles and tortoises. 2. *Saurians*, having the body covered with scales, including crocodiles, and their congeners. 3. *Ophidians*, destitute of feet, such as serpents. *Batrachians*, whose bodies are covered with a naked skin; exemplified in frogs, &c.

In the *Histoire Naturelle des Reptiles* of Latreille, published in Deterville's edition of the *Histoire Naturelle* of Buffon, as also in his *Familles Naturelles du Regne Animal*, published in 1825, he has attempted some trivial changes on the classification of Brongniart; retaining, however, all the principal features of his arrangement untouched.

Duméril, in his *Elemens des Sciences Naturelles*, has also made some changes; but these are unimportant.

Daudin published his *Histoire Naturelle des Reptiles*, in eight volumes 8vo., at Paris, in 1802, 1803. In this elaborate work much curious information is brought forward, and many particular facts, which were before unknown; but in his arrangement he has followed Brongniart, with some slight modification in the genera.

In the Linnæan Transactions and Zoological Journal are some interesting papers on Reptiles by Mr Thomas Bell. His monography of the tortoises having a movable sternum in the second volume of the Zoological Journal, and also his essay on *Leptophina*, a group of serpents, contain some valuable additions to our knowledge of reptiles.

The heart in reptiles is so constructed, that at each of its contractions, only a portion of the blood which it receives is transmitted to the lungs, the remainder of this fluid is returned to circulate again, without having passed into the lungs, and, consequently without having been subjected to respiration; hence it results that the action of oxygen on the blood is greatly less than in mammiferous animals and birds, where all the blood, by passing through their lungs, is exposed to the action of the air. Consequently, as respiration causes the heat in the blood, and gives to the muscular fibre its susceptibility for nervous irritation, the temperature of reptiles is much lower, and their muscular power greatly weaker than that of the mammalia, and birds. Therefore they are said to be cold blooded animals. Their general habits are also much less energetic, almost all their motions consisting of crawling and swimming, and although several species run or leap, at times with considerable facility, yet upon the whole, their actions are sluggish,

and their sensations obtuse, with a slow digestion ; and in temperate countries they pass the winter in an almost constant state of torpidity.

The brain in reptiles is proportionably small, and not so essential to the exercise of their animal and vital functions as to the mammalia and birds ; and their sensations appear to be referred to a common centre, for they continue to live, and exhibit voluntary motions long after being deprived of their brain, and in many instances after the head has been cut off. The connection of the nervous system with the muscular fibre is also less necessary to its contractions, and their muscles preserve their irritability after being severed from the body much longer than in the higher animals. The pulsations of the heart have been known to continue for many hours after being separated from the body; and even without it, the body will move for a considerable length of time. It has been observed that the cerebellum in several of the species is extremely small, which facts agree with their slight propensity to motion.

The smallness of the pulmonary vessels in reptiles enables them to suspend respiration without retarding the circulation of the blood ; this enables them to dive with more facility, and to remain longer under water than quadrupeds or birds. The cells of their lungs are also less numerous, and generally large, in consequence of their having fewer vessels to lodge on their parietes, and the lungs take sometimes the form of simple sacs, scarcely cellular in their structure.

The whole class are provided with a trachea and larynx, yet many of them are incapable of producing articulate sounds.

As their blood is cold, teguments for retaining heat are unnecessary, and instead of these, therefore, they are clothed with scales, or simply with a naked skin.

The females are provided with a double ovary and two oviducts, and the males of several genera are furnished with furcated organs of generation, but the batrachians are destitute of this organ. Those females which couple deposit eggs which are protected by a shelly covering, and those species which do not, produce soft and glary eggs, destitute of any crust. These they abandon after the deposition in some convenient situation ; but there are a few species which carry them about with them. The young is hatched perfect in its form in many species: but there are other species, which, on quitting the ova, have the organization of fishes, and whose form is not perfectly developed until after a certain time has elapsed, when they undergo a complete metamorphosis. This is well exemplified in the frog being hatched as a tadpole. These are provided with branchiæ, or gills, like fishes, and some of the genera retain these organs even after the developement of their lungs. In several of the oviparous reptiles, particularly in the coluber, the young animal in the egg is formed and considerably advanced at the moment it is deposited by the mother ; and there are even some species which may be artificially rendered viviparous, by simply retarding the time of laying the egg, which M. Geoffrey St Hilaire has proved by depriving the colubra of water.

The quantity of respiration in reptiles is not fixed, as is the case with mammalia and birds, but varies with the proportions of the diameter of the pulmonary artery, compared to that of the aorta. Tortoises and lizards, for example, respire much more than frogs, &c. ; and hence results a much greater difference of sensibility and nervous energy than can exist between one mammiferous animal and another, or between birds.

A greater variety of form prevails amongst reptiles than is found among the mammalia and birds, and it is in the production of these forms that Nature seems to have imagined shapes of the most fantastic description, and modifying in every possible manner the general plan which she has prescribed to herself in the vertebrata, and in the oviparous class in particular.

Reptiles are endowed with five senses, but none of them in great perfection. In those species which are covered with scales or plates, the sense of touch is very obtuse ; and in the species which have a naked skin, such as the frog, it is also weak, in consequence of not being adherent to the body, but invelopes it like a bag. In the serpents, the eyes are immovable, and are destitute of eyelids ; and the eyes covered with a corneous substance ; in some genera, three eyelids are distinguishable, while others are destitute of sight. They have no cochlea, and only provided with a small bone under the tympanum. Their nostrils are small, and they appear to have a very weak sense of smell. They have no delicacy of taste, for almost all the species swallow their food entire, and those in which the tongue is soft and flexible, this organ serves chiefly as an instrument for the seizure of their food. None of them have true fleshy lips ; and some, such as the tortoises, are provided with a horny bill, like that of a parrot; others have teeth of various forms, which are not, however, formed for mastication, but to assist in holding their prey: various serpents have hollow fangs, which they can erect at pleasure, when they open their mouths to bite, and these fangs have apertures, from which they inject into the wounds made by them an active and deadly poison. The anal opening in serpents serves for rejected matters, as well as for organs of generation.

The physical construction of reptiles varies considerably in the different orders ; deviating in several essential particulars, to which no general characters will apply. The following is an outline of these particulars.

I. The *Chelonia*, or *Tortoises*, have a heart with two auricles, and a ventricle, divided into two unequal cavities, which communicate with each other. The blood from the body is poured into the right auricle, and from the lungs into the left, but both kinds of blood are partially mixed in passing through the ventricle: their body is inveloped by two plates, or bucklers, formed by the ribs and sternum, supported by four feet. The envelope of the body permits no part to project, except the head, neck, tail, and four feet. The upper shield, which is called the *carpace*, is formed by the ribs, of which there are eight pairs; these are widened and reunited by denticulated sutures, and with plates adhering to the annular portion of the dorsal vertebræ, in such a manner, that all these parts are deprived of mobility. The lower shell, called the *plastron*, is formed of pieces, usually nine or ten in number, analogous to a sternum; and this has been denominated the *sternum* by the more recent writers on natural history. A frame work, consisting of bony pieces, which have been considered as analogous with the cartilaginous portion of the ribs in the mammalia, generally encompasses the upper shell, uniting all the ribs which comprise it. The vertebræ of the neck and tail are alone movable. These two bony envelopes being covered with skin or by scales, the scapula and all the muscles of the arms and neck, instead of being articulated to the ribs and spine, as in other animals, are attached beneath; the same arrangement is found in the bones of the pelvis, and also in all the muscles of the thigh, so that in this respect tortoises have been termed retroverted animals. The vertebral extremity of the scapula is articulated with the shield, and the opposite extremity of the clavicle with the breastplate or sternum, in such a manner, that the shoulders form a ring for the passage of the trachea and œsophagus. A third and larger bony branch, is directed downward and backwards, representing the coracoid apophysis in birds. The lungs are extensive, and situated in the same cavity with the other viscera. The thorax being immovable in the greater number, it is by the action of the mouth that the tortoise respires; this process being effected by keeping the jaws closed, and alternately raising and depressing the *os hyoides*. The first movement permits the air to enter by the nostrils, and the tongue afterwards closing the interior opening, the second movement forces the air into the lungs. Tortoises are devoid of teeth; their jaws are invested by a horny covering, similar to the mandibles of birds, ex-

cept in the Chelids, where they are covered with a skin only. Their tympanum and palatine arch are fixed to the cranium and immovable; the tongue is short and bristled with fleshy filaments; their stomach simple and strong; their intestines of medium length, and destitute of a cæcum. Tortoises lay numerous eggs, which are invested by a hard shell. These are deposited in the warm sand, under the influence of a southern sun, where they are abandoned by the parents, and are hatched in summer by the influence of the atmosphere. The animals of this order possess great tenacity of life, and they have been known to move for several weeks after amputation of the head. They require but little nourishment and can pass whole months, and even years, without food.

II. The *Sauria*, or *Lizards*, have a heart with two auricles, and a ventricle sometimes divided by imperfect partitions and their body covered by scales, supported by four or two feet. The ribs are movable, and partially attached to the sternum, and can be raised or depressed during respiration. The lung extends more or less towards the posterior part of the body; it frequently penetrates very far into the lower part of the abdomen, the transverse muscles of which pass under the ribs, and even towards the neck to clasp it. Those species in which this organ is very large, possess the singular faculty of changing the colours of their skin, according to the excitement produced on them by their wants or passions. Their mouth is invariably provided with teeth, and in most instances, their toes are armed with nails; their skin is covered with scales, more or less compact, and in a few species with scaly granules. All the species have a tail more or less long, which is very thick at the base. Most of them have four legs, but a few have only two. They subsist on animal food. Like the animals of the former order, they deposit their eggs favourably to their being hatched, where they abandon them; the young animal is hatched perfect in its form, and never undergoes any metamorphosis.

III. The *Ophidia*, or *Serpents*, have a heart with two auricles, and are destitute of feet, consequently they are the only order of this class, to which the name reptile is strictly applicable. Cuvier divides this order into three families. In the first, the terms *Anguines*, the teeth and tongue of which are similar to those of the genus Seps, of the preceding order, and the eye is provided with three eyelids. In the second family, or the true serpents, all the genera are destitute of a sternum or the slightest developement of collar bones; the ribs are articulated to each other by a convex and a concave surface, and encompass almost the entire circumference of the trunk. They are devoid of the third eyelid and tympanum. Although their heads are large, the true cranium forms but a small portion of it. Their eyes are fixed, but they are destitute of external ears. Their nostrils are short, and but slightly developed, and are generally situate at the extremity or sides of the muzzle. The Tongue varies much with the species; and although it is soft, moist, long, and forked, it seems rather destined to assist in seizing their prey, than as an organ of taste. The scaly covering with which they are invested, necessarily renders their sense of touch rather obtuse. They change their skin at least once a year. The third family embraces the Naked serpents, or those remarkable animals which form the genus *Cæcilia*. The whole animals of this order are provided with conical and curved teeth, which seem rather fitted for securing their prey, than for gnawing their food. Some of the genera are furnished with previous fangs in the superior jaw, which, when erected, press a gland or sac, in which is a deadly poison, which flows through the tube, and is injected into the wounds pierced by the fangs. In many species, the jaws are united in the middle, which renders the mouth susceptible of considerable dilatation, and enables them to swallow their prey entire. The process of digestion is extremely slow in all the animals of the order; and after feeding, they assume a lethargic condition, in which they continue frequently for weeks. Serpents possess a heart with two auricles and one ventricle, divided into two compartments, and they have only a single lung. Their circulation is slow. The only sound emitted by serpents is a hissing noise. The eggs are usually protected by a covering, or shell, which is somewhat calcareous; when laid, they are commonly united like a string of beads, or in the form of a wreath. Some species are, however, viviparous.

IV. The *Batrachia* are provided with a heart which has but one auricle, and a single ventricle; their body is naked; most of the species are metamorphosed from the form of a fish, breathing by the branchiæ, or gills, to that of a quadruped, breathing by lungs, when in a perfect condition. In two genera, however, namely, the *Serena* and *Proteus*, they retain the gills. In the former condition the aorta leading from the heart is branched into as many stems as there are gills. In those species, the branches which lead to the gills are all obliterated except two, which unite in a dorsal artery, give off each a small branch to the lung. This fact, as observed by Cuvier, is the circulation of a fish, changed into that of a reptile. All the Batrachian reptiles are destitute of scales, shields, or nails on their toes; the whole body and limbs being covered only by a naked skin. Their eggs have a membranous covering. In some species fecundation is performed during the extrusion of the eggs; in others they are deposited in some favourable situation, and afterwards impregnated in the same manner as the spawn of fishes.

ORDER I.—CHELONIA.

Heart provided with two auricles; body inveloped in two bony plates or shields, which are formed from the ribs and sternum; furnished with four feet.

Subdivision I.—Land Tortoises.

Testudo.
Testudo radiata, the Radiated Tortoise. Pl. 25, fig. 1.

Subdivision II.—Freshwater Tortoises.

Emys Europœa, European Emys.
Emys picta, the Painted Tortoise, pl. 25, fig. 2.
Cistuda.
Cistuda clausa, the Close Tortoise, pl. 25 fig. 3. Inhabits North America.
Chelonura Serpentina.

Subdivision III.—Sea Tortoises.

Chelonia.
Chelonia imbricata, the Hawk-billed Turtle. Pl. 25, f. 4. Inhabits the seas of the Torrid Zone.
Chelys fimbricata.
Trionyx feroœ.

ORDER II.—SAURIA.

Body elongated, invested with scales, generally furnished with four feet; toes armed with claws, at least in part; tail more or less long; mouth generally with numerous teeth.

Family I.—Crocodilidæ.

Body elongated, covered with square scales, of which the upper and under are the largest, and those above, raised into a ridge or corina in the middle; provided with four feet, with five toes before, and five behind, the three interior armed with nails, and all of them more or less united by membranes; each jaw provided with a single row of acute teeth; tongue fleshy, depressed, and almost entirely attached to the lower jaw; tail compressed, and provided above with a strongly dentated crest. The whole animals of this family are large, their bodies are covered with square, or oblong scales, of which those above form elevated lines, which are raised into a double crest on the tail. Their heads are long in proportion to the body, and ponderous; their jaws are articulated behind the cranium. Their nostrils form an elongated canal, which has its origin in the throat, and terminates at the point of the muzzle, where it is provided with a semilunar orifice, which it can open or shut at pleasure. Their eyes are furnished with three eyelids; the exterior ear is very small and can be closed at the will of the animal, by means of two fleshy coverings; under the throat there are two glands which secrete a musky substance, through small orifices. The crocodiles are the only family of this order which are destitute of clavicles, or collar bones; but their coracoid

apophysis is attached to the sternum, as in all the others.

Gaviala.

Gaviala Gangetica, the Gangetic Crocodile. Pl. 25, f. 6. Grows from twelve to eighteen feet in length. Inhabits the rivers of India, and is very numerous in the Ganges.

Crocodilus.

Crocodilus vulgaris, the Common Crocodile. Pl. 25, f. 5. This animal grows to the great size of from twenty to thirty feet in length.

Alligator.

Alligator sclerops, the Common Alligator. Pl. 25, f. 7. Grows from eighteen to twenty feet in length. Inhabits Guiana and Brazil. Crocodile's Egg, f. 12.

Family II.—Lacertinidæ.

The members of this family are characterised by a slender extensible tongue, terminating in two long filamentary processes like the viper. Their bodies are elongated, and their motions rapid. All their feet are provided with five toes, armed with nails, which are separate and unequal, particularly those on the hind feet. Under the abdomen and around the tail, their scales are disposed in traverse and parallel bands. Their tympanum is on a level with the head; the eyes are protected by a produced skin, which is longitudinally cleft, and which shuts by a sphincter. Under the anterior angle there is a rudimentary third eyelid. Their false ribs do not form a complete circle.

Monitor.

This genus is divided into sections. 1. With a compressed and carinated tail. 2. Tail nearly round, with a dentated ridge above. 3. Tail nearly round without a carinated ridge above. Of the last section is the land Monitor, which inhabits Egypt, and is trained by the jugglers of Cairo, to perform tricks, they having previously extracted their teeth.

Dracæna.

Dracæna Guianensis. Pl. 25, f. 10. Body reddish brown, blended with green. From four to six feet long. Inhabits Guiana. Its flesh is eaten by the natives. There are two sections of this genus, viz. 1. With a carinated tail. 2. With the tail smooth and compressed towards the point.

Teius. There are two sections of this genus. 1. Tail carinated. 2. Tail smooth; compressed towards the point.

Teius Teguixin, the Teguixin Lizard. Pl. 25, f. 15. Body black, spotted with blue above, and of a bluish hue below. Nearly six feet long. Inhabits Brazil.

Amevia.

Amevia lemniscata, the Striped Amevia. Pl. 25, f. 11. Inhabits Africa.

Lacerta.

Tachydromus.

Family III.—Iguanidæ.

Lizard shaped; with a thick, fleshy, and not extensible tongue, which is notched at the point.

Cordylus. Head simple.

Stellio. Head inflated behind.

Amblyrhynchus. Head short and truncated.

Agama. With a tumid head.

Agama muricata, the Muricated Agama. Pl. 25, f. 8.

Trapelus. Head tumid; scales small and destitute of spines. The only species of this genus is the Egyptian Trapelus, which has the property of changing the colour of its skin, in a still more remarkable degree than the cameleon.

Calotes. Upwards of a foot long. Inhabits New South Wales.

Lophyrus.

Basilicus.

Basilicus mitratus, the Mitred Basilisk. Pl. 25, f. 9. Inhabits Brazil. The flesh is eatable. There are only two species of this genus known, that above described, and the Aboyna Basilisk; they are disagreeable looking animals, but are entirely destitute of the deadly properties attributed by the ancients to the fabulous animal of that name.

Draco.

Draco lineatus, the Flying Dragon. Pl. 25, f. 16. Never exceeding nine or ten inches in length. Inhabits Asia and Africa.

Iguana.

Iguana vulgaris, the Common Guana. Pl. 25, f. 13.

Polychrus. Like the chameleon, the animals of this genus have the power of changing colour.

Anolius. There are two sections of this genus. 1. With the tail crested. 2. With the tail rounded.

Family IV.—Geckotidæ.

Gecko. Head considerably depressed; eyes large; tongue fleshy, but not extensible; jaws provided with a series of small close-set teeth, body flattened, covered above with small shagreen-like scales, and frequently tuberculate; below the scales are smaller, flat, and imbricated; tail with circular folds; toes widened their whole length, or at the extremity only, with the skin plated or scaly. The animals of this genus have the power of ascending perpendicular walls, and they can even walk on ceilings. Cuvier divides the genus into the following subgenera:—

I. *Platydactyli.*
II. *Hemidactyli.*
III. *Thecadactyli.*
IV. *Ptyodactyli.*

Ptyodactyli caudiverbera, the Scalloped-tailed Gecko. Pl. 25, f. 14. Inhabits Arabia.

V. *Phyluri.* Animals similar in form to the Gecko.

Family V.—Chamæleonidæ.

Chamæleon. Tongue fleshy, cylindrical, and extremely extensible; teeth trilobed; eyes large, but nearly covered by a skin, and with separate movements; destitute of an external ear; occiput pyramidal; body compressed, back edged or carinated, the whole covered with small shagreen-like granules; all the feet furnished with five toes, which are divided into two sets: the one with three toes, and the other with two, each united to the nails by a membrane; tail round and prehensile.

Chamæleon vulgaris, the Common Chameleon. Pl. 25, f. 17. Twenty-two inches long, including the tail. Inhabits India and Africa.

Family VI.—Scincidæ.

Tongue not extensible; body covered with equal-sized imbricated scales; legs short.

Scincus.

Scincus occiduus, the Galley wasp. Pl. 25, f. 26. From twelve to eighteen inches in length. Inhabits Jamaica.

Seps.

Seps palustris, the Great Water Newt. Pl. 25, f. 18. Inhabits stagnant waters in Europe.

Bipes.

Bipes apus, the Apoidal Apus. Pl. 25, f. 27. Inhabits the shores of the Volga.

Cholcides.

Chirotes.

Order III.—Ophidia.

Body greatly cylindrical, elongated, generally covered with scales, and destitute of feet.

Family I.—Anguines.

With small teeth nearly of equal size; tongue uniformly notched; ribs more or less united, being a substitute for a sternum: eyes provided with three eyelids.

Ophisaurus.

Anguis.

Acontias.

Family II.—Serpentes.

The species of this family are very numerous, and are all destitute of a sternum and scapular bones, and want the third eyelid, and also the tympanum. Cuvier subdivides them. The first subdivision includes those which have the lower jaw supported by a tympanal bone articulated to the cranium; the two branches of this jaw fixed before, and those of the upper jaw to the cranium, and to an intermaxilliary bone; which

prevents their dilatation. The eyes are small; the body cylindrical and covered with scales; the tongue short; the trachea long; the heart situate far behind, and provided with a single lung only.

I.—JAWS NOT DILATABLE.

Amphisbæna.
Amphisbæna fuliginosa, the Shining Amphisbæna. Two feet long. Inhabits Ceylon. Pl. 25. f. 25.
Typhlops.

II.—JAWS DILATABLE.

(1.) *Body Cylindrical, with Short Tongue.*

Tortrix.

(2.) *Occiput more or less gibbous; Tongue Forked and Extensible.*

Boa.
Boa canina, the South American Boa. Pl. 25, f. 24. Inhabits South America. In this genus are included the largest serpents, some of which reach from thirty to forty feet in length.
Erix.
Erpeton.

(3.) *Shields under the tail ranged in pairs.*

Python.
Hurria.
Dipsas.
Coluber.
Dryinus.
Leptophis.
Acrochordus.

(4.) *Serpents provided with Poison Fangs.*

The teeth in this section are fewer in number in the exterior row, than in the preceding section; the first of those teeth is larger than the others, it is hollow and conducts the poison from the sac into the wound.
Pseudoboa.
Trimeresurus.
Hydrophis.
Pelamis.
Chersydrus.

(5.) *With isolated Fangs.*

Crotalus.
Crotalus horridus, the Common Rattlesnake. Pl. 25, f. 23. From four to six feet long. Inhabits America.
Scytalus.
Acanthophis.
Langaha.

(6.) *Abdomen with Transverse Plates, divided into two under the Tail.*

Trigonocephalus.
Plataurus.
Naia.
Elaps.
Cobra.
Vipera.

Family III.—Naked Serpents.

Cæcilia. Eyes extremely small; body cylindrical, skin naked, with longitudinle folds.

ORDER IV.—BATRACHIA.

Heart with one auricle; body covered with naked skin; lungs two, in the mature condition, but provided with branchiæ, like fishes, in their early state.
Rana.
Rana taurina, the Bull Frog. Pl. 25, f. 21. Inhabits North America.
Hyla.
Bufo.
Bufo fuscus, the Brown Toad. Pl. 25, f. 22. Inhabits Germany.
Pipa.
Salamandra.

This genus is divided into sections:

1. *Terrestial*—Tail rounded in the adult state.
2. *Aquatic*—Tail compressed.

Proteus.
Proteus anguinus, the Proteus. Pl. 25, f. 20. This is the only species of the genus, and has several remarkable peculiarities. Besides being furnished with lungs, it has three tufted branchiæ on each side, which it seems to retain through life. The skeleton is nearly allied to that of the salamander, but is provided with more numerous vertebræ; and the general form of the cranium is considerably different. It inhabits dark subterraneous streams, in Carniola; and is the only animal known to exist in such situations.
Siren. Provided with a short thick adherent tongue; having both persistant branchiæ and interior lungs; body elongated, cylindrical, and furnished with a compressed tail; it has two feet only, which are placed forwards on the body, each provided with four toes.
Siren lacertina, the Siren. Pl. 25, f. 19. From two to three feet long. Inhabits the marshes of South Carolina. There is but one species of this remarkable genus: which, like the Proteus, retains during its life, three free branchial tufts, situate on each side of the neck, while it has at the same time lungs for breathing, formed in the ordinary manner.

HISTORY OF INSECTS, &c.

BOOK I.

INSECTS OF THE FIRST ORDER.

CHAP. I.

OF INSECTS IN GENERAL.[1]

HAVING gone through the upper ranks of Nature, we descend to that of insects; a subject almost inexhaustible, from the number of its tribes, and the variety of their appearance. Those who have professedly written on this subject, seem to consider it as one of the greatest that can occupy the human mind, as the most pleasing in animated nature.—"After

[1] *Insects.*—The following is Blummenbach's description of Insects. We have already given his account of Birds and of Fishes.

Insects (he says) derive their name from the circumstance, that, at least in the perfect state, the head, thorax, and abdomen are separated from one another, as though by incisions, nay, in many cases, seem as though connected only by a thread. Besides this, however, they are distinguished, with a few exceptions among the Genera of the Apterous Order, by peculiar and often very sensible organs, which, in the perfect state, are affixed to the head, (*Antennæ* or *feelers*,) which are always articulated at the root and, in addition, often formed into several joints; and lastly, by their horny, jointed legs, the number being always greater than in other animals; in perfect insects at least six, and in many instances, as many as one hundred and fifty, &c.

These characters excepted, insects, in general, have but little in their external appearance that is common to all. The almost incalculable number of species, the endless variety of offices they are destined to perform, and the consequent difference of their modes of life, wants, &c. require an extreme diversity in their forms, in which respect, as well as in the inequality of their sizes, we find remarkable contrasts.

Even their external coverings are much more diversified than is the case among other animals. Many are protected by a horny coat, composed of several portions, moving on one another like the pieces of a gauntlet, which serve to secure them from the effects of various accidents, and to compensate the deficiency of bones, which in other animals afford attachment to muscles, &c. Many are covered with fine hairs, and in butterflies, &c. the wings with little feathers or rather scales, which are occasionally of most beautiful colours: indeed, I may remark, that many animals of undescribable beauty are included in this class.

Insects also differ materially from other animals, with regard to the disposition of their organs of sense, and, probably, their mode of sensation, insomuch that, many naturalists have refused them certain of our external senses, as hearing and smell; but without justice, as the former clearly exists in many which emit certain sounds, as an enticement at the time of breeding, and the latter in a still greater number, which are capable of smelling out their food, though hidden.

The eyes of insects are particularly remarkable, and with respect to their structure, are of two kinds. The first are large hemispheres, mostly composed of thousands of facets, but in some instances, of numerous conical points, and covered on the inner surface with a layer sometimes glittering, sometimes variegated. Such are found in most winged insects, but also in many Aptera, as the lobster, &c. Those of the second kind (stemmata, ocelli,) are simple, small, and vary as well in number as position. Eyes of the first kind seem calculated for seeing at a distance; of the second, for looking at near objects; at least it may be supposed so, as we find that butterflies, in their winged perfect state, have such large, compound, telescopic eyes, whilst as caterpillars, they have small myopic ones. Only a few insects, crabs, for instance, can move their eyes.

The Antennæ (feelers) which vary much in different species, in many instances even according to the sex, and which many naturalists have supposed to be organs of smell, taste, &c., seem to be nothing more than their name implies—organs of feeling, probes, which are of great importance to insects on account of their hard, insensible covering, and the immobility of their eyes in most instances. They appear to possess their most acute feeling in the Antennæ, as man has in the tips of the fingers; and as for the most part they live in darkness, supply the want of light by this contrivance. On the other hand, the purposes of the *Palpi*, placed near the organs of mastication, found in almost all insects, and considered by some naturalists to be organs of sense, are as yet undetermined.

In their internal structure also, insects differ materially from red-blooded animals.—For instance, what has been considered as a heart in caterpillars, is a long canal of unequal width, placed along the back, but without any vessel arising from it; consequently, the nutrition of these insects must be effected in a peculiar manner, totally different from that of red-blooded animals. On

an attentive examination," says Swammerdam, "of the nature and anatomy of the smallest as well as the largest animals, I cannot help allowing the least an equal, or, perhaps, a superior degree of dignity. If, while we dissect with care the largest animals, we are filled with wonder at the elegant disposition of their parts; to what a height is our

---

the other hand, they are provided with an incalculable number of air-vessels of an astonishingly delicate structure, and with numerous muscles, differing, however, as well in form as in colour, from those of red-blooded animals.

Although insects stand in need of the exchange of carbon of oxygen to effect the continuance for life, there are but few, as crabs, grasshoppers, many cicadæ and chafers, in which a motion resembling respiration can be observed. Insects in general breathe, not by the mouth, but by many *spiracula**. The greater number of them can live in a vacuum much longer than red-blooded animals, and many in mephitic atmospheres so fatal to others, and in which animal and vegetable substances become putrid, as carburetted hydrogen gas, &c.

The abode of insects on and under the surface of the earth, is much less limited than that of the other classes of animals. They are found on almost all warm-blooded animals, and even the larger insects, as bees, chafers, &c., are infested by peculiar kinds of lice. There are but few plants, also, (such as perhaps, the yew, savine, and most tree-mosses,) which do not serve for the abode and support of known insects. Many again, as the oak, are frequented and inhabited by more than a hundred distinct species. Generally, however, as insects are diffused over the earth, the residence of individual species is not less frequently limited to a very small number of animals and plants, or even particular parts of them.

Only a few insects live in a social state, affording mutual assistance in their labours. The greater number follow their pursuits singly: many, as spiders, live in society when young, but afterwards separate and live in a state of solitude, seeing creatures of the same species only at the time of pairing.

The remarkable edifices and habitations, which so many insects are capable of executing, have been already mentioned in speaking of instinct. There are but few creatures of this class which do not, at least once in their life, give proofs of this natural power of construction; either, as the cloth-moth and water-moth, form a habitation in their complete and larva state; or, like others, spin and prepare a receptacle to contain them during their metamorphosis and death-like sleep; or like the lion-ant, dig pits; and like the spider, weave webs for their prey; or like many species of the genus *Dyticus*, and some spiders, form bags or nets for the security of their posterity, and in which they deposit their eggs. Many of those which live in communities, build common residences, by their united powers, and under the guidance of an extremely regular, geometrical, innate instinct.

As to the kind of nourishment in insects, it is easy to see that it is not, as in most red-blooded animals, calculated merely for the preservation of the individual, but more particularly for the purpose of *consuming* organized matter. Insects must eat, not solely to satisfy hunger, but also to destroy carrion, to annihilate other insects, to extirpate weeds, &c.—An admirable provision, to the execution of which, besides the almost incalculable number of species, the extremely rapid multiplication of many, the unexampled voracity of others, and the quickness with which digestion is carried on in their very short intestinal canal, all tend to contribute. Thus it is known that a caterpillar will in twenty-four hours consume more than three times its own weight.—The organs of mastication in insects are more diversified than in any other class of animals: many are provided with jaws, having teeth and moving laterally; others, with a horny, pointed snout, (*rostrum*) for boring; others with a fleshy snout having a wide opening, (*proboscis*); and others with a tongue, so called, rolled into a spiral shape.

Some insects are secured from the attacks of their enemies by their deceptive form; others by having the same colour as the plants on which they live, and consequently being less readily noticed; others, by the powerful smell which they can diffuse in case of necessity; others by their social mode of life; others again by their astonishing strength, &c. Many are provided with weapons, as horns like forceps or nippers, or with stings and venom.

In the mode of propagation of insects there are also many peculiarities. Thus the two sexes in one and the same species are often so extremely different in form that they seem like animals of distinct kinds: in bees, and many similar insects, the greater number is without sex; that is to say, they are themselves produced without being destined in the ordinary course of nature for generation or impregnation.

This peculiarity extends in different insects to the mode of copulation. In not a few species, for instance, it is effected in flying, and many possess wings only during the short season of breeding. In general, the greater number live in a state of compulsory monogamy, inasmuch as they are incapable of copulating more than once in the course of life: death is with them so inevitable a result of their first copulation, that life may be prolonged by delaying the period of sexual connection.

Among other peculiarities of the business of propagation in insects, many, as the cochineal-worm, the land-flea, become of an enormous size during pregnancy: thus, in the white ant, it has been calculated that the abdomen of the female, when about to lay her eggs, is 2000 times larger than previous to impregnation.

Most insects lay eggs, which the mother, by a truly wonderful instinct, always deposits precisely in the situations best adapted for the future progeny. Many, for instance, lay their eggs in the bodies of living insects of other kinds, as in caterpillars, pupæ, &c.; or even in the eggs of other kinds of insects. The eggs of insects are occasionally, particularly among butterflies, of very various and remarkable form and appearance, and when deposited by the mother in the open air, are covered with a kind of varnish, protecting them from the destructive influence of rain and other accidents. Some few insects are viviparous, and many, as the plant-lice (Aphides), propagate in both ways.

A very remarkable phenomenon, almost confined to this class of animals, or at least much less striking in the others, is their metamorphosis. There is not any winged insect which escapes from the egg as such, but all, as well as many insects which have not wings, must first undergo a kind of change at certain periods of their existence. By this, not only their external form, but also at the same time their internal structure, contrary to common opinion, is altered in a certain degree, a circumstance which by no means coincides with the supposed pre-existence of pre-formed germs.

If the moth existed already formed in the caterpillar, we should at least expect that similar moths should be produced by similar caterpillars. But many American caterpillars, which resemble European ones in the closest manner posible, give origin to moths having totally dif-

* On the other hand, this class, in proportion to its vast number of species, contains but few aquatic animals: and of these, but very few exist in the ocean, which forms the abode of by far the greater number of species in the preceding and succeeding classes.

astonishment raised, when we discover all these parts arranged in the least in the same regular manner! Notwithstanding the smallness of ants, nothing hinders our preferring them to the largest animals; if we consider either their unwearied diligence, their wonderful strength, or their inimitable propensity to labour. Their amazing love to their young is still more unparalleled among the larger classes. They not only daily carry them to such places as may afford them food; but if, by accident, they are killed, and even cut into pieces, they, with the utmost tenderness, will carry them away, piecemeal, in their arms. Who can show such an example among the larger animals, which are dignified with the title of perfect? Who can find an instance in any other creature, that can come in competition with this?"

Such is the language of a man, who, by long study, become enamoured of this subject; but to those who judge less partially, it will be found that the insect tribe, for every reason, deserve but the last and lowest rank in animated nature. As in mechanics the most complicated machines are required to perform the nicest operations, so in anatomy the noblest animals are most variously and wonderfully made.—Of all living beings, man offers the most wonderful variety in his internal conformation; quadrupeds come next, and other animals follow in proportion to their powers or their excellencies. Insects seem, of all others, the most imperfectly formed: from their minuteness, the dissecting knife can go but a short way in the investigation; but one thing argues an evident imperfection, which is, that many of them can live a long time, though deprived of those organs which are necessary to life in the higher ranks of nature. Many of them are furnished with lungs and a heart, like nobler animals; yet the caterpillar continues to live, though its heart and lungs, which is often the case, are entirely eaten away.

But it is not from their conformation alone, that insects are inferior to other animals, but from their instincts also. It is true that the ant and the bee present us with very striking instances of assiduity; but how far are theirs beneath the mark of sagacity exhibited in the hound or the stag! A bee, taken from the swarm, is totally helpless and inactive, incapable of giving the smallest variation to its instincts: it has but one single method of operating, and, if put from that, it can turn to no other. In the pursuits of the hound, there is something like a choice; in the labours of

---

ferent forms:—and on the other hand, many remarkably similar moths of both these parts of the world, are developed from caterpillars altogether unlike.

Insects which undergo metamorphosis are called *Larvæ*, whilst in the state in which they escape from the egg. They are mostly very small on their first appearance, so that a full grown caterpillar of the willow moth for instance, is 72,000 times heavier than when it issues from the egg. On the other hand, they grow with great rapidity, so that as an example, the maggot of the meat-fly, at the end of twenty-four hours, is 155 times heavier than at its birth. Some larvæ have feet, as caterpillars and the grubs of chafers; others have not, as maggots: none have wings. In this state also they are incapable of propagating; they merely feed, increase, and change their covering several times.

The form into which the larva is converted is called nympha. Many can move about and take food when in this state. Others, on the contrary, are covered up, as pupæ (chrysalis, Aurelia), and pass this portion of their life in a state of torpor without eating or moving.

During the time, however, that the creature thus lies insensible and torpid within its coverings, a great change is going forward, by which it quits the larva-state, and is enabled to leave its prison as a perfect insect (*Insectum declaratum, imago*). Many insects finish this last portion of their existence in a very short time. Several, when they break from the coverings of the larva-state are unprovided with a mouth, and cease to eat or grow. These two functions of all organized bodies they performed while *larvæ;* a third only remains—to propagate the species, and then to give way to their posterity and perish.

The immediate utility of insects to man, is but limited; but, on the other hand, the parts which these small and unnoticed animals perform in the general economy of nature, is in an equal degree varied and incalculable. Some destroy numerous kinds of weeds in the bud, or extirpate them when full grown. Another extremely useful object is effected by many insects which feed on carrion, live in dung, &c., and by that means destroy, disperse and change noxious animal substances; on the one hand, obviating the infection of the air, and on the other, promoting the fertilization of the earth. It is in this way, for instance, that flies are so serviceable in warm climates. So again, there are innumerable insects which effect the impregnation of plants in a very remarkable manner, as a species of *Cynips* is employed for the artificial fructifications of the fig. Various kinds of insects are used as baits for fishing. Many animals of this class, as crabs and some kinds of locusts, are eatable. So also is the honey of bees, from which mead is prepared in many parts of Europe and Africa. Silk is employed for clothing and many other purposes. Several insects afford excellent dyes, as cochineal, &c. Galls are employed for ink,—wax for lights, and other purposes. Lac, which is the product of certain Indian species of coccus, is employed to make varnish, sealing-wax, &c. As medicines, we have spanish flies, wood-lice, ants—the oil-beetle, recommended in hydrophobia, and many beetles for relieving toothache.

Great as is the utility of insects, the injury done by many is also very considerable. Many are noxious to the products of the earth in general, cause scarcity, or as locusts, destroy every thing in their course. Some are especially injurious to corn; others, as caterpillars, grubs, &c., to garden-plants, or fruit-trees; the various species of coccus, to orange-trees in particular; the larvæ of some species of dermestes, &c. to forest trees; ants, &c. to meadows; cock-roaches, to victuals; the white ants, &c. to furniture; moths to woollen goods, fur, &c.; the larvæ of many small insects, to books, collections of natural history, &c. Lastly, some kinds of vermin infest man, horses, sheep, fowls, other domestic animals, and even other serviceable insects, as bees, silk-worms. Others again, as scorpions, are formidable by their venom.

the bee, the whole appears like necessity or compulsion.

If insects be considered as bearing a relation to man, and as assisting him in the pleasures or necessities of life, they will, even in this respect, sink in the comparison with the larger tribes of nature. It is true that the bee, the silk-worm, the cochineal fly, and the cantharides, render him signal services; but how many others of this class are either noxious or totally unserviceable to him? Even in a country like ours, where all the noxious animals have been reduced by repeated assiduity, the insect tribes still maintain their ground, and are but too often unwelcome intruders upon the fruits of human industry. But in more uncultivated regions, their annoyance and devastations are terrible. What an uncomfortable life must the natives lead in Lapland, and some parts of America, where, if a candle be lighted, the insects swarm in such abundance, as instantly to extinguish it with their numbers; where the inhabitants are obliged to smear their bodies and faces with tar, or some other composition, to protect them from the puncture of their minute enemies; where, though millions are destroyed, famished millions are still seen to succeed, and to make the torture endless!

Their amazing number is also an argument of their imperfection. It is a rule that obtains through all nature, that the nobler animals are slowly produced, and that nature acts with a kind of dignified economy; but the meaner births are lavished in profusion, and thousands are brought forth merely to supply the necessities of the more favourite objects of creation. Of all other productions in nature, insects are the most numerous. Vegetables that cover the surface of the earth, bear no proportion to their multitudes; and though, at first sight, herbs of the field seem to be the parts of organized nature produced in the greatest abundance; yet, upon minuter inspection, we shall find every plant supporting a number of scarcely perceptible creatures, that fill up the various stages of youth, vigour, and age, in the compass of a few days' existence.

All other animals are capable of some degree of education; their instincts may be suppressed or altered: the dog may be taught to fetch and carry; the bird to whistle a tune; and the serpent to dance: but the insect has but one invariable method of operating; no arts can turn it from its instincts; and, indeed, its life is too short for instruction, as a single season often terminates its existence.

For these reasons, the insect tribe are deservedly placed in the lowest rank of animated nature; and, in general, they seem more allied to the vegetables on which they feed, than to the nobler classes above them. Many of them are attached to one vegetable, often to a single leaf; there they increase with the flourishing plant, and die as it decays; a few days fill up the measure of their contemptible lives; while the ends for which they were produced, or the pleasures they enjoyed, to us at least, are utterly unknown.

Yet while I am thus fixing the rank of a certain class of animals, it seems necessary to define the nature of those animals which are thus degraded. Definitions in general produce little knowledge; but here, where the shades of nature are so intimately blended, some discrimination is necessary to prevent confusion. The smallness of the animal, for instance, does not constitute an insect; for then, many of the lizard kind, which are not above two inches long, would come under this denomination; and if the smaller lizards, why not the crocodile? which would be a terrible insect indeed! In the same manner, smallness, with a slow creeping motion, does not constitute an insect; for, though snails might be called insects, with the same propriety the whole tribe of sea shell-fish would then have equal pretensions; and a very troublesome innovation would be brought into our language, which is already formed. Excluding such animals, therefore, from the insect tribe, we may define insects to be *little animals without red blood, bones, or cartilages, furnished with a trunk, or else a mouth, opening lengthwise, with eyes which they are incapable of covering, and with lungs which have their opening on the sides.* This definition comprehends the whole class of insects, whether with or without wings; whether in their caterpillar or butterfly state; whether produced in the ordinary method of generation between male and female, or from an animal that is itself both male and female, or from the same animal cut into several parts, and each part producing a perfect animal.

From hence it appears, that in this class of animals there are numerous distinctions, and that a general description will by no means serve for all. Almost every species has its own distinct history; and exhibits manners, appetites, and modes of propagation, peculiarly its own. In the larger ranks of existence, two animals that nearly resemble each other in form, will be found to have a similar history; but here insects almost entirely alike will be often found perfectly dissimilar, as well in their manner of bringing forth and subsisting, as in the changes which they undergo during their short lives. Thus, as this class is prolific beyond computation, so are its varieties multiplied beyond the power of description. The attempt to enumerate all the species of a fly or a moth would be very fruitless; but to give a history of all would be utterly impracticable: so various are the appetites, the manners, and the lives of this humble class of

beings, that every species requires its distinct history. An exact plan, therefore, of Nature's operations in this minute set of creatures, is not to be expected; and yet such a general picture may be given, as is sufficient to show the protection which Providence affords its smallest as well as its largest productions, and to display that admirable circulation in nature by which one set of living beings find subsistence from the destruction of another; and by which life is continued without a pause in every part of the creation.

Upon casting a slight view over the whole insect tribe, just when they are supposed to rouse from their state of annual torpidity, when they begin to feel the genial influence of spring, and again exhibit new life in every part of nature, their numbers and their varieties seem to exceed all powers of calculation, and they are indeed too great for description. When we look closer, however, we shall find some striking similitudes, either in their propagation, their manners, or their form, that give us a hint for grouping several of them into one description, and thus enabling us to shorten the labour of a separate history for every species. Swammerdam, Reaumur, and Linnæus, have each attempted to abridge the task of description, by throwing a number of similar animals into distinct classes, and thus making one general history stand for all. I will avail myself of their labours; and uniting their general distinctions, throw the whole class of insects into four separate distributions, giving under each the history of every species that seems to me considerable enough to deserve our notice. Thus our labour will be shortened; and the very rank in which an insect is placed, will, in some measure, exhibit a considerable part of its history.[1]

In our cursory inspection of the insect tribe, the first animals that offer themselves are those which want wings, that appear crawling about on every plant, and on every spot of earth we

[1] *Sketch of the History of Insects.*—The observation of this numerous, diversified, and interesting class of beings, and, consequently, the origin of entomological science, must necessarily have been coeval with the creation of man. About five hundred years before Christ Hippocrates wrote upon insects. Aristotle describes them as consisting of three parts—head, trunk and abdomen: he then speaks of what he calls *tribes* of insects, dividing them, from their mode of progression, into those that walk and those that fly, noticing and commenting on their wings, proboscis, antennæ, and feet, carefully observing the latter, and exhibiting in this, as in every other department of zoology, that accuracy which so eminently distinguished the philosophical preceptor of Alexander the Great. Pliny is the next author of any note whose attention seems to have been directed to the study in question, for, in his eleventh book, he speaks of various bees, wasps, &c. From this period, down to 1519, when the work of Albertus Magnus upon insects was published, the science made a silent but certain progress. Its advance in the succeeding thirty years is visible in the efficient attempt at a better system of classification than had hitherto prevailed, in the *De Animalibus Subterraneis* of the last mentioned author, in 1549. He there divides insects into three classes—those that walk, those that fly, and those that swim, describing several species of each class. In 1552, Wotton published his *De Differentiis Animalium*, and was followed by numerous writers on the subject of insects, whose books possessed more or less merit: some of them were illustrated with figures, and all tended to render the study more worthy of the name of a science. We may mention in particular the folio of the learned and liberal Aldrovandus, 1602, and Mouffet's *Insectorum Theatrum*. The *Experimenta*, &c. of Redi, 1671, also deserves especial attention for its triumphant refutation of the then popular error of equivocal generation—an error whose origin is buried in the remotest antiquity, upheld by the ancient philosophers, and not even yet eradicated from the minds of the common people. Redi demonstrated the fact, that every living animal is derived from an egg, deposited by a parent every way similar to itself.

Previous to this, in 1669, the great work of Swammerdam—*Historia Insectorum Generalis*—was given to the public, but was utterly neglected until the death of the author, in 1680, when it was instantly discovered to be of such value as to demand a translation. No bookseller could be found who would risk the expense of printing the *Biblia Naturæ*, a second work from the same pen, until it accidentally fell into the possession of the learned Boerhaave, who published it, together with the life of Swammerdam, in 1738. In that book, which is still considered as one of the most valuable we possess on the anatomy of insects, he divides them into the four following classes:—1. those whose characters are constant, undergoing no change whatever, and which preserve for life the form in which they leave the ovum; spiders, &c.: 2. those which, on their liberation from the ovum, have the appearance of an insect without wings, but otherwise completely formed, and that pass into the state of a nymph or chrysalis, from which they issue provided with wings, and fitted for continuing the species; dragon-flies, &c.: 3. those which, having existed in the ovum in a disguised form, leave it under the appearance of an insect (caterpillar), which feeds and increases in size, while the various parts of the new animal, into which it is to be converted, are forming under its skin, and finally becomes a nymph; moths, butterflies, &c.: 4. those which, having arrived at maturity, do not divest themselves of their skin, but pass into the chrysalis state under it, remaining there till the metamorphosis is completely effected, when, quitting both skins at once, they come forth in their final and perfect form; ichneumons, &c.

Malpighi and Vallisnieri also enriched the science with the results of their observations, in common with others of less note. The *Mémoires*, &c., of Perrault (Paris, 1671), Lister's book on spiders, the *Historia Animalium Angliæ*, &c., (1678), and those of Ferrand, Mollerus, and Berelio, all tended to the same result. In 1685, a Latin edition of the works of Goedart was published by Dr Lister, just named, a learned entomologist of that period, and physician to queen Anne, who gave a new arrangement to the materials collected by his industrious though not very acute author, who was more of a collector and painter of insects than a scientific observer. In that work, Lister establishes ten classes of Insects:—1. moths with erect wings, or diurnal butterflies; 2. moths with horizontal wings, the perfect insect of the caterpillar, called the *geometra* by Goedart; 3. moths with deflected wings; 4. libellulæ; 5. bees; 6. beetles; 7. grasshoppers; 8. dipterous flies; 9. millipedes; and, 10. spiders. There is nothing, however, in this mode of division, which merits any peculiar praise, or that should

regard with any degree of attention. Of these, some never obtain wings at any period of their existence: but are destined to creep on the vegetable, or the spot of earth, where they are stationed for their whole lives. On the contrary, others are only candidates for a more happy situation; and only wait their growing wings, when they may be said to arrive at their state of full perfection.

Those that never have wings, but creep

prevent us from passing immediately to the microscopical discoveries of the celebrated Leuwenhoeck, from whose inventive genius and patient observations the science received such essential benefit, not more by what he himself discovered, than by the foundation he laid for that system of close and minute observation which alone leads to truth. Our limits will only permit us to designate Blankaart and Geyerus, as occupying a similar rank with Goedart.

Ray, however, deserves more particular notice. His descriptions are very exact and detailed, and his various works, *Synopis Methodica Animalium*, &c., (Lond., 1783), *Synopsis Methodica Avium et Piscium*, (Lond., 1713), and the *Historia Insectorum* (Lond., 1710), sufficiently demonstrate his claim to the title of the first true systematist. His was the glory of serving as a zoological guide to the illustrious Swedish reformer, of whom we shall soon have to speak. Ray divides insects into two great classes—those which undergo a metamorphosis after having been produced, and those which do not. He again subdivides each of these classes into orders, characterized by the feet, or by their absence; by their habitations; by the size or conformation of the various parts of the body; by their larvæ, &c. In this arrangement were included certain tribes of *vermes*, subsequently separated by Linnæus. The voluminous productions, upon this subject, of the indefatigable Reaumur who directed his researches into every department of science, appeared in Paris in 6 vols., 4to., 1734.—1742. His *Mémoires pour servir á l' Histoire des Insects*—for such is its modest title—is an admirable work, both with respect to the number and value of the observations it contains. It is to be lamented that the 7th volume, which is completed, remains unpublished. The intended remaining ones were not commenced when Reaumur died, in 1757.

But a greater name than any we have yet mentioned is that of the illustrious reformer of the nomenclature of the natural sciences. Notwithstanding the labours of so many ingenious, learned and acute observers of nature, the history of animals, and that of insects in particular, remained in a confused state until the illustrious Linnæus reduced the chaotic pile to order. Directing all the energies of his clear and comprehensive mind to the subject, he produced, in his well known *Systema Naturæ*, 1735, the first truly methodical work. In a final edition of the same book, we find an arrangement of insects differing from that contained in the former; and, as that is the one always referred to at the present day, and as his divisions are, to a certain extent, still retained, we deem it proper to notice it here. He divides insects into *caleoptera*, *hemoptera*, *lepidoptera*, *neuroptera*, *hymenoptera*, *diptera*, and *aptera*. In this class were also included the *crustacea* and *arachnides*, now forming the first and second classes of the third great division of the animal kingdom, or the *animalia articulata*. The system of Linnæus, though not a natural one, was well adapted to the limited number of animals then known, and which, with respect to insects, did not exceed 800 or 900. Its subsequent alterations necessarily arose from the immense number of new ones which the increasing zeal of observers detected in every part of the globe.

L'Admiral, Letharding, Lesser, Degeer, Roesel, Scopoli, and Geoffroy, all contributed and some of them greatly, to multiply facts and detect errors. Lyonnet, however, merits something more than the bare mention of his name. Animated by a zeal that no disappointment could damp, and armed with a patience that set obstacles at defiance, this untiring inquirer devoted seven years of his life to the anatomy of a single insect—the larva of a species of *cossus* that inhabits the willow. The plates of his work, the *Traité Anatomique de la Chenille du Saule* (4to., 1762), eighteen in number, were all engraved by his own hand, with a minuteness, fidelity, and elegance that have seldom, if ever, been equalled. The *ensemble* is pronounced, by the greatest authority of our age, a *chef-d'œuvre* both of anatomy and engraving.

We cannot stop to notice particularly the labours of Schæffer, Seba, Forster, and Drury, each of whom added something to the general fund of knowledge. With respect to those of Fabricius, it is otherwise. This celebrated entomologist, and pupil of Linnæus, published numerous and valuable works on his favourite science, of which we will only cite the *Entomologia Systematica, emendata et aucta* (4 vols., 8vo., 1792—1794), the *Supplementum Entomologiæ Systematicæ* (1798), and the *Systema Eleutheratorum, Rhyngotorum*, &c., (from 1801 to 1805). He was the first who had recourse to the parts of the mouth, or organs of manducation, as a basis of distribution; and a vast number of new species of insects were described by him, in his remarkably concise but clear manner, with which Gmelin, a naturalist, or or rather editor, of a very different class, enriched the *Systema* of Linnæus. The splendid and costly works of Oliver (5 vols., fol., Paris, 1789—1808), Donovan (London, 1778—1805), Palisot de Beauvois, (Paris, fol., 1805, et seq.) Cramer, (4 vols., 4to, with 400 coloured plates, Amsterdam, 1779, continued by Stoll, in 1 vol., 4to., 1790 et seq.), together with a multitude of others of a less magnificent description, bring our sketch down to a period in the annals of the natural sciences which is graced by the name of Cuvier. It is to him that we are indebted for what is termed the *natural method*, or an arrangement in which, to use his own words, "all beings of the same genus are placed nearer to each other than to those of all other genera of the same order similarly disposed with respect to those of all other orders, &c." The energy and discrimination of this modern *oracle of the natural sciences*, as he has justly been styled, aided by untiring industry, have fixed the foundations of zoology upon the immutable basis of comparative anatomy. From the moment his *Table au élémentaire de l' Histoire naturelle des Animaux*, and his *Leçons d' Anatomie Comparée*, made their appearance, the entomologist, in common with the cultivators of every other branch of zoology, was sensible that he at last held the clew by which he could hope to traverse the hitherto impracticable labyrinth. The study now became a greater object of interest than ever. Lamarck produced his work upon invertebral animals, and Latreille, guided by Cuvier, soon gave to the world his famous entomological system.

Among the modern writers of eminence on the subject of insects, MacLeay, Leach, and Kirby stand pre-eminent in England. Prussia boasts of her Klug and Illiger; Germany of her Knoch, Mannerheim, and Germar; Russia of her Fischer; Sweden of her Paykull, Gyllenhal, and Schoenherr; and France, that favourite seat of science, gave birth to Latreille, the greatest of entomologists. There, too, count Dejean is busied with his admirable work on coleopterous insects, which, when completed, will leave nothing to be desired with respect to that order. Leon Dufour, of the same country, by his various memoirs on the anatomy of a new species of *brachinus*, on that of the *coleoptera*, of the *cicaderiæ*, of the *cicadella*, of the *forficulæ*, &c., has given ample

about till they die, may be considered as constituting the FIRST CLASS of insects. All these, the flea and the woodlouse only excepted, are produced from an egg; and when once they break the shell, they never suffer any further change of form, but continue to grow larger till they die. Thus the louse or the spider are produced from an egg, never suffering any al-

proofs of his devotion to the science, and of his title to the rank of the first entomological anatomist of the age. Savigny, also, who sacrificed his sight to his anatomical investigations, and was one of the *savants* who accompanied the expedition to Egypt, has rendered the most important services to this branch of zoology, by his work on the mouths of insects. In America, Melsheimer (who furnished Knoch with the greater part of his species), Say, Hentz, Le Conte, Harris, and many others, have successfully exerted themselves in detecting and describing the insects of the United States.

In the earlier writings of Lamarck, he included the Crustacea, as well as the Arachnides, in his Class Insecta. These have since been formed into separate Classes by him, but as the latter of these is so nearly allied to the true insects, we retain it at the head of that Class, under its own proper title.

ARACHNIDES.

The Arachnides are oviparous animals, provided with articulated members, but do not undergo a metamorphosis, similar to insects. They respire, either by bronchiæ or by means of a trachea, the openings for the admission of air being stigmatiform; and they are destitute of antennæ.

ORDER I.—PULMONARIÆ.

With a heart; each side of the abdomen with bronchial sacs; six to eight eyes; two pedipalpi; two jaws and palpi; and four pair of feet: sexual organs double.

SECTION I.—PEDIPALPI.

Very large palpi; abdomen distinctly annulated, having no web-spinning papillæ.

FAMILY I.—SCORPIONIDES.

With a sessile abdomen, provided with four spiracles, the six terminal segments forming a tail; the last one pointed, and serving as a sting, perforated for the passage of poison; palpi forceps-shaped. *Scorpio Afer*, pl. 26. f. 1.

FAMILY II.—TARANTULÆ.

With a pedunculated abdomen, each side below furnished with two spiracles, and terminated by a stingless, jointed filament; palpi arm-shaped, with spinous extremities; mandibles monodactyle; anterior feet longer than the others; tongue long and dart-shaped. *Thelyphonus Caudatus*, pl. 26. f. 2.

SECTION II.—ARANEIDES.

Palpi like small feet, ending in a hook; last joint bearing the sexual organs in the male; four or six mamillæ placed near the anal opening, in both sexes, for the purpose of spinning.

I.—TETRAPNEUMONES.

Provided with two spiracles, and two pulmonary sacs on both sides. *Mygale Cæmentaria*, pl. 26. f. 3.

II.—DIPNEUMONES.

Having only one spiracle, and one pulmonary sac, on each side; six spinning orifices: the four exterior quadrangular, and two smaller ones in the middle.

FAMILY I.—TUBITELÆ.

Spinning orifices fasciculated, approximated, and cylindrical; feet strong. *Aranea Domestica*, pl. 26, f. 4.

FAMILY II.—INÆQUITELLÆ.

Spinning papillæ converging and conical; feet very slender; first and last pairs are usually longer than the others; jaws inclined upon the labium. *Scytodes thoracica*, pl. 26, f. 5.

FAMILY III.—ORBITELÆ.

Differing from the preceding family, in the first and second pair of feet being usually longest; the jaws are straight, and wider above. *Epeira diadema*, pl. 26, f. 6.

FAMILY IV.—LATERIGRADÆ.

When in a state of repose the feet are horizontally extended, four anterior longest and nearly equal; eyes forming the segment of a circle in one division, and in two parallel lines in another. *Thomisus castaneus*, pl. 26, f. 7.

FAMILY V.—CITIGRADÆ.

Eyes, eight in number, placed curvilinearly triangular, or ovally truncated. They spin no webs; capture their prey by leaping. *Lycosa Tarantula*, pl. 26, f. 8.

FAMILY VI.—SALTIGRADÆ.

Legs formed for leaping; eyes either in a single or double quadrangular group, the smaller ones within the other. *Eresus moniligerus*, pl. 26, f. 9.

ORDER II.—TRACHEARIÆ.

Without a heart, but in its stead a single dorsal vessel; they respire through a radiated trachea, the air passing through spiracles in the abdomen or thorax; eyes from two to four; some are blind; mouth usually syphon-shaped; sexual organs single.

FAMILY I.—PYCNOGONIDES.

With a projecting syphon; four eyes placed on a single tubercle; feet mostly long, terminated by unequal hooks; at the base of the first are two oviferous feet. *Pycnogonon Balænarum*, pl. 26, f. 10.

FAMILY II.—PSEUDOSCORPIONES.

With very large, pediform palpi, with a didactyle hand or a vascular button. *Chelifer Cancroides*, pl. 26, f. 11.

FAMILY III.—PHALANGITA.

With slender filiform palpi, terminated by a hook. *Siro rubens*, pl. 26, f. 12.

FAMILY IV.—ACARIDES.

With an oval or globular extremely minute body; generally with two filiform palpi; eyes minute; eight hairy feet, each terminated with two or three hooks. *Trombidium tinctorum*, pl. 26, f. 13.

FAMILY V.—HYDRACHNELLÆ.

Mouth generally produced and feet adapted for swimming. *Hydrachna geographica*, pl. 26, f. 14.

FAMILY VI.—RICINIÆ.

Mouth produced, legs formed for walking, wandering, or parasitical land animals. *Argas reflexus*, pl. 26, f. 15.

FAMILY VII.—MICROPHTHIRA.

Having six legs, and always parasitical. *Leptus Autumnalis*. Pl. 26, f. 15.

INSECTS.

ORDER I.—THYSANOURA.

These are apterous insects, with six feet, and under-

teration when once they are excluded; but, like the chicken or the duck, remaining invariably the same, from their birth to their dissolution.

The SECOND ORDER of insects consists of such as have wings; but which, when produced from the egg, have those wings cased up in such a manner as not to appear. This casing

---

go no metamorphosis; head distinct; two antennæ, which are longer than the head; abdomen with a terminal forked or filamentary tail.

FAMILY I.—LEPISMENÆ.

Antennæ with many small joints; palpi produced; abdomen provided with a series of movable appendages on each side. *Machilis polypoda*, pl. 28, f. 1.

FAMILY II.—PODURELLÆ.

Antennæ four jointed; mouth destitute of palpi; no lateral appendages on the abdomen; tail forked (used in leaping) while in repose it is folded under the abdomen. *Podura Plumbea*, pl. 28, f. 2.

ORDER II.—PARASITA.

With six feet; no abdominal appendages; two or four small eyes; exterior mouth, nipple or snout-shaped, inclosing a retractile sucker; sometimes having membranous lips, with doubly hooked mandibles.

FAMILY I.—MANDIBULATA.

Having two lips, mandibles, and jaws. *Ricinus corvicoracis*, pl. 28, f. 3.

FAMILY II.—SIPHUNCULATA.

No mandibles; mouth consisting of a beak, from which a sucker can be protruded at will. *Pediculus coturnicis*, pl. 28, f. 4.

ORDER III.—SYPHONAPTERA.

With a compressed body; mouth provided with a two-pieced sucker, inclosed between two articulated laminæ; these form a conical or cylindrical beak, covered with scales at the base. It consists of but one genus.

Pulex irritans, pl. 28, f. 5. With an oval compressed body, consisting of twelve segments; three of which compose the thorax, and the remaining the abdomen; six feet; beak, jointed, consisting of two plates inclosing a sucker.

ORDER IV.—COLEOPTERA.

Having four crustaceous elytra or wings, the two upper ones in the form of cases, and covering the under ones when at rest, which are folded across; they are provided with mandibles and jaws for mastication; the suture betwixt the elytra straight.

SECTION I.—PENTAMERA.

Tarsi with five joints.

FAMILY I.—ADEPHAGI.

Each jaw with two palpi, in all six; antennæ generally filiform, and simple. Tribe i.—Cicendeletæ. Terrestrial. *Cicendela octonotata*, pl. 28, f. 6. Tribe ii.—Carabici. *Brachinus Jurinæ*, f. 7. Tribe iii.—Hydrocanthari. Aquatic. *Colymbetes marmoratus*, f. 8. Tribe iv.—Gyrinites. *Gyrinus sulcatus*, f. 9.

FAMILY II.—BRACHYPTERA.

Body elongated, narrow; antennæ moniliform; each jaw provided with a palpus; elytra shorter than the abdomen, but covering the wings; anal appendages hairy. Tribe i.—Fissilabri. *Oxyporus rufus*, pl. 28, f. 10. Tribe ii.—Longipalpi. *Pæderus ruficollis*, f. 11. Tribe iii.—Depressi. *Lesteva dichroa*, f. 12. Tribe iv.—Microcephali. *Tachinus atricapillus*, f. 13.

FAMILY III.—SERRICORNES.

With filiform or setaceous antennæ, tufted, serrated, or pectinated in the males; some ending in a toothed club; upper part of abdomen covered by the elytra, except in one genus; tarsal penult joint frequently bilobed. Tribe i.—Buprestides. *Buprestis rufipes*, pl. 28, f. 14. Tribe ii.—Elaterides. *Elater areolus*, f. 15. Tribe iii.—Cebrionites. *Rhipicera cyanea*, pl. 29, f. 16. Tribe iv.—Lampyrides. *Lampyris Savignyi*, pl. 28, f. 17. Tribe v.—Melyrides. *Malachius æneus*, pl 29, f. 18. Tribe vi.—Clerii. *Opilo mollis*, f. 19. Tribe vii.—Xylotrogi. *Hylecœtus Dermestoides*, f. 21. Tribe viii.—Ptiniores. *Anobium tesselatum*, f. 20.

FAMILY IV.—CLAVICORNES.

With four palpi, elytra nearly covering the abdomen; antennæ eleven jointed, knobbed at their points; tarsi five jointed. Tribe i.—Hystroida. *Hololepta glabra*, pl. 28, f. 22. Tribe ii.—Peltoides. *Necrophorus mallei*, f. 23. Tribe iii.—Palpatores. *Mastigus palpatis*, pl. 29, f. 25. Tribe iv.—Dermestini. *Dermestes lardarius*, pl. 28, f. 26. Tribe v.—Byrrhi. *Byrrhus pilula*, f. 27. Tribe vi.—Macrodactyli. Aquatic. *Heterocerus marginatus*, pl. 29, f. 28.

FAMILY V.—PALPICORNES.

Antennæ compressed, six or nine jointed, with a perfoliated or solid claviform termination; body hemispherical, or ovoid; mentum large; maxillary palpi long. Tribe i.—Hydrophilii. *Hydrophilus caraboides*, pl. 29, f. 29. Tribe ii.—Sphæridiota. *Sphæridium scarabæoides*, f. 30.

FAMILY VI.—LAMELLICORNES.

Antennæ eight to eleven jointed, but nine or ten the prevailing number, placed in a furrow, short and claviform, consisting of pectinated laminæ; two anterior legs externally dentated; chin large, frequently covering the labium. Tribe i.—Scarabæides. *Oryctes Chevrolatii*, pl. 28, f. 31. The animals of this tribe are numerous, subject to great variety, and are, in consequence, arranged in six sub-tribes. Tribe ii.—Lucanides. *Lucanus cinnamoneus*, f. 32.

SECTION II.—HETEROMERA.

First four tarsi five, and last two four jointed.

FAMILY I.—MELASOMA.

Tarsal joints mostly entire; antennæ moniliform, third joint elongated, always inserted under the projecting borders of the head; point of mandibles bifid; internal side of jaws with a tooth or hook. Tribe i.—Pimeliariæ. *Pimelia vestita*, pl. 28. f. 33. Tribe ii.—Blapsides. *Blaps mortisaga*, f. 34. Tribe iii.—Tenebrionites. *Crypticus gibbulus*, f. 35.

FAMILY II.—TAXICORNES.

Mandibles bifid at their points; joints of tarsi, except the anterior four, entire; antennæ length of head and thorax, with claviform tips, and usually partly perfoliated. Tribe i.—Diaperiales. *Diaperis boleti*, pl. 29, f. 36. Tribe ii.—Cossyphenes. *Cossyphenes Hoffmanseggii*, pl. 28, f. 37. Tribe iii.—Crassicornes. *Cnodalon nodosum*, f. 38.

FAMILY III.—STENELYTRA.

Mandibles sometimes pointed, jaws unarmed; penult joint of tarsi bilobate, antennæ, filiform or setaceous, often longer than the head and thorax. Tribe i.—Helopii. *Helops violaceus*, pl. 28, f. 39. Tribe ii.—Cistelides. *Cistela sulphurea*, pl. 29, f. 40. Tribe iii.—Securipalpi. *Melandrya caraboides*, f. 41. Tribe iv.—Œdemerites. *Œdemera podograria*, f. 42. Tribe v.—Rhynchostoma. *Stenostoma rostrata*.

up of the wings, however, does not prevent the animal's running, leaping, and moving with its natural celerity; but when the case bursts, and the wings have a power of expanding, all the animal's motions become more extensive, and the animal arrives at full perfection. Thus the grasshopper, the dragon-fly, and the earwig, have their wings at first bound down;

FAMILY IV.—TRACHELIDES.

With a cordiform, triangular head, apart from the thorax; antennæ simple, filabelliform, pectinated, or serrated; jaws without corneous teeth; tarsal hooks entire; penult joint usually bilobed. Tribe i.—Lagriariæ. *Lagriaria hirta*, pl. 29, f. 44. Tribe ii.—Pyrochroides. *Pyrochroa coccinea*, f. 45. Tribe iii.—Mordellonæ. *Mordella aculeata*, pl. 28, f. 46. Tribe iv.—Anthicides. *Notoxus monoceros*, pl. 29, f. 47. Tribe v.—Horiales. *Horia maculata*, pl. 28, f. 48. Tribe vi.—Cantharidiæ. *Cantharis vesicatoria*, f. 49.

SECTION III.—TETRAMERA.

All the tarsi four-jointed.

FAMILY I.—RHYNCHOPHORA.

Head rostriform, mouth terminal; antennæ generally claviform, geniculate, and inserted on the proboscis; abdomen large; penult joint of tarsi usually bilobate. Tribe i.—Bruchelæ. *Bruchus pisi*, pl. 29, f. 50. Tribe ii.—Anthribides. *Anthribus latirostris*, f. 51. Tribe iii.—Attelabides. *Attelabus femoralis*, pl. 28, f. 52. Tribe iv.—Brentides. *Brentus anchorago*, pl. 29, f. 52. Tribe v.—Curculionites. *Curculio imperialis*, pl. 28, f. 53.

FAMILY II.—XYLOPHAGI.

Tarsal joints usually entire, or when the penult joint is bilobed, the palpi are small and conical; antennæ frequently with less than eleven joints, claviform, and perfoliated at the base. Tribe i.—Scolytarii. *Scolytus ulmi*, pl. 29, f. 54. Tribe ii.—Bostrichini. *Bostrichus capucinus*, f. 55. Tribe iii.—Paussili. *Paussus microcephalus*, f. 56. Tribe iv.—Trogossitarii. *Dasycerus sulcatus*, f. 57.

FAMILY III.—PLATYSOMA.

Tarsal joints entire; body depressed, oblong; head breadth of body, narrowed behind into a sort of peak; mandibles projecting, especially in the males; labrum small; palpi short; thorax nearly square; antennæ filiform. *Cucujus Dejeanii*, pl. 28, f. 58.

FAMILY IV.—LONGICORNES.

First three joints of tarsus provided with pencils below, two intermediate broad, triangular, or cordiform, third deeply bifoliate; labium triangular, cordiform, or notched; antennæ filiform, generally longer than the body, sometimes inserted in a notch at the eyes, sometimes outside; foot long, slender, with long tarsi; body elongated. Tribe i.—Prionii. *Prionis coriarius*, pl. 28, f. 59. Tribe ii.—Cerambycini. *Ceramblyx hirtipes*, pl. 28, f. 50. Tribe iii.—Necydalides. *Necydalis major*, pl. 29, f. 61. Tribe iv.—Lamiariæ. *Saperda albicans*, pl. 28, f. 62. Tribe v.—Lepturetæ. *Leptura annulata*, pl. 29. f. 63.

FAMILY V.—EUPODA.

Body oblong, antennæ filiform, gradually thickening to the points, and inserted near the eyes; about the length of head and thorax, which is narrow, cylindrical, or square: head sunk in the thorax to nearly the eyes; exterior and terminal lobe of jaws widening towards the extremity. Tribe i.—Sagrides. *Sagra Cayanea*, pl. 29, f. 64. Tribe ii.—Criocerides. *Crioceris merdigera*, pl. 28, f. 65.

FAMILY VI.—CYCLICA.

Labium thick, square, or oval, entire, or slightly notched; exterior and terminal division of jaws cylindrical; body oval, ovoid, globular, or somewhat square; antennæ filiform or setaceous, sometimes slightly claviform, but not rounded or oval; three first joints of tarsi spongy, or provided with brushes below. Tribe i.—Cassidariæ. *Cassida viridis*, pl. 28, f. 66. Tribe ii.—Chrysomelinæ. *Chlamys cuprea*, pl. 29, f. 67. Tribe iii.—Galerucitæ. *Galeruca tanaceti*, pl. 29, f. 68.

FAMILY VII.—CLAVIPALPI.

Three first joints of tarsi with brushes, and the last bifid; antennæ with a terminal, oval, perfoliated club; jaws with a horny tooth interiorly; palpi with a large terminal joint; body orbicular or oval. *Erotylus giganteus*, pl. 28, f. 69.

SECTION IV.—TRIMERA.

Tarsi three jointed; antennæ clavate; body hemispherical or oval.

FAMILY I.—APHIDIPHAGI.

Tarsi with two terminal hooks, first joint distinct; elytra covering the abdomen; antennæ shorter than the thorax, with a terminal club in the form of a reversed triangle; last joint of maxillary palpi being large, dolabriform; body hemispherical; thorax short, and nearly luniform. *Cocinella septempunctata*, pl. 28, f. 70.

FAMILY II.—FUNGICOLÆ.

Tarsi with two terminal hooks, the first joint distinct, elytra covering the abdomen; antennæ longer than the head and thorax; maxillary palpi filiform, or simply thickened towards the tips; body oval. *Eumorphus tetraspilotus*, pl. 29, f. 71.

FAMILY III.—PSELAPHII.

With short truncated elytra; first tarsal joint short and indistinct. *Chennium bituberculatum*, pl. 29, f. 72.

SECTION V.—MONOMERA.

Tarsi having but one joint.

FAMILY I.—DERMESTINI.

Antennæ shorter than the thorax, radical joint large, ovate, seven following short, slender, remaining three forming an ovate compressed club, two lower joints somewhat dilated in the inner side, terminal smaller and rounded. *Dermestes lardarius*, pl. 29, f. 157.

ORDER V.—ORTHOPTERA.

With coriaceous elytra, the margin of the one covering that of the other; mouth provided with mandibles; wings longitudinally folded, and sometimes transversely besides; metamorphosis semi-complete.

SECTION I.

Elytra and wings horizontal; feet formed for running.

FAMILY I.—FORFICULARIÆ.

Tarsi three jointed; elytra nearly crustaceous, not reticulated, very short, posteriorly truncate, joining in a straight suture, and covering the wings, which are plicated, and their extremities projecting beyond the elytra, while in repose; abdomen terminating in a horny forceps. *Forficula spongiphora*, pl. 28, f. 73.

FAMILY II.—BLATTARIÆ.

Tarsi five jointed; wings simply doubled longitudinally, and covered by elytra, frequently coriaceous and thin, reticulated or crossing each other; body depressed, oval, or orbicular; head concealed under the semicircular or orbicular thorax; maxillary palpi long, terminal joint axe-shaped; feet spinous. *Blatta maculata*, pl. 28, f. 74.

but when the skin, that like a pair of stays, kept them confined, bursts, they are then expanded, and the animal pursues the purposes for which it was produced.

FAMILY III.—MANTIDES.

Tarsi five jointed; wings simply folded longitudinally; body elongated, head uncovered; palpi short, filiform; two anterior feet greatly longer than the others, haunches long, thighs strong, compressed; legs terminated by a strong hook, capable of being folded under the thighs; thorax large. *Mantis religiosa*, pl. 28, f. 75.

FAMILY IV.—SPECTRA.

Under lip unequally divided; anterior margin of upper lip notched; antennæ placed nearer the mouth than the centre of the head; head projecting, elongated, and posteriorly rounded; eyes small; first segment of the thorax short, being scarcely longer than the second. *Phyllium psama*, pl. 29, f. 76.

SECTION II.

With the exception of the first family, the elytra and wings are sloping like a roof; posterior thighs and feet very large, and formed for leaping.

FAMILY I.—GRYLLIDES.

Elytra and wings horizontal; antennæ setaceous or filiform, tarsi three jointed. *Gryllus trifasciatus*, pl. 28, f. 77.

FAMILY II.—LOCUSTARIÆ.

Elytra and wings sloping like a roof; tarsi four jointed, antennæ setaceous. *Locusta viridissima*, pl. 29, f. 158.

SECTION III.

Elytra and wings sloping like a roof; posterior feet formed for leaping; tarsi five jointed; elytra alike in both sexes; antennæ sword-shaped, filiform in both sexes, claviform in the males only, in some species.

ACRIDITES.

Posterior feet weak, shorter than the body, hardly formed for leaping; abdomen turned. *Acridium ornatum*, pl. 28, f. 78.

ORDER VI.—HEMIPTERA.

Two wings covered by elytra; mouth constructed for suction; the rostrum composed of a tubular articulated sheath, enveloping four scaly setæ, instead of mandibles and jaws; elytra in some of the species crustaceous, with the posterior extremity membranous; in others nearly similar to wings, but more extended, thicker, and coloured.

SECTION I.—HETEROPTERA.

Rostrum placed on the anterior extremity of the head; elytra and wings horizontal, terminated abruptly by a membranous appendage.

FAMILY I.—GEOCORISÆ.

Antennæ placed near the internal margin of the eyes, and somewhat longer than the head; tarsi three jointed, the first in some species very short. Tribe i.—Longilabra. *Scutellera vasalis*, pl. 28, f. 79. Tribe ii.—Membranaceæ. *Cimex lectularius*, f. 80. Tribe iii.—Nudicollis. *Reduvius raptatorius*, f. 81. Tribe iv.—Oculatæ. *Leptopus littoralis*. Tribe v.—Ploteres. *Hydrometra linearis*, pl. 29, f. 82.

FAMILY II.—HYDROCORISÆ.

Antennæ placed under the eyes, concealed, and even longer than the head; tarsi two jointed. Tribe i.—Nepides. *Belostoma marginata*, pl. 28, f. 84. Tribe ii.—Notonectides. *Noctonecta glauca*, f. 85.

The THIRD ORDER of insects is of the moth and butterfly kind. These all have four wings, each covered with a mealy substance of various colours, which when handled comes off

---

SECTION II.—HOMOPTERA.

Rostrum projected from the lower part of the head, between the two anterior feet; elytra generally inclined, of equal thickness throughout, sometimes resembling wings.

FAMILY III.—CICADARIÆ.

With wings and elytra; tarsi three jointed; antennæ small, conical, or subulate; three to six jointed, including the setæ, which terminate them; female ovipositor dentated. Tribe i.—Stridulantes. *Cicada flavopunctata*, pl. 28, f. 86. Tribe ii.—Fulgorellæ. *Fulgora punctata*, f. 87. Tribe iii.—Membracides. *Darnis camelus*, f. 88. Tribe iv.—Cicadella. *Ledra aurata*.

FAMILY IV.—HYMENELYTRA.

Tarsi two jointed, generally with two terminal hooks, or simply vesicular; antennæ ten or eleven jointed, longer than the head; body soft. Tribe i.—Psyllides. *Livia juncorum*, pl. 28, f. 90. Tribe ii.—Physapi. *Thrips physapus*, f. 91. Tribe iii.—Aphidii. *Aphis rosiæ*, f. 92. f. 92 *a*, larva of the same.

FAMILY V.—GALLINSECTA.

Tarsi of one joint, with a terminal hook. Males two winged, or with two elytra, and devoid of a rostrum. Females apterous; antennæ eight, nine, and eleven jointed, and in some instances twenty-two to twenty-four. *Coccus cacti*, pl. 28, f. 93.

ORDER VII.—NEUROPTERA.

Wings four, naked, reticulated and transparent; mouth formed for mastication; jaws and lips straight, extended; joints of the tarsi various, mostly entire.

SECTION I.—SUBULICORNES.

Antennæ little longer than head; subulate, seven jointed, the last formed of a seta; mandibles and jaws covered by lips, or by an anterior projection of the head; eyes projecting, large; wings extended horizontally, or perpendicular.

FAMILY I.—LIBELLULINÆ.

Tarsi three jointed; mandibles and jaws corneous, very strong; dentated; wings equal. *Libellula varia*, pl. 28, f. 94.

FAMILY II.—EPHEMERINÆ.

Tarsi four jointed; body very soft; lower wings much smaller than the upper ones, in some species exceedingly minute; abdomen terminated by two or three filaments. *Ephemera bioculata*, pl. 28, f. 95.

SECTION II.—FILICORNES.

Joints of antennæ generally numerous, thickened towards the end, filiform, or setaceous, and longer than the head.

FAMILY III.—PLANIPENNES.

Tribe i.—Panorpatæ. *Panorpa rufa*, pl. 28, f. 96. Tribe ii.—Myrmeleonides. *Ascalaphus barbarus*, f. 97. Tribe iii.—Hemerobini. *Hemerobius longicornis*, pl. 29, f. 98. Tribe iv.—Psoquillæ. *Psocus bipunctatus*. Tribe v.—Termitinæ. *Termes lucifugum*. Tribe vi.—Raphidinæ *Raphidia ophiopsis*. Tribe vii.—Semblides. *Corydalis cornuta*. Tribe viii.—Perlides. *Perla lutea*.

upon the fingers; and, if examined by the microscope, will appear like scales, with which the wing is nicely embroidered all over. These insects also are produced in a manner peculiar to themselves. They are at first hatched from an egg, from whence proceeds a caterpillar that eats, and often casts its skin; the caterpillar having divested itself for the last time,

FAMILY IV.—PLICIPENNES.

Destitute of mandibles; lower wings broader than the upper, longitudinally folded; antennæ setaceous, usually long, with numerous joints; tarsi five jointed; maxillary palpi long and setaceous. *Phryganea striata.*

ORDER VIII.—HYMENOPTERA.

Four naked veined wings of unequal size; mouth with jaws, mandibles, and two lips; lip tubular at its base, terminating by a labium, either doubled or folded inwards, and forming a kind of sucker; females provided with a compound ovipositor.

SECTION I.—TEREBRANTIA.

Abdomen in many species sessile; females furnished with an ovipositor; antennæ twelve or thirteen jointed, in some more or less.

FAMILY I.—SECURIFERA.

Abdomen perfectly sessile, or connected at its base to the metathorax. Tribe i.—Tenthredinetæ. *Pergu scutellata*, pl. 29, f. 101. Tribe ii.—Urocerata. *Termex columba*, f. 102.

FAMILY II.—PUPIVORA.

Wings of many species cellular, in others devoid of nerves; first abdominal segment posteriorly inclosing the metathorax, and forming part of it; the second, which appears like the first, fixed to the preceding by a pedicle. Tribe i.—Evaniales. *Pelecinus policerator*, pl. 29, f. 103. Tribe ii.—Ichneumonides. *Ichneumon unifasciatorius*, pl. 28, f. 104. Tribe iii.—Gallicolæ. *Cinips quercus folii.* Tribe iv.—Chalcidites. *Chalcis clavipes*, f. 106. Tribe v.—Chrysides. *Chrysis ignita*, f. 107. Tribe vi.—Oxyuri. *Bethyllus hemipterus.*

SECTION II.—ACULEATA.

Abdomen pedunculated, inclosing in the females and neuters a sting; antennæ of the male thirteen jointed, female twelve.

FAMILY III.—HETEROGYNA.

Females and neuters or those which live in society, devoid of wings; antennæ geniculated; labium small, rounded, vaulted. Tribe i.—Formicariæ. *Formica Herculanea*, pl. 28, f. 109. Tribe ii.—Mutillariæ. *Mutilla Klugii*, f. 110.

FAMILY IV.—FOSSORES.

Wings extended; in some the prothorax laterally prolonged, in others short. Tribe i.—Scolietæ. *Scolia tricincta*, pl. 29, f. 111. Tribe ii.—Sapygites. *Sapyga prisma.* Tribe iii.—Pompilii. *Pompilus viaticus*, pl. 28, f. 113. Tribe iv.—Sphegides. *Podium nigripes*, f. 114. Tribe v.—Bembecides. *Bembex rostrata*, f. 115. Tribe vi.—Labratæ. *Labra Ichneumoniformis.* Tribe vii.—Nyssonii. *Nysson maculatus*, pl. 29, f. 117. Tribe viii.—Crabronites. *Crabro cribrarius*, f. 118.

FAMILY V.—DIPLOPTERA.

Wings longitudinally folded; antennæ geniculate, clavate; eyes notched; prothorax reaching insertion of upper wings; feet not fitted for collecting pollen. Tribe i.—Vespariæ. *Synagris cornuta*, pl. 29, f. 119. Tribe ii.—Masarides. *Masaris apiformis*, f. 120.

FAMILY VI.—MELIFERA.

Wings extended; first joint of posterior tarsi large, compressed, square, or triangular, provided with a tuft of hair adapted for collecting pollen of flowers; jaws and lip long, narrow, produced into a proboscis; chin elongated, supported on a pedicle; labium mostly lanceolate or filiform, long and hairy. Tribe i.—Andrenetæ. *Andrena pilipes*, pl. 29, f. 121. Tribe ii.—Apiariæ. *Apis centhuncularia*, pl. 28, f. 122.

ORDER IX.—LEPIDOPTERA.

Four membranaceous wings, covered with a farina composed of minute scales, and having a trunk spirally rolled up, inserted at the mouth.

FAMILY I.—DIURNA.

Wings free in repose, perpendicular to the plane of position, and devoid of a scaly bristle at the base of the inferior wings; antennæ, in many, claviform, or terminating in a button, more or less conical or triangular, in others slender, and hooked at the termination. Tribe i.—Papilionides. *Papilio Childreni*, pl. 29, f. 123. Tribe ii.—Hesperides. *Hesperia malvæ*, f. 124.

FAMILY II.—CREPUSCULARIÆ.

With a stiff, horny bristle near the insertion of the lower wings, at their margin, entering a groove below the upper ones, keeping them horizontal in repose; antennæ claviform elongated, frequently pectinated or serrated. Caterpillars with sixteen large feet. Tribe i.—Hesperia—Sphinges. *Castnia acroeoides*, pl. 29, f. 125. Tribe ii.—Sphingides. *Sphinx convolvuli*, f. 126. Tribe iii.—Zygænides. *Zygæna pulchella*, f. 127.

FAMILY III.—NOCTURNA.

Wings horizontal or inclined in repose; antennæ setaceous. Tribe i.—Bombycites. *Bombyx pavonia*, pl. 29, f. 128. Tribe ii.—Noctuo-Bombycites. *Cossus ligniperda*, f. 127. Tribe iii.—Tineites. *Tinea tapizana*, f. 129. Tribe iv.—Noctuælites. *Noctua oculata*, f. 130. Tribe v.—Tortrices. *Herminia Sidonia*, f. 131. Tribe vi.—Phalænites. *Phalæna machaonaria*, f. 132. Tribe vii.—Crambites. *Crambus retusalis*, f. 133. Tribe viii.—Pterophorites. *Orneodes hexadactylus*, f. 134.

ORDER X.—STREPSIPTERA.

Wings two, naked and membranous, accompanied by two balancers, longitudinally folded, forming nearly the quadrant of a circle; metamorphosis incomplete.

This order consists but of two genera. *Stylops Childreni*, pl. 29, f. 135.

ORDER XI.—DIPTERA.

With two membranous extended wings, and a balancer under each in most species; six feet; provided with a sucker, composed of a variable number of scaly, setæform pieces, either inclosed in the upper furrow of a sheath, or inarticulated proboscis, terminated by two lips, or cased in one or two plates.

SECTION I.

Head large or of medium size, distinct from the thorax; tarsal hooks simple, or unidentated; sucker inclosed in a sheath.

FAMILY I.—NEMOCERA.

Antennæ with six joints at least, but usually with fourteen to sixteen. Tribe i.—Culicides. *Culex pipiens*, pl. 29, f. 136. Tribe ii.—Tipulariæ. *Tipula oleracea*, f. 137

FAMILY II.—TANYSTOMA.

Rostrum frequently lengthened, sometimes nearly concealed; sucker of six pieces. Tribe i.—Tabanii. *Tabanus Africanis*, pl. 29, f. 138. Tribe ii.—Sicarii. *Cœnomyia pallida*, f. 139. Tribe iii.—Mydasii. *Mydas Lusitanicus*, f. 140, *a* and *b*. Tribe iv.—Leptides. *Leptis*

assumes a new covering, which is called a chrysalis, or the cone in the silkworm, in which it continues hidden till it come forth a perfect moth, or butterfly.

The FOURTH ORDER is of those winged insects which come from a worm instead of a caterpillar, and yet go through changes similar to those which moths and butterflies are seen to undergo. They are first excluded from the egg as a worm, and then become a chrysalis; in some, their wings and legs are seen; in others, the animal is quite detached from the cone in which it is concealed; but all at length break their prison and come out perfect winged animals; some furnished with two wings, and some with four. The wings of all these differ from those of the butterfly and moth kind, by not having the mealy scales which are ever found on the wings of the former. In this class we may place the numerous tribes of gnats, beetles, bees, and flies.

To these I will add, as a FIFTH ORDER, a numerous tribe lately discovered, to which naturalists have given the name of Zoophytes. These do not go through the ordinary forms of generation but may be propagated by dissection. Some of these, though cut into a hundred parts, still retain life in each, and are endued with such a vivacious principle, that every part will in a short time become a perfect animal. They seem a set of creatures placed between animals and vegetables, and make the shade that connects animated and insensible nature. To this class belong the polypus, the earth-worm, and all the varieties of the sea-nettle.

Having thus given a general distribution of insects, I will proceed to describe each class in the order I have mentioned them; beginning with insects without wings, as they more nearly resemble the higher ranks of nature, as well in their habits as their conformation.

CHAP. II.

OF INSECTS WITHOUT WINGS.

EVERY moment's observation furnishes us with instances of insects without wings; but the difficulty is to distinguish those which are condemned continually to lead reptile lives, from such as only wait the happy moment of

---

fasciata, f. 141. Tribe v.—Dolichopoda. *Porphyrops diaphanus*, f. 142. Tribe vi.—Asilici. *Asilus crabroniformis*, f. 143. Tribe vii.—Hybotini. *Ocydromya glabricula*, f. 144. Tribe viii.—Empides. *Empis pennipes*, f. 145. Tribe ix.—Anthracii. *Anthrax marginicollis*, f. 146. Tribe x.—Bombyliarii. *Bombylius major*, f. 147. Tribe xi.—Vesiculosa. *Henops marginatus*, f. 148.

FAMILY III.—NOTACANTHA.

Rostrum generally membranous, short, concealed, except the terminal lips; sucker of two pieces; in others long, syphon shaped, and concealed by a produced beak, which supports the antennæ; terminal joint of antennæ, with many rings; wings resting on the body, and provided with a central radiated ariola. Tribe i.—Xylophagei. *Beris violaceus*, pl. 29, f. 149. Tribe ii.—Stratiomydes. *Stratiomys chamæleon*, f. 150.

FAMILY IV.—ATHERICERA.

Sucker consisting of two or four pieces, the two contiguous ones provided with palpi; retracted within the sucker into a furrow of the proboscis. Tribe i.—Syrphiæ. *Syrphus obscurus*, pl. 29, f. 151. Tribe ii.—Conopsariæ. *Conops macrocephala*, f. 152. Tribe iii.—Œstrides. *Œstrus Bovis*, f. 153. Tribe iv.—Muscides. *Musca Vomitoria*, f. 154.

SECTION II.

Proboscis consisting of two setæ, emerging from the buccal cavity, covered by two plates or palpi, instead of a sheath.

FAMILY V.—PUPIPARÆ.

Tribe i.—Coriaceæ. *Hippobosca equina*, pl. 29, f. 155. Tribe ii.—Phthyromyiæ. *Nycteribia vespertilionis*, f. 156.

DESCRIPTION OF EXTERNAL PARTS OF INSECTS.

PLATE XXVI.

THE HEAD AND ITS EXTERNAL ORGANS.

The *Head* furnishes the most distinctive characters of insects. It is exceedingly varied in its general form, as well as in its several parts. The most important of these are the *mouth*, *antennæ*, and *eyes*. The head of a Dipterous insect is represented, figure 22, with all its appendages; but the head, independently of these is confined within the limits of *a a* f. 22, 25.

Mouth. This organ is very complicated, and subject to great diversity of form, and construction, admirably adapted to the nature of its food. It consists of six parts, the *labrum*, *mandibles*, *maxillæ*, *palpi*, *labium*, *and mentum*. *Labrum*, or upper lip, figs. 22, 23, 25, *e*, *e*, *e*. *Mandibles*, f. 25, *k*, *k*. *Maxillæ*, f. 24, *i*. *Palpi*, f. 22, 23, 24, 25, *b*, *b*, *b*, *b*, *b*, and f. 29, *b*. *Labial lobes*, f. 22, 23, 25, *g*, *g*, *g*. *Mentum*, f. 29, *a*. *Proboscis*, f. 29, *b*. *Lingua* or tongue, f. 29, *c*.

Antennæ. Horn-like processes consisting of several joints; considered by some naturalists as organs of touch, and by others, organs of hearing, f. 24, 25, *d*, *d*. *Nasus* or nose, f. 22, *f*. *Eyes*, f. 22, *l*, *l*. *Neck*, f. 22, *h*.

The *Thorax* and its several divisions; f. 26. *Collar*, or prothoracic scutellum, f. 22, 26, *m*, *m*. *Præscutum*, f. 26, *n*. *Scutum*, *o*. *Scutellum*, *p*. *Metathoracic Scutum*, f. 26, *q*.

To the thorax are attached the *Wings*, *r*, *r*; the rudimental *alulæ* or winglets *s*; the base of the intermediate *femur t*; the balancers *u*; the base of the posterior femur *v*, and the legs. *Wings*, f. 25, *w*. *Elytra*, are membranous, or horny substances which cover the wings of insects of the order Coleoptera, f. 25, *x*, *x*. *Upper* or superior wing of a Lepidopterous insect, f. 27. *Anterior margin*, or costal nerve, *a*. *Interior margin*, *b*. *Exterior margin*, *c*. *Post-costal nerve*, *d*. *Anal nerve*, *e*. *Compound ocellus*, or the *discoidal cell*, *f*. *Dentate fascia*, *g*.

Lower or inferior wing of a Lepidopterous insect, f. 28. *Anterior margin*, *a*. *Exterior margin*, *b*. *Interior margin*, *c*.

The *Abdomen* is that part which is attached to the posterior extremity of the thorax, and consists of six segments or wings, to which there are never any legs attached, f. 29.

In the whole insect tribe, they are provided with but six *Legs*: they are composed of five parts, f. 30. *Coxa*, or haunch, is the first joint, *a*. *Trochanter*, or second joint, *b*. *Femur*, or thigh, *c*. *Tibia*, or shank, *d*. *Tarsus*, *e*. This member consists of from three to five articulate parts, among Coleopterous insects, and most others. To the last of these articulations are attached the claws.

transmutation. For this, nothing but a long and intimate acquaintance will suffice; but, in general, all animals resembling the flea, the louse, the spider, the bug, the wood-louse, the water-louse, and the scorpion, never acquire wings, but are produced from the egg in that form which they never change afterwards.

If we consider this class as distinct from others, we shall find them in general longer lived than the rest, and often continuing their term beyond one season, which is the ordinary period of an insect's existence. They seem also less subject to the influence of the weather; and often endure the rigours of winter without being numbed into torpidity. The whole race of moths, butterflies, bees, and flies, are rendered lifeless by the return of cold weather; but we need not to be told, that the louse, the flea, and many of these wingless creatures, that seem formed to tease mankind, continue their painful depredations the whole year round.

They come to perfection in the egg, as was said before; and it sometimes happens, that when the animal is interrupted in performing the offices of exclusion, the young ones burst the shell within the parent's body, and are thus brought forth alive. This not unfrequently happens with the wood-louse, and others of the kind, which are sometimes seen producing eggs, and sometimes young ones perfectly formed.

Though these creatures are perfect from the beginning yet they are often, during their existence, seen to change their skin: this is a faculty which they possess in common with many of the higher ranks of animals, and which answer the same purposes. However tender their skins may seem to our feel, yet, if compared to the animal's strength and size, they will be found to resemble a coat of mail, or, to talk more closely, the shell of a lobster. By this skin these animals are defended from accidental injuries, and particularly from the attacks of each other. Within this they continue to grow, till their bodies become so large as to be imprisoned in their own covering, and then the shell bursts, but is quickly replaced by a new one.

Lastly, these animals are endued with a degree of strength, for their size, that at first might exceed credibility. Had man an equal degree of strength, bulk for bulk, with a louse or flea, the history of Samson would be no longer miraculous. A flea will draw a chain a hundred times heavier than itself; and to compensate for this force, will eat ten times its own size of provision in a single day.

CHAP. III.

OF THE SPIDER, AND ITS VARIETIES.[1]

The animal that deserves our first notice in this principal order of insects is the Spider,

[1] Modern naturalists do not rank spiders among insects, because they have no antennæ, and no division between the head and the shoulders; they breathe by leaf-shaped gills, situated under the belly, instead of spiracles in the sides; have a heart connected with these; have eight legs instead of six; and eight fixed eyes. But as spiders are popularly considered insects, it will sufficiently suit our purpose to introduce them here as such. The neatest, though the smallest spider's nest which we have seen, was constructed in the chink of a garden post, which we had cut out the previous summer in getting at the cells of a carpenter-bee. The architect was one of the larger hunting-spiders erroneously said by some naturalists to be incapable of spinning. The nest in question was about two inches high, composed of a very close satin-like texture. There were two parallel chambers placed perpendicularly, in which position also the inhabitant reposed there during the day, going, as we presume, only abroad to prey during the night. But the most remarkable circumstance was, that the openings (two above and two below) were so elastic, that they shut almost as closely as the boat cocoon of the *Tortrix chlorana*. We observed this spider for several months, but at last it disappeared, and we took the nest out, under the notion that it might contain eggs; but we found none, and therefore concluded that it was only used as a day retreat. The account which Evelyn has given of these hunting-spiders is so interesting, that we must transcribe it.

"Of all sorts of insects," says he, "there is none has afforded me more divertisement than the *venatores* (hunters), which are a sort of *lupi* (wolves) that have their dens in rugged walls and crevices of our houses; a small brown and delicately-spotted kind of spiders, whose hinder legs are longer than the rest. Such I did frequently observe at Rome, which, espying a fly at three or four yards distance upon the balcony where I stood, would not make directly to her, but crawl under the rail, till being arrived at the antipodes, it would steal up, seldom missing its aim; but if it chanced to want any thing of being perfectly opposite, would, at first peep, immediately slide down again,—till, taking better notice, it would come the next time exactly upon the fly's back: but if this happened not to be within a competent leap, then would this insect move so softly, as the very shadow of the gnomon seemed not to be more imperceptible, unless the fly moved; and then would the spider move also in the same proportion, keeping that just time with her motion as if the same soul had animated both these little bodies; and whether it were forwards, backwards, or to either side, without at all turning her body, like a well managed horse: but if the capricious fly took wing and pitched upon another place behind our huntress, then would the spider whirl its body so nimbly about, as nothing could be imagined more swift; by which means she always kept the head towards her prey, though, to appearance, as immovable as if it had been a nail driven into the wood, till by that indiscernible progress (being arrived within the sphere of her reach) she made a fatal leap, swift as lightning, upon the fly, catching him in the pole, where she never quitted hold till her belly was full, and then carried the remainder home."

One feels a little sceptical, however, when he adds, "I have beheld them instructing their young ones how to hunt, which they would sometimes discipline for not

whose manners are of all others the most subtle, and whose instincts are most various. Formed for a life of rapacity, and incapable of living upon any other than insect food, all its habits are calculated to deceive and surprise: it spreads toils to entangle its prey; it is endued with patience to expect its coming; and is possessed of arms and strength to destroy it when fallen into the snare.

In this country, where all the insect tribes

---

well observing; but when any of the old ones did (as sometimes) miss a leap, they would run out of the field and hide themselves in their crannies, as ashamed, and haply not to be seen abroad for four or five hours after; for so long have I watched the nature of this strange insect, the contemplation of whose so wonderful sagacity and address has amazed me; nor do I find in any chase whatsoever more cunning and stratagem observed. I have found some of these spiders in my garden, when the weather, towards spring, is very hot, but they are nothing so eager in hunting as in Italy."

We have only to add to this lively narrative, that the hunting spider, when he leaps, takes good care to provide against accidental falls by always swinging himself from a good strong cable of silk, as Swammerdam correctly states, and which any body may verify, as one of the small hunters, known by having its back striped with black and white like a zebra, is very common in Britain.

As a contrast to the little elastic satin nest of the hunter, we may mention the largest with which we are acquainted,—that of the labyrinthic spider. Our readers must often have seen this nest spread out like a broad sheet in hedges, furze, and other low bushes, and sometimes on the ground. The middle of this sheet, which is of a close texture, is swung like a sailor's hammock, by silken ropes extended all around to the higher branches; but the whole curves upwards and backwards, sloping down to a long funnel-shaped gallery which is nearly horizontal at the entrance, but soon winds obliquely till it becomes quite perpendicular. This curved gallery is about a quarter of an inch in diameter, is much more closely woven than the sheet part of the web, and sometimes decends into a hole in the ground, though oftener into a group of crowded twigs, or a tuft of grass. Here the spider dwells secure, frequently resting with her legs extended from the entrance of the gallery, ready to spring out upon whatever insect may fall into her sheet net. She herself can only be caught by getting behind her and forcing her out into the web; but though we have often endeavoured to make her construct a nest under our eye, we have been as unsuccessful as in similar experiments with the common house spider.

The house spider's proceedings were long ago described by Homberg, and the account has been copied, as usual, by almost every subsequent writer. Goldsmith has, indeed, given some strange mis-statements from his own observations, and Bingley has added the original remark, that, after fixing its first thread, creeping along the wall and joining it as it proceeds, it "*darts itself to the opposite side*, where the other end is to be fastened!" Homberg's spider took the more circuitous route of travelling to the opposite wall, carrying in one of the claws the end of the thread previously fixed, least it should stick in the wrong place. This we believe to be the correct statement, for as the web is always horizontal, it would seldom answer to commit a floating thread to the wind, as is done by other species. Homberg's spider, after stretching as many lines by way of *warp*, as it deemed sufficient between the two walls of the corner which it had chosen, proceeded to cross this in the way our weavers do in adding the *woof*, with this difference, that the spider's threads were only laid on and not interlaced. The domestic spiders, however, in these modern days, must have forgot this mode of weaving, for none of their webs will be found to be thus regularly constructed.

The geometric, or net-working spiders, are as well known in most districts as any of the preceding; almost every bush and tree in the gardens and hedge rows having one or more of their nets stretched out in a vertical position between adjacent branches. The common garden spider and the long-bodied spider are the best known of this order.

The chief care of a spider of this sort is, to form a cable of sufficient strength to bear the net she means to hang upon it; and, after throwing out a floating line as above described, when it catches properly she doubles and redoubles it with additional threads. On trying its strength she is not contented with the test of pulling it with her legs, but drops herself down several feet from various points of it, as we have often seen, swinging and bobbing with the whole weight of her body. She proceeds in a similar manner with the rest of the frame-work of her wheel-shaped net: and it may be remarked that some of the ends of these are not simple, but in form of a Y, giving her the additional security of two attachments instead of one.

In constructing the body of the net, the most remarkable circumstance is her using her limbs as a measure, to regulate the distances of her *radii* or wheel-spokes, and the circular meshes interweaved into them. These are consequently always proportional to the size of the spider. She often takes up her station in the centre, but not always, though it is so said by inaccurate writers; for she as frequently lurks in a little chamber constructed under a leaf or other shelter at the corner of her web, ready to dart down upon whatever prey may be entangled in her net. The centre of the net is said also to be composed of more viscid materials than its suspensory lines,—a circumstance alleged to be proved by the former appearing under the microscope studded with globules of gum. We have not been able to verify this distinction, having seen the suspensory lines as often studded in this manner as those in the centre.

A no less wonderful structure is composed by a sort of spiders, natives of the tropics and the south of Europe, which have been justly called the mason-spiders by M. Latreille. One of these (*Mygale nidulans*, Walckn.) found in the West Indies, "digs a hole in the earth obliquely downwards, about three inches in length, and one in diameter. This cavity she lines with a tough thick web, which, when taken out, resembles a leathern purse; but what is most curious, this house has a door with hinges, like the operculum of some sea-shells, and herself and family, who tenant this nest, open and shut the door whenever they pass and repass. This history was told me," says Darwin, "and the nest, with its door, shown me by the late Dr Butt, of Bath, who was some years a physician in Jamaica."

are kept under by human assiduity, the spiders are but small and harmless. We are acquainted with few but the house-spider, which weaves its web in neglected rooms; the garden-spider, that spreads its toils from tree to tree, and rests in the centre; the wandering spider, that has no abode like the rest; and the field-spider, that is sometimes seen mounting, web and all, into the clouds. These are the chief of our native spiders; which, though reputed venomous, are entirely inoffensive. But they form a much more terrible tribe in Africa and America. In those regions, where all the insect species acquire their greatest growth, where the butterfly is seen to expand a wing as broad as our sparrow, and the ant to build a habitation as tall as a man, it is not to be wondered at that the spiders are seen bearing a proportionable magnitude. In fact, the bottom of the Martinico spider's body is as large as a hen's egg, and covered all over with hair. Its web is strong, and its bite dangerous. It is happy for us, however, that we are placed at a distance from these formidable creatures, and that we can examine their history without feeling their resentment.

Every spider has two divisions in its body. The fore part, containing the head and breast, is separated from the hinder part or belly by a very slender thread, through which, however, there is a communication from one part to the other. The fore part is covered with a hard-shell, as well as the legs, which adhere to the breast. The hinder part is clothed with a supple skin, beset all over with hair. They have several eyes all round the head, brilliant and acute; these are sometimes eight in number, sometimes but six; two behind, two before, and the rest on each side. Like all other insects, their eyes are immovable, and they want eye-lids; but this organ is fortified with a transparent horny substance, which at once secures and assists their vision. As the animal procures its subsistence by the most watchful attention, so large a number of eyes was necessary to give it the earliest information of the capture of its prey. They have two pincers on the fore part of the head, rough, with strong points, toothed like a saw, and terminating in claws, like those of a cat. A little below the point of the claw there is a small hole, through which the animal emits a poison, which, though harmless to us, is sufficiently capable of instantly destroying its prey. This is the most powerful weapon they have against their enemies; they can open or extend these pincers as occasion may require; and when they are undisturbed, they suffer them to lie one upon the other, never opening them but when there is a necessity for their exertion. They have all eight legs, jointed like those of lobsters, and similar also in another respect; for if a leg be torn away, or a joint cut off, a new one will quickly grow in its place, and the animal will find itself fitted for combat as before. At the end of each leg there are three crooked movable claws, namely, a small one, placed higher up, like a cock's spur, by the assistance of which it adheres to the threads of its web. There are two others larger, which meet together like a lobster's claw, by which they can catch hold of the smallest depressions, walking up or down the very polished surfaces, on which they can find inequalities that are imperceptible to our grosser sight. But when they walk upon such bodies as are perfectly smooth, as looking-glass or polished marble, they squeeze a little sponge, which grows near the extremity of their claws, and thus diffusing a glutinous substance, adhere to the surface until they make a second step. Besides the eight legs

Among our native spiders there are several which, not contented with a web like the rest of their congeners, take advantage of other materials to construct cells where, "hush'd in grim repose," they "expect their insect prey." The most simple of those spider-cells is constructed by a longish-bodied spider, which is a little larger than the common hunting spider. It rolls up a leaf of the lilac or poplar, precisely in the same manner as is done by the leaf-rolling caterpillars, upon whose cells it sometimes seizes to save itself trouble, having first expelled, or perhaps devoured, the rightful owner. The spider however, is not satisfied with the tapestry of the caterpillar, and always weaves a fresh set of her own, much more close and substantial.

Another spider common in woods and copses weaves together a great number of leaves to form a dwelling for herself, and in front of it she spreads her toils for entrapping the unwary insects which stray thither. These, as soon as caught, are dragged into her den, and stored up for a time of scarcity. Here also her eggs are deposited and hatched in safety. When the cold weather approaches, and the leaves of her edifice wither, she abandons it for the more secure shelter of a hollow tree, where she soon dies; but the continuation of the species depends upon eggs, deposited in the nest before winter, and remaining to be hatched with the warmth of the ensuing summer.

The spider's den of united leaves, however, which has just been described, is not always useless when withered and deserted; for the dormouse, or the harvest mouse, we are not certain which, usually selects it as a ready-made roof for its nest of dried grass. That those old spiders' dens are not accidentally chosen by the mouse, appears from the fact, that out of about a dozen mouse-nests of this sort found during winter in a copse between Lewisham and Bromley, Kent, every second or third one was furnished with such a roof.

That spiders may be able to breath under water, we can well understand from their breathing like amphibious reptiles by means of gills; but there is an aquatic spider which is not contented, as a frog would be, with the air furnished by the water, but actually carries down a supply of air from the atmosphere to her subaqueous nest. This spider does not like stagnant water, but prefers slow-running streams and ditches, where she may often be seen, in the vicinity of London and elsewhere, living in her diving-bell, which shines through the water like a little globe of silver: her singular economy was first, we believe, described by Clerck, L. M. de Lignac, and De Geer.—*Rennie's Insect Architecture.*

just mentioned, these animals have two others, which may more properly be called arms, as they do not serve to assist motion, but are used in holding and managing their prey.

The spider, though thus formidably equipped, would seldom prove successful in the capture, were it not equally furnished with other instruments to assist its depredations. As it lives wholly upon flies, and is without wings to pursue them, it is obvious they must for ever escape so important an adversary; but the spider is a most experienced hunter, and spreads its nest to catch those animals it is enabled to pursue. The spider's web is generally laid in those places where flies are most apt to come and shelter; in the corners of rooms, round the edges of windows, and in the open air among the branches of trees. There the little animal remains for days, nay, weeks together, in patient expectation, seldom changing its situation though never so unsuccessful.

For the purposes of making this web, nature has supplied this animal with a large quantity of glutinous matter within its body, and five dugs or teats for spinning it into thread. This substance is contained in a little bag, and at the first sight it resembles soft glue; but when examined more accurately, it will be found twisted into coils of an agate colour, and upon breaking it, the contents may be easily drawn out into threads, from the tenacity of the substance, not from those threads being already formed. Those who have seen the machine by which wire is spun, will have an idea of the manner in which this animal forms the threads of its little net, the orifices of the five teats above mentioned, through which the thread is drawn, contracting or dilating at pleasure. The threads which we see, and appear so fine, are, notwithstanding, composed of five joined together, and these are many times doubled when the web is in formation.

When the house-spider purposes to begin a web, it first makes choice of some commodious spot, where there is an appearance of plunder and security. The animal then distils one little drop of its glutinous liquor, which is very tenacious, and then creeping up the wall, and joining its thread as it proceeds, it darts itself in a very surprising manner, as I have often seen, to the opposite place, where the other end of the web is to be fastened. The first thread thus formed, drawn tight, and fixed at each end, the spider then runs upon it backward and forward, still assiduously employed in doubling and strengthening it, as upon its force depends the strength and stability of the whole. The scaffolding thus completed, the spider makes a number of threads parallel to the first, in the same manner, and then crosses them with others; the clammy substance of which they are formed, serving to bind them, when newly made, to each other. The insect, after this operation, doubles and trebles the thread that borders its web, by opening all its teats at once, and secures the edges, so as to prevent the wind from blowing the work away. The edges being thus fortified, the retreat is next to be attended to: and this is formed like a funnel at the bottom of the web, where the little creature lies concealed. To this are two passages, or outlets, one above and the other below, very artfully contrived, to give the animal an opportunity of making excursions at proper seasons, of prying into every corner, and cleaning those parts which are observed to be clogged or encumbered. Still attentive to its web, the spider, from time to time, cleans away the dust that gathers round it, which might otherwise clog and incommode it: for this purpose, it gives the whole a shake with its paws; still, however, proportioning the blow so as not to endanger the fabric. It often happens, also, that from the main web there are several threads extended at some distance on every side; these are, in some measure, the outworks of the fortification, which, whenever touched from without, the spider prepares for attack or self-defence. If the insect impinging be a fly, it springs forward with great agility; if, on the contrary, it be the assault of an enemy stronger than itself, it keeps within its fortress, and never ventures out till the danger be over. Another advantage the spider reaps from this contrivance of a cell or retreat behind the web, is, that it serves for a place where the creature can feast upon its game with all safety, and conceal the fragments of those carcases which it has picked, without exposing to public view the least trace of barbarity, that might create a suspicion in any insects that their enemy was near.

It often happens, however, that the wind, or rustling of the branches, or the approach of some large animal, destroys in a minute the labours of an age. In this case, the spider is obliged to remain a patient spectator of the universal ruin; and when the danger is passed away, it sets about repairing the calamity. For this purpose, it is furnished with a large store of the glutinous substance of which the web is made; and with this, it either makes a new web, or patches up the old one. In general, however, the animal is much fonder of mending than making, as it is furnished originally with but a certain quantity of glutinous matter, which when exhausted nothing can renew. The time seldom fails to come, when the reservoirs are entirely dried up, and the poor animal is left to all the chances of irretrievable necessity. An old spider is thus frequently reduced to the great-

est extremity; its web is destroyed, and it wants the materials to make a new one. But as these animals have been long accustomed to a life of shifting, it hunts about to find out a web of another spider, younger and weaker than itself, with whom it ventures a battle. The invader generally succeeds; the young one is driven out to make a new web, and the old one remains in quiet possession. If however, the spider is unable to dispossess any other of its web, it then endeavours, for a while, to subsist on accidental depredation; but in two or three months it inevitably dies of hunger.[1]

The garden-spider seems to work in a different manner. The method with this insect is, to spin a great quantity of thread, which floating in the air in various directions, happens, from its glutinous quality, at last to stick to some object near it, a lofty plant or the branch of a tree. The spider only wants to have one end of the line fast, in order to secure and tighten the other. It accordingly draws the line when thus fixed, and then by passing and repassing upon it, strengthens the thread in such a manner as to answer all its intentions. The first cord being thus stretched, the spider walks along a part of it, and there fastens another, and dropping from thence, fastens the thread to some solid body below, then climbs up again and beginsa third, which it fastens by the same contrivance. When three threads are thus fixed, it forms a square, or something that very nearly resembles one, and in this the animal is generally seen to reside. It often happens, however, when the young spider begins spinning, that its web becomes too buoyant, and not only the thread floats in the air, but even the little spinster. In this manner we have often seen the threads of spiders floating in the air; and what is still more surprising, the young spiders themselves attached to their own web. The reason is obvious; for as even gold itself may be so finely drawn out as to float in the air, so the finer threads of a spider are so buoyant as not only to swim in the air, but also to lift the spider itself; which, like the tail of a kite, rises with its own manufacture.

The spider's web being thus completed, and fixed in a proper place, its next care is to seize and secure whatever insect happens to be caught in the toil. For this purpose, it remains for weeks, and even months, upon the watch, without ever catching a single fly; for the spider, like most other insects, is surprisingly patient of hunger. It sometimes happens that too strong a fly strikes itself against the web, and thus, instead of being caught, tears the net to pieces. In general, however, the butterfly or the hornet, when they touch the web, fly off again, and the spider seems no way disposed to interrupt their retreat. The large blue-bottle-fly, the ichneumon-fly, and the common meat-fly, seem to be its favourite game. When one of these strikes into the toils, the spider is instantly seen alert and watchful at the mouth of its hole, careful to observe whether the fly be completely immeshed; if that be the case, the spider walks leisurely forward, seizes its prey, and instantly kills it by instilling a venomous juice into the

[1] From its having been frequently remarked that spiders spread their webs in solitary and confined places, to which it is difficult for flies to penetrate, M. de Vaillant naturally concluded that these creatures must often remain long without food, and that consequently they were capable of enduring considerable abstinence. To ascertain the truth of this circumstance, he took a large garden spider, whose belly was about the size of a nut, and enclosed it under a glass bell, which he secured with cement round its bottom, and left it in that situation for ten months. Notwithstanding this deprivation of food, it appeared during the whole time equally vigorous and alert; but its belly decreased, till at last it was scarcely larger than the head of a pin. He then put under the bell to it another spider of the same species. For a little while they kept at a respectful distance from each other, and remained motionless, but presently the meagre one, pressed by hunger, approached and attacked the stranger. It returned several times to the charge; and, in these different conflicts, its enemy became deprived of almost all its claws; it carried these away, and retired to its former situation to devour them. The meagre one had likewise lost three of its own claws, on which also it fed; and M. de Vaillant perceived that by this repast, its plumpness was in some measure restored. The day following, the new comer, deprived of all its means of defence, fell a complete sacrifice. It was speedily devoured; and in less than twenty-four hours, the old inhabitant of the bell became as plump as it was at the first moment of its confinement.

When two spiders of the same size meet in combat, neither of them will yield; they hold each other by the fangs so fast, that in general one of the two must die before they are separated. M. Leeuwenhoeck says, he saw one spider that was, however, only wounded in one leg by his antagonist. A drop of blood as large as a grain of sand issued from the sore; and not being able to use this wounded leg in running away from his adversary, he held it up, and presently afterwards the whole limb dropped away from his body. When spiders are wounded in the breast, or upper parts of the body, they always die.

The spider, the ptinus, and many insects of the beetle kind, exhibit an instinct of a very extraordinary nature. When put in terror by a touch of the finger, the spider runs off with great swiftness; but if he finds in whatever direction he takes he is opposed by another finger, he then seems to despair of being able to escape, contracts his limbs and body, lies perfectly motionless, and counterfeits every symptom of death. "In this situation," says Smellie, "I have pierced spiders with pins, and torn them to pieces, without their discovering the smallest marks of pain. This simulation of death has been ascribed to a strong convulsion, or stupor, occasioned by terror. But this solution of the phenomenon is erroneous. I have repeatedly tried the experiment, and uniformly found, that, if the object of terror be removed, in a few seconds the animal runs off with the greatest rapidity. Some beetles, when counterfeiting death, will suffer themselves to be gradually roasted without moving a single joint."

wound it makes. If, however, the fly be not entirely immeshed, the spider patiently waits, without appearing until its prey has fatigued itself by its struggles to obtain its liberty; for if the ravager should appear in all its terrors while the prey is but half involved, a desperate effort might give it force enough to get free. If the spider has fasted for a long time, it then drags the fly immediately into its hole, and devours it; but if there has been plenty of game, and the animal be no way pressed by hunger, it then gives the fly two or three turns in its web, so as completely to immesh it, and there leaves it impotently to struggle until the little tyrant comes to its appetite. Why the spider should at one time kill its prey, and at another suffer it to struggle in the toils for several hours together, I am not able to say; perhaps it only likes its prey newly killed, and therefore delays to put the captive to death until it is to be eaten.

It has been the opinion of some philosophers, that the spider was in itself both male and female; but Lister has been able to distinguish the sexes, and to perceive that the males are much less in size than the females. But this is not the chief peculiarity; for, different from all other animals, except the fish called the *Ray*, it has its instruments of generation placed in the fore arms, which have been already described. When these animals copulate, they for some time seize each other with their legs and arms, then appear the instruments of generation in the male, as if bursting out from the points of its fore-feet, and are inserted into the receptacle beneath the body of the female.

The female generally lays from nine hundred to a thousand eggs in a season; they are of a bluish colour, speckled with black, and separated from each other by a glutinous substance, not unlike frog-spawn water. These eggs are large or small in proportion to the size of the animal that produces them. In some they are as large as a grain of mustard-seed; in others they are scarcely visible. The female never begins to lay till she be two years old at the least, and her first brood is never so numerous as when she has come to her greatest maturity.

When the number of eggs which the spider has brought forth have remained for an hour or two to dry after exclusion, the little animal then prepares to make them a bag, where they are to be hatched until they leave the shell. For this purpose she spins a web four or five times stronger than that made for catching flies; and besides, lines it within-side by a down, which she plucks from her own breast. This bag, when completed, is as thick as paper, is smooth within-side, but rougher without. Within this they deposit their eggs; and it is almost incredible to relate the concern and industry which they bestow in the preservation of it. They stick it by means of their glutinous fluid to the end of their body; so that the animal, when thus loaded, appears as if she had one body placed behind another. If this bag be separated from her by any accident, she employs all her assiduity to stick it again in its former situation, and seldom abandons her treasure but with her life. When the young ones are excluded from their shells, within the bag, they remain for some time in their confinement, until the female, instinctively knowing their maturity, bites open their prison, and sets them free. But her parental care does not terminate with this exclusion; she receives them upon her back for some time, until they have strength to provide for themselves, when they leave her never to return, and each begins a separate manufactory of its own. The young ones begin to spin when they can scarcely be discerned; and prepare for a life of plunder before they have strength to overcome. Indeed, Nature seems to have formed them in every respect for a life of hostility. No other insect is possessed of such various powers of assault and defence; and they are able to destroy animals ten times bigger than themselves. Even after a severe defeat, they quickly recover of their wounds; and as for their legs, they consider the loss of them as but a small misfortune, as they grow again very speedily to their former magnitude.

Thus there is no insect to which they are not an enemy; but what is more barbarous still, spiders are the enemies of each other. M. Reaumur, who was fond of making experiments upon insects, tried to turn the labours of the spider to human advantage, and actually made a pair of gloves from their webs.

For this purpose, he collected a large number of those insects together: he took care to have them constantly supplied with flies, and the ends of young feathers, fresh picked from chickens and pigeons, which being full of blood, are a diet that spiders are particularly fond of. But, notwithstanding all his care, he was soon convinced that it was impracticable to rear them, since they were of such a malignant nature, that they could never be brought to live in society; but instead of their usual food, chose to devour each other. Indeed, were it practicable to reconcile them to each other, it would require too much attendance to rear up a sufficient number to make the project any way useful. Their thread is four, if not five times finer than that of the silk-worm; so that, upon the smallest calculation, there must have been sixty thousand spiders to make a single pound of silk. That which Reaumur made use of was only the web in which they deposited their eggs, which is five

times stronger than their ordinary manufacture.

Of this animal, there are several kinds, slightly differing from each other, either in habits or conformation.[1] The Water-spider is the most remarkable of the number. This insect resembles the common spider in its appearance, except that its hinder part is made rather in the shape of a nine-pin than a ball. They differ in being able to live as well by land as water; and on being capable of spinning as well in one element as the other. Their appearance under water is very remarkable; for though they inhabit the bottom, yet they are never touched by the element in which they reside, but are inclosed in a bubble of air that, like a box, surrounds them on every side. This bubble has the bright appearance, at the bottom, of quicksilver: and within this they perform their several functions of eating, spinning, and sleeping, without its ever bursting, or in the least disturbing their operations; sometimes the bubble is seen divided into three distinct apartments; and in the spring, the male enters one of these to impregnate the female in the manner mentioned above, while the bubble in which he was contained unites with the other, like two drops of water when approached to each other. They spin their webs as well in the water as upon land; and it is most probable that they make their food of the small insects of either element.

The Tarantula is also of this species, and deserves particular notice, not for any remarkable properties that really attend it, but for the numerous falsehoods which have been propagated concerning it. What may be said with truth concerning it is, that it is the largest of the spider kind known in Europe, and is a native of Apulia in Italy. Its body is

[1] The gossamer, bird-catching, and branded spiders are among the most remarkable. *Gossamer spiders* first appear in the beginning of October, in woods, gardens, and meadows, where their eggs are hatched in safety; thence they spread themselves over whole districts, and, during the rest of October, and till the middle of November, may be found in dry fields throughout Europe. Extensive tracts of land are sometimes seen swarming with them. In the beginning of October, when but very few are hatched, some single threads of their webs, extending from twig to twig, are seen only in the sunshine: about the middle of the month their threads are more perceptible; and toward the end, if a person stand in such a position as to see the sunbeams play upon their slender threads, hedges, meadows, cornfields, stubble land, and even whole districts, appear covered as with a sort of white gauze. The gossamer spider does not weave a web, but only extends its threads from one place to another. These are so delicate, that a single thread cannot be seen unless the sun shines on it. One of them, to be visible at other times, must be composed of at least six common threads twisted together. In serene, calm days, these spiders work with great diligence, especially after the disappearance of the morning fogs. Between twelve and two, however, their industry excites the greatest admiration. A person with a pretty quick eye, or by the help of a glass, may sometimes perceive among the barley stubble such a multitude of these insects extending their threads, that the fields appear as if covered with swarms of gnats. Several of the single threads become twisted together by the gentlest breath of wind, and form perceptible threads, which, being broken by stronger winds, unite into thick threads, or even into balls, and float through the atmosphere. These are then called in Germany, the *flying summer*, because the summer seems to fly away at the same time. The spiders are conveyed in them: but it is not uncommon to find spiders of other species in them, which have been entangled and dragged away; and even the webs of other spiders, and the dried husks of insects that have been caught by them, are often found in the gossamer. The gossamer-spiders appear in swarms only during the harvest; but single spiders are to be found through the whole summer.

The *Bird-catching Spider* is of gigantic size, and great muscular power, extending with its feet a space of near ten inches. From the head to the extremity of the abdomen it often measures above three inches. The legs are as thick as a goose's quill, and closely covered with hair. The body is brown, and the fangs are as strong and sharp as in some of the rapacious species of birds. It is not uncommon in many parts of America, but is generally found in the southern division of that continent, and particularly in Guinea, and is a terror to all the feathered tribe. It resides in the trees, and frequently seizes on small birds, which it destroys by sucking their blood, after having first wounded them by its fangs, which distil a poisonous liquid into the wound. The slit or orifice near the tip of the fangs, through which this poison is emitted, is so visible as to be distinctly perceived without a glass. The eight eyes of this terrible insect are placed somewhat in the form of an oblong square in the front of the thorax; of these the two middle ones are so large as to be capable of being set in the manner of glasses, and used as microscopes; the rest are smaller, and of an oval shape. The thorax is orbicular, and has a transverse excavation. Captain Stedman, while residing in Surinam, had one of them given to him, which he put into a case bottle above eight inches long; and, when this was filled with spirits, the animal reached the surface with some of its claws, while others rested on the bottom. On the whole, he says, this spider is so hideous a creature, that the very sight of it is sufficient to occasion a tremor of abhorrence, even in persons most accustomed to inspect the deformities of nature.

The *Banded Spider* is a native of Barbary, and is as large as a man's thumb. It has yellow bands round the belly, and dusky rings round the legs. It inhabits hedges and thickets. Its webs have large meshes, and it resides in the centre; the snares are spread for large flies, wasps, drones, and even locusts; the lesser insects can escape through the meshes. The animal which it entangles is soon bound with strong threads, killed by the spider's jaws, and partly eat if the spider be hungry; the rest is concealed under some neighbouring dry leaves, covered with a kind of web, and blackish blue in great abundance: its larder is said to be often plentifully stored. Its nest is of the size of a pigeon's egg, divided horizontally, and suspended by the threads of the insect, which are of a silvery white, and stronger than silk. The young ones live in amity, but when grown up are mortal enemies; they never meet but they fight with violence, and their battle only ends with the death of the weakest: the dead body is carefully stored in the larder. Twelve of these spiders, by way of experiment, were shut up together, and after a battle of eight days the strongest only remained alive.—*Rennie.*

three quarters of an inch long, and about as thick as one's little finger; the colour is generally an olive brown, variegated with one that is more dusky; it has eight legs and eight eyes, like the rest, and nippers, which are sharp and serrated: between these and the fore legs, there are two little horns, or feelers, which it is observed to move very briskly when it approaches its prey. It is covered all over the body with a soft down, and propagates, as other spiders, by laying eggs. In the summer months, particularly in the dog days, the tarantula, creeping among the corn, bites the mowers and passengers; but in winter it lurks in holes, and is seldom seen.

Thus far is true; but now the fable begins: for though the bite is attended with no dangerous symptoms, and will easily cure of itself, wonderful stories are reported concerning its virulence. The part which is bitten, as we are told, is soon after discoloured with a livid, black, or yellowish circle attended with an inflammation. At first the pain is scarcely felt; but a few hours after, come on a violent sickness, difficulty of breathing, fainting, and sometimes trembling. The person bit, after this does nothing but laugh, dance, skip about, putting himself into the most extravagant postures, and sometimes also is seized with a most frightful melancholy. At the return of the season in which he was bit, his madness begins again; and the patient always talks of the same things. Sometimes he fancies himself a shepherd, sometimes a king; appearing entirely out of his senses. These troublesome symptoms sometimes return for several years successively, and at last terminate in death. But so dreadful a disorder has, it seems, not been left without a remedy; which is no other than a well-played fiddle. For this purpose the medical musician plays a particular tune, famous for the cure, which he begins slow, and increases in quickness as he sees the patient affected. The patient no sooner hears the music, but he begins to dance; and continues so doing till he is all over in a sweat, which forces out the venom that appeared so dangerous. This dancing sometimes continues for three or four hours, before the patient is weary and before the sweating is copious enough to cure the disorder. Such are the symptoms related of the tarantula poison; symptoms which some of the best and gravest physicians have credited, and attempted to account for. But the truth is, that the whole is an imposition of the peasants upon travellers who happen to pass through that part of the country, and who procure a trifle for suffering themselves to be bitten by the tarantula. Whenever they find a traveller willing to try the experiment, they readily offer themselves, and are sure to counterfeit the whole train of symptoms which music is supposed to remove. A friend of mine, who passed through that part of the country, had a trusty servant bitten, without ever administering the musical cure: the only symptoms were a slight inflammation, which was readily removed, and no other consequence ever attended the bite.—It is thus that falsehoods prevail for a century or two; and mankind at last begin to wonder how it was possible to keep up the delusion so long.

CHAP. IV.

OF THE FLEA.

The history of those animals with which we are the best acquainted, is the first object of our chiefest curiosity.—There are few but who are well-informed of the agility and blood-thirsty disposition of the Flea; of the caution with which it comes to the attack; and the readiness with which it avoids the pursuit. This insect, which is not only the enemy of mankind, but of the dog, cat, and several other animals, is found in every part of the world, but bites with greater severity in some countries than in others. Its numbers in Italy and France are much greater than in England; and yet its bite is much more troublesome here, than I have found it in any other place. It would seem that its force increased with the coldness of the climate; and, though less prolific, that it becomes more predaceous.[1]

[1] *The Common Flea.*—At a meeting of a Scientific Society at Oxford, some time ago, Mr Hussey, of Christ Church, read a paper on the growth of the flea, in which the changes through which the flea passes were described, and an account was given of some observations of the manner in which changes may be retarded. The flea, it was stated, lays from eight to twelve eggs, which fall down into crevices, or among dust, where they are hatched in about five days; they produce small white maggots like cheese-mites, which increase in size for about fourteen days, when they spin a bag or case of silk around them, and become chrysalids. Within this case they gradually darken in colour, until, at the end of about sixteen days, they come out of it perfect fleas; having been, on the whole, about thirty-four days from the laying of the egg to the perfect state. M. Defrance's opinion concerning the food of the young maggot, was quoted: namely, that it is fed by small grains of dried blood, which the parent has the power of extracting from the skin of the animals on which it feeds.

The strength of this animal is astonishing for its size. A flea will drag after it a chain a hundred times heavier than itself; and, to compensate for this force, will eat ten times its own weight of provisions in a day. Mr Boverich, an ingenious watch-maker who some years ago lived in the Strand, London, exhibited to the public a little ivory chaise, with four wheels, and all its proper apparatus, and a man sitting on the box, all of which were drawn by a single flea. He made a small landau, which opened and shut by springs, with six horses harnassed to it; a coachman sitting on the box, and a dog between his legs, four persons in the carriage, two foot-

If the flea be examined with a microscope, it will be observed to have a small head, large eyes, and a roundish body. It has two feelers, or horns, which are short, and composed of four joints: and between these lies its trunk, which it buries in the skin, and through which it sucks the blood in great quantities. The body appears to be all over curiously adorned with a suit of polished sable armour, neatly jointed, and beset with multitudes of sharp pins, almost like the quills of a porcupine. It has six legs, the joints of which are so adapted, that it can, as it were, fold them up one within another; and when it leaps, they all spring out at once, whereby its whole strength is exerted, and the body raised above two hundred times its own diameter.

The young fleas are at first a sort of nits or eggs, which are round and smooth; and from these proceed white worms, of a shining pearl colour: in a fortnight's time they come to a tolerable size, and are very lively and active; but if they are touched at this time, they roll themselves up in a ball: soon after this they begin to creep like silk-worms that have no legs; and they seek a place to lie hid in, where they spin a silken thread from their mouth, and with this they inclose themselves in a small round bag or case, as white within as writing-paper, but dirty without: in this they continue for a fortnight longer; after which they burst from their confinement perfectly formed, and armed with powers to disturb the peace of an emperor.[1]

men behind it, and a postilion riding on one of the fore horses, which was easily drawn along by a flea. He likewise had a chain of brass, about two inches long, containing two hundred links, with a hook at one end, and a padlock and key at the other, which the flea drew very nimbly along.

[1] The *Chigoe*.—This troublesome insect, which is a kind of small sand flea, is so diminutive as to be almost imperceptible. Its legs have not the elasticity of those of fleas; for had the chigoes their power of leaping, there is not a living creature of the climates where they abound that would not be full of them; and this lurking race would destroy three-fourths of mankind by the evils they would produce. They are common in Surinam, and in many parts of America, and are always found among the dust, and principally in filthy places; they fix themselves on the legs, to the soles of the feet, and even to the fingers.

The chigoe gets in between the skin and the flesh, and generally under the nails of the toes, in such a subtile manner, that, at the time, the person is not sensible of it; nor is it to be perceived till it begins to extend itself. At first it is not difficult to extract it; but, although it may only have introduced its head, it makes so firm a lodgment that a part of the skin must be sacrificed before it will quit its hold. If it be not soon perceived, the insect completes its lodgment, sucks the blood, and forms a nest of a white thin tunicle, in the shape of flat pearl. It extends itself in this space in such a manner, that its head and feet are towards the exterior side, for the convenience of nourishment; and the other part of the body answers to the inner side of the tunicle, in order to lay its eggs there. In proportion as these are laid, the little pearl is enlarged; and in four or five days it is at least four or five lines in diameter. It is then of the utmost consequence to have it extracted; for if this be neglected it bursts of itself, and spreads an infinity of nits, which, when hatched, fill the whole part, and produce excessive anguish; and the difficulty of dislodging them becomes very great. These penetrate to the very bones; and even when the sufferer has got rid of them, the pain will last till the flesh and skin are entirely healed.

The operation of extracting them, at which the black girls are extremely dexterous, is long and painful. It consists in separating, with the point of a needle, the flesh next to the membrane where the eggs are lodged; which is not easily done without bursting the tunicle. After having separated even the most minute ligaments, the nest is to be extracted. If unfortunately it bursts, particular care must be taken to extract every root of it, and especially not to leave behind the principal insect. This would begin to lay its eggs again before the wound could be healed; and penetrating much farther into the flesh, would increase the difficulty of extracting. During the great heats extreme care must be taken not to wet the part affected. Without this precaution, experience has proved that the patient is subject to consequences that frequently prove fatal. Tobacco ashes are put into the orifice, by which, in a little time, the sore is perfectly healed. Some, by having neglected in time to root out these detestable vermin, have not only lost their limbs by amputation, but even their lives.

CHAP. V.

OF THE LOUSE AND ITS VARIETIES.

The antipathies of mankind are various; some considering the toad, some the serpent, some the spider, and some the beetle, with a strong degree of detestation: but while all wonder at the strangeness of each other's aversions, they all seem to unite in their dislike to the Louse, and regard it as their natural and most nauseous enemy. Indeed, it seems the enemy of man in the most odious degree, for wherever wretchedness, disease, or hunger, seize upon him, the louse seldom fails to add itself to the tribe, and to increase in proportion to the number of his calamities.

In examining the human louse with the microscope, its external deformity first strikes us with disgust: the shape of the forepart of the head is somewhat oblong; that of the hind part somewhat round: the skin is hard, and being stretched, transparent, with here and there several bristly hairs: in the forepart is a proboscis or sucker, which is seldom visible: on each side of the head are antennæ, or horns, each divided into five joints, covered with bristly hair; and several white vessels are seen through these horns: behind these are the eyes, which seem to want those divisions observable in other insects, and appear encompassed with some few hairs: the neck is very short, and the breast is divided into three parts; on each side of which are placed six

legs, consisting of six joints, covered also with bristly hairs; the ends of the legs are armed with two smaller and larger ruddy claws, serving these insects as a finger and thumb, by which they catch hold of such objects as they approach: the end of the body terminates in a cloven tail, while the sides are all over hairy; the whole resembling clear parchment, and, when roughly pressed, crackling with a noise.

When we take a closer view, its white veins and other internal parts appear, as likewise a most wonderful motion in its intestines, from the transparency of its external covering. When the louse feeds, the blood is seen to rush, like a torrent, into the stomach; and its greediness is so great, that the excrements contained in the intestines are ejected at the same time, to make room for this new supply.

The louse has neither beak, teeth, nor any kind of mouth, as Dr Hooke described it, for the entrance into the gullet is absolutely closed. In the place of all these, it has a proboscis or trunk: or, as it may be otherwise called, a pointed hollow sucker, with which it pierces the skin, and sucks the human blood, taking that for food only. The stomach is lodged partly in the breast and back; but the greatest portion of it is in the abdomen. When swollen with blood, it appears of a dark brown colour, which is visible through the skin; and is either a faint red, or a full or bright brown, as the contents of the stomach are more or less changed. When it is empty, it is colourless; but when filled, it is plainly discernible, and its motion seems very extraordinary. It then appears working with very strong agitations, and somewhat resembles an animal within an animal. Superficial observers are apt to take this for the pulsation of the heart: but if the animal be observed when it is sucking, it will then be found that the food takes a direct passage from the trunk to the stomach, where the remainder of the old aliment will be seen mixing with the new, and agitated up and down on every side.

If this animal be kept from food two or three days, and then placed upon the back of the hand, or any soft part of the body, it will immediately seek for food; which it will the more readily find, if the hand be rubbed till it grows red. The animal then turns its head, which lies between the two fore-legs, to the skin, and diligently searches for some pore: when found, it fixes the trunk therein, and soon the microscope discovers the blood ascending through the head, in a very rapid, and even frightful stream. The louse has at that time sufficient appetite to feed in any posture; it is then seen sucking with its head downward, and its tail elevated. If, during this operation, the skin be drawn tight, the trunk is bound fast, and the animal is incapable of disengaging itself; but it more frequently suffers from its gluttony, since it gorges to such a degree, that it is crushed to pieces by the slightest impression.

Whether lice are distinguished by the parts of generation into males and females is not yet discovered: Swammerdam is inclined to think that they are hermaphrodites, having found an ovary in all those he examined; and he dissected not less than forty-two. In one of these animals were found ten large eggs; and forty-four smaller, that were not yet come to their full perfection.

There is scarce any animal that multiplies so fast as this unwelcome intruder. It has been pleasantly said, that a louse becomes a grandfather in the space of twenty-four hours: this fact cannot be ascertained; but nothing is more true than that the moment the nit, which is no other than the egg of the louse, gets rid of its superfluous moisture, and throws off its shell, it then begins to breed in its turn. Nothing so much prevents the increase of this nauseous animal as cold and want of humidity; the nits must be laid in a place that is warm, and moderately moist, to produce any thing. This is the reason that many nits laid on the hairs in the night-time, are destroyed by the cold of the succeeding day; and so stick for several months, till they at last come to lose even their external form.

The louse is found upon every part of the human body: but particularly in the heads of children.[1] Those found upon the miners in

[1] All lice live on blood, some on that of man, others on that of quadrupeds. They suck it with their proboscis, which is hardly ever perceived, unless it be in action. There is no quadruped which has not its particular louse, and some nourish several. Man, as we have already seen, is attacked by three species.

Swammerdam, who has given us the anatomy of the human louse, was unable to discover any male among those which he examined. He always found in them an ovary; which occasioned him to suspect that they were hermaphrodites. But the observations of Leeuwenhock, differ much from those of that author. He has observed individuals among these insects provided with all the parts which characterize the male sex, and he has given the figures of those parts. The same author has also discovered in those which he regards as males, a recurved sort of sting, situated under the abdomen, with which, according to him, they can prickle. He believes that the great itching which they occasion proceeds from the pricking of this sting, having remarked that the introduction of their proboscis into the flesh produces scarcely any sensation, unless perchance that it touch on any of the nerves. Degeer tells us, that he has seen a similar sting situated at the end of the abdomen in several human lice as well those of the body, as of the head. The individuals, which according to the opinion of Leeuwenhock are the males, have, according to Degeer, the end of the abdomen rounded, whereas the females, or those which have no sting, have it emarginated. M. Latreille has also observed, very distinctly in a great number of individuals, the sting, or at least the conical and scaly point of which the aforesaid authors have made mention.

Sweden, are said, by Linnæus, to be very large; and he is of opinion that the head and the body-louse differ in no respect from each other. The phthiriasis, or lousy disease, though very little known at present, was frequent enough among the ancients: Herod, Antiochus Epiphanes, Alcman the poet, Pherecydes, Cassander, Callisthenes, and Sylla,

---

The multiplication of these insects is unfortunately far too great, but they are not quite so prolific as some have represented. Experiments have proved that in six days a louse can lay fifty eggs, and that some will still remain in the belly. The young ones soon issue from the eggs, (at the end of six days,) and change their skin several times, after which, they are in a state to reproduce. This occurs about eighteen days after, when they begin to lay in their turn. According to these observations, and the calculations to which they have given rise, two female lice may have eighteen thousand descendants in the course of two months.

Linnæus considered the louse, which remains constantly on the human head, as a variety of the common louse. It is, however, from its characters, and also from its undeviating locality, proved to be a distinct species. This same great naturalist also informs us, that the largest lice he ever met with, are to be found in the warm caverns of Fahlun, in Sweden.

Children, and persons who totally neglect their hair, and are otherwise of filthy habits, are generally infested by the head-lice. When powder was fashionable, and preposterously esteemed an embellishment to the hair, it frequently proved a productive cause of these vermin. Those who left too long upon their head the dandriff produced by the use of powder, or who employed adulterated powder for the ornament of their hair, were very liable to the intrusion of these unamiable guests. The other species, which is found on all parts of the body, excepting those of generation, comes generally in consequence of the neglect of personal cleanliness, and the not changing the linen and internal garments sufficiently often. It is from this same species that those persons suffer who are afflicted with that most dreadful and disgusting malady *phthiriasis*. It may be observed that their appearance, though in fewer numbers, is sometimes indicative of the approach, or even of the crisis of other diseases, and that where there is no neglect of personal cleanliness.

As for the third species, we believe, that its appearance is invariably the result of indiscriminate debauchery, accompanied of course with personal neglect.

Dirt attracts these insects, and prepares for them a nidus favourable to the reproduction of their posterity. This is the vice which must be first eradicated if we are desirous of being protected from their inroads, or if already attacked by them, of rendering more efficacious any other means employed for their destruction.

The remedies employed against these vermin act in two ways. Some of them, such as oily and fatty substances, or such as contain azotic gas, close up the stigmata of these insects, or the apertures destined for the admission of air, and smother them. Others, such as the seeds of *staphis agria*, of larks-spur, tobacco, &c. reduced to a powder, produce the effect of a violent poison, and exercise their influence on the general organization of the animals. Mercurial preparations are, of all others, the most certain and speedy agents of their destruction. They may also be employed for the extinction of the species which infest our domestic animals.

It is said that lice, by piercing the skin, often produce pustules which may be converted into itch or tinea. Their multiplication, in certain subjects, is carried to such an extent as to produce the mortal malady which has been already noticed, namely, *morbus pedicularis* or *phthiriasis*. History has afforded us many examples of this; Pheretima, mentioned by Herodotus; Sylla, Antiochus Epiphanes, the two Herods, Maximin, and

---

Philip the Second, perished of this disease, or something very analogous to it. Mr Kirby is prone to think that it has fallen particularly as a judgment from God on the oppressors of mankind and the persecutors of religion. But this and all such notions ought to be admitted with caution, or rather rejected altogether. Until it is shown that the disease in question has fallen upon such persons alone, and on no others, we must discard the idea of its being an instrument of Divine vengeance. But this is so far from being the case, that the reverend entomologist himself informs us that "this most loathsome of all maladies, or one equally disgusting, has been the inheritance of the rich, the wise, the noble, and the mighty; and in the list of those who have fallen victims to it, you will find poets, philosophers, princes, kings, and emperors." It would be somewhat hard to believe that among all these there was not one less bloody than the first, or less profligate than the second Herod, less oppressive than Maximin, or less bigotted than Philip. The fact is, diseases of all kinds, like the rain of heaven, fall upon the just and the unjust. They follow, to be sure, as a pretty certain consequence, the indulgence in some vices. Intemperance of all kinds will entail them on the practiser as a necessary, but a *natural* punishment. But the man who unites a sound constitution to a prudent care of his health, may be at once supremely wicked and remarkably healthy. He may cheat and rob, and oppress and murder, but while he avoids the vices which are ruinous to health, he is more likely to find the reward of his villanies here from the indignation of mankind than from any heaven-descended visitation of disease.

Mr Kirby seems doubtful whether all the cases recorded as of *morbus pedicularis* are referrable to the same specific cause. He believes there is sufficient reason for thinking that three different kinds of insects are concerned in the production of diseases which have all been confounded under the name of *phthiriasis*. Besides those produced by *pediculi*, this eminent naturalist refers many cases to the agency of *acari*, or mites, and *larvæ* in general.

It has never been proved, in any well authenticated way, that the species of the genus pediculus burrow beneath the skin, or are *subcutaneous*. This remark is equally applicable to man, and the lower animals, as far as we know anything of the habits of the genus in question. For this we have the highest medical authority, as far as man is concerned. Dr Mead informs us that "the louse feeds on the surface of the skin," and Dr Willan, in a work on cutaneous diseases, states, respecting the body-louse, that "the nits or eggs, are deposited on the small hairs of the skin, and the animals are found on the skin, or on the linen, and not under the cuticle, as some authors have represented." The same writer informs us, "that many marvellous stories are related by Forestus, Schenkius and others, respecting lice bred under the skin, and discharged in swarms from abscesses, strumous ulcers, and vesications. The mode in which pediculi are generated being now so well ascertained, no credit can be given to these accounts." He thinks, however, that those authors have mistaken some other insects for lice, as some such animals may sometimes be found in putrid ulcers.

It appears, therefore, that cases of disease from animals residing under the cuticle, cannot be referred to pediculi. The poet Alcman, and Pherecydes Syrius, the philosopher, are mentioned by Aristotle, as having died of some complaint of this kind. But it could not have been a true phthiriasis, as that great philosopher,

all died of this disorder. The use of mercury, which was unknown among the ancients, may probably have banished it from among the moderns; for certain it is, that these animals seldom attack any in our climate, but such as from sloth or famine invite their company.

Such is the history of the human louse, which, from its connection with mankind, deserves first notice: but it would be endless to describe the various tribes that go under this name, and swarm upon every part of Nature. There is scarce an animal, and scarce even a vegetable, that does not suffer under its own peculiar louse. The sheep, the horse, the hog, and the elephant, are all teased by them; the whale, the shark, the salmon, and the lobster, are not without their company; while every hot-house, and every garden, is infested with some peculiarly destructive. Linnæus tells us, that he once found a vegetable-louse upon some plants newly arrived from America; and, willing to trace the little animal through its various stages, he brought it with him from London to Leyden, where he carefully preserved it during the winter, until it bred in the spring; but the louse it seems did not treat him with all the gratitude he expected; for it became the parent of so numerous a progeny, that it soon overran all the physic-garden of that beautiful city; and leaves, to this day, many a gardener to curse the Swede's too indulgent curiosity.

---

who attributed it to lice, imagined; for he tells us, that "they are produced in the flesh, in small pustules, like tumours, which have no pus, and from which, when punctured, they issue." Dr Heberden, in his Commentaries, informs us of a similar case, which he terms *morbus pedicularis*, but which could not be so, for the same reason. He represents the insect as inhabiting tumours, from which, when opened, they issue. He also tells us, that in all respects they resemble the common louse, but in being whiter. But an observer not accurately skilled in entomology, might, as Mr Kirby very justly remarks, easily mistake an *acarus* for a *pediculus*.

Dr Willan has cited two other cases, which he seems to think may with propriety be referred to true *phthiriasis*. In one of these cases, it is stated that the pediculi so abounded, that two black servants had no other employment than that of carrying baskets full of these insects, and throwing them into the sea. This, as Mr Kirby observes, appears to be somewhat exaggerated and hyperbolical. We shall conclude this part of the subject, by observing, that phthiriasis must vary in its types, according to the species of pediculus by which it is produced.

The facts mentioned by Cuvier, that lice abandon the Spanish sailors, in a certain degree of latitude when going to the Indies, and revisit them again on their return, and that body lice are unknown in India, are observations that have need of being corroborated by more certain testimonies than we are yet in possession of. But, if true, there would be nothing in the fact very surprising. A degree of considerable heat, and a more abundant transpiration, might prove unfavourable to the propagation of the *pediculi corporis*. As their skin is more tender, the influence of the air might prove detrimental to them in those burning climates.

The disgusting fact, of these vermin being eaten, is not confined to the Hottentots, the Negroes of Western Africa, and the Simiæ. It has been observed to prevail among some of the American tribes, and is not uncommon even in Europe, as amongst the beggars in Spain and Portugal. Some authors have pointed out the courses which should be adopted to protect or free the person from these disgusting insects. The best of all, in ordinary cases, is cleanliness. Of the medical uses to which these animals have been applied, it is unnecessary to dilate here. No one, we fancy, of the least degree of intelligence, gives any credit to such remedies at present. It was imagined that their introduction into the uretha of new-born infants, troubled with suppression of urine, might, by the titillation which they caused in that canal, force the sphincter to relax, and give passage to the urine. Farriers used to employ the same remedy with horses in similar cases.

The *pediculi* proper, are confined to men and quadrupeds. The *ricini*, or bird-lice, to the feathered race.

It appears that the ancients designated under the name of *ricinus*, those acarides, or acari, vulgarly called ticks, which attach themselves to the skin of dogs, oxen, &c. Degeer might, therefore, have better employed another denomination for the present genus, and which preceding naturalists confounded with that of lice. Accordingly, Dr Leach has adopted, from Herman, the denomination of *nirmus*.

It was by no means surprising, that the earlier naturalists did not distinguish these animals from the lice; their external physiognomy is almost the same, but their organization is different in many essential points, and it is evident that these two genera approximate in a natural series. From the consideration of their resemblances and differences, and from some other facts, furnished by the trachean arachnida, and the branchiopoda, we may see that nature, in preserving always the same type of general forms, is pleased to modify, and sometimes rather abruptly, that of the manducatory apparatus, or that she easily converts organs adapted for grinding, into sucking organs, and *vice versa*. Her views in this respect are subordinate to the model on which the body of the animal is at first formed. This consideration caused M. Latreille to reject as a primary character, the division of insects into two lines—one composed of the grinding, and the other of the sucking insects.

The ricini live exclusively on animals of the class Aves. Degeer, it is true, makes mention of a ricinus found on the body of a dog; but this species M. Latreille refers to pediculus, and could discover no mandibles on it.

These insects remain by preference under the wings, about the axilla, and on the head of birds; they attach themselves there very strongly, by means of the two robust and equal crotchets which terminate their tarsi. They multiply there sometimes, in such quantities, that the birds grow considerably thinner, and may even die in consequence. Care should be taken to examine domestic birds, supposed to be infested by these vermin, and often to clean out the places in which they are kept, and where they are accustomed to rest. By such means they may also be protected from a species of mite, which multiplies prodigiously in such places, and by which these domestic animals are seriously incommoded.

The genus of the ricini is very numerous; there is no bird without one or two species. Redi has figured a great number of them, and though his figures are rude, one may easily see how many varieties the forms of these insects present. Their characters, manners, &c., are, with the exceptions already stated, the same as those of the lice. There is one singularity in the *ricinus pavonis*, and that is, that the antennæ are forked.—*Supplement to the English edition of Cuvier.*

The animal which some have called the Leaf-Louse, is of the size of a flea, and of a bright green, or bluish-green colour; the body is nearly oval, and is largest and most convex on the hinder part; the breast is very small, and the head is blunt and green: the eyes may be seen very plainly, being prominent on the fore part of the head, and of a shining black colour; near these there is a black line on each side; and the legs are very slender.[1]

These animals are usually found on the leaves of the orache, and other plants; and the weaker the leaves and buds are, these insects swarm upon them in greater abundance. Some plants are covered over with them; though they are not the cause of the plant's weakness, but the sign: however, by wounding and sucking the leaf, they increase the disease. They generally assume their colour from the plant on which they reside. Those that feed upon pot-herbs and plum-trees, are of an ash-colour; only they are greenish when they are young: those that belong to the alder and cherry-tree, are black; as also those upon beans, and some other-plants: those on the leaves of apples and rose-trees, are white: but as they leap, like grasshoppers, some place them in the number of the flea kind. The most uncommon colour is reddish; and lice of this sort may be found on the leaves of tansey; and their juice, when rubbed in the hands, tinges them with no disagreeable red. All these live upon their respective plants; and are often engendered within the very substance of the leaf.

All these bring forth their young alive; and the fœtus, when it is ready to be brought forth, entirely fills the belly of the female; its fore parts being excluded first, and then the hinder. The young one does not begin to move till the horns or feelers appear out of the body of the old one; and by the motion of these it first shows signs of life, moving them in every direction, and bending all their joints. When the horns and head are excluded, the two fore-feet follow, which they move with equal agility; after this follow the middle feet, and then the hinder: still, however, the young one continues sticking to its parent, supported only at one extremity, and hanging, as it were, in air, until its small and soft members become hardened and fitted for self-support. The parent then gets rid of its burden; by moving from the place where she was sitting, and forcing the young one to stand upon its legs, leaves it to shift for itself.

As the animal has not far to go, its provisions lying beneath it, during the summer it continues to eat and creep about with great agility. But as it is viviparous, and must necessarily lurk somewhere in winter, where its body may be defended from the cold, it endeavours to secure a retreat near the trees or plants that serve to nourish it in the beginning of spring. They never hide themselves in the earth, like many other insects, because they have no part of their bodies fitted to remove the earth: nor can they creep into every chink, as their legs are too long: besides, their bodies are so tender, that the least rough particle of the earth would hurt them. They, therefore, get into the deep chinks of the bark, and into the cavities of the stronger stalks, from whence they sally out upon the branches and leaves when the warmth of the sun begins to be felt. Neither the cold in the autumnal season, nor the lesser degree of heat in the spring, ever hurts them; they seldom, therefore, seek for hiding-places before the fall of the leaf, and are alert enough to take the earliest advantage of the returning spring.

Like many other insects, they cast their skins four several times: and, what is very remarkable, the males have four wings, but the females never have any. They all have

[1] *Of the Aphides, or Plant Lice.*—The minute animals which compose this singular tribe live entirely on vegetables, and the loftiest trees are as liable to their attacks as the most humble plant. Their numbers are often incalculably great. They prefer the young shoots on account of their tenderness, and frequently insinuate themselves into the very hearts of the plants, doing irreparable mischief even before they are discovered. But for the most part they beset the foliage, and are always found on the under side of the leaf. This they prefer, not only on account of its being most tender, but because it affords them protection from the weather.

Some of the species are constantly and unalterably attached to one or more particular kind of plants; but others feed indiscriminately on most sorts of herbage.

These insects are sometimes winged, and sometimes destitute of wings, without any distinction of sex. In the spring they are viviparous, producing their offspring alive; and in the autumn they are oviparous, depositing their eggs, like most other insects, in places where they remain secure through the winter till the ensuing spring, when they are hatched. The aphides afford also another surprising deviation from the general laws of nature; one impregnation of a female is sufficient for nine generations.

The *larvæ*, *chrysalides*, and perfect insects, have so little difference in external appearance, that they cannot be distinguished from each other.

If the aphides had not many enemies, their increase in summer would be so great, as by wounding and exhausting the tender shoots of the trees, sometimes to suppress their vegetation. Among their enemies, one of the principal is a small black species of ichneumon-fly, which darts its pointed tail into the bodies of the aphides, and at the same time deposits an egg in each. This egg afterwards produces a grub, which feeds on the body of the insect till it has acquired its full growth, when it undergoes its change, and entirely destroys its living nidus.

After a mild spring, most of the species of aphis become so numerous as to do considerable injury to the trees on which they are found. The best mode to remedy this evil is to lop off the infected shoots before the insects greatly multiplied, repeating the same operation before the time that the eggs are deposited. By the first pruning, a very numerous present increase will be prevented; and by the second, the following year's supply may in a great measure be cut off.

long legs, not only to enable them to creep over the long hairs of plants of leaves, but also to travel from one tree to another when they happen to stand at a distance. Their trunk or snout lies under their breast; and this they thrust into the pores of the plant to suck out the juice, for they do not gnaw them, like the caterpillar; but so hurt them by sucking, that the leaves become spotted, and as it were overrun with scabs; for which reason their edges always turn up towards the middle.

It has been said, that these insects are often carried away and devoured by ants; but this Frysch, from whom this description is taken, could never observe. The ants, indeed, are fond of those trees where there is a great number of these insects; but then it is only to suck the juice which flows from the leaves that have been just wounded. This more particularly happens in the heat of summer, when other moisture is wanting: however, he never found them hurting or carrying away any of these insects while alive; nor, indeed, were they able, for the leaf-louse is more than a match for the ant at single combat. Whenever they perceive the ant approaching behind them, they kick back with their hinder-feet, and thus drive off the invader, as a horse would a lion.

The three principal and constant enemies to these insects are, first, the fire-fly, which lays its eggs where these insects are in greatest number, which, producing a worm, seizes and devours all the leaf-lice that come near it: another enemy is the worm of a peculiar kind of beetle, which destroys them in great numbers: but the most formidable of all enemies, is the ichneumon fly, that seizes upon one of the largest females, and laying its egg upon her, this is hatched into a worm, which soon devours and destroys the animal from whose body it sprung.

CHAP. VI.

OF THE BUG AND ITS VARIETIES.

The Bug is another of those nauseous insects that intrude upon the retreats of mankind; and that often banish that sleep, which even sorrow and anxiety permitted to approach. This, to many men, is of all other insects the most troublesome and obnoxious. The night is usually the season when the wretched have rest from their labour; but this seems the only season when the bug issues from its retreats, to make its depredations. By day it lurks, like a robber, in the most secret parts of the bed; takes the advantage of every chink and cranny, to make a secure lodgment; and contrives its habitation with so much art, that scarce any industry can discover its retreat. It seems to avoid the light with great cunning; and if candles be kept burning, this formidable insect will not issue from its hiding-place. But when darkness promises security, it then issues from every corner of the bed, drops from the tester, crawls from behind the arras, and travels with great assiduity to the unhappy patient, who vainly wishes for rest and refreshment. It is generally vain to destroy one only, as there are hundreds more to revenge their companion's fate; so that the person who thus is subject to be bitten, remains the whole night like a centinel upon duty, rather watching the approach of fresh invaders, than inviting the pleasing approaches of sleep.[1]

Nor are these insects less disagreeable from their nauseous stench, than their unceasing appetites. When they begin to crawl, the whole bed is infected with the smell: but if they are accidentally killed, then it is insupportable.

These are a part of the inconveniences that result from the persecution of these odious insects; but happily for Great Britain, they multiply less in these islands than in any part of the continent.[2] In France and Italy the

[1] *Bugs.*—Female bugs lay their eggs four times a-year, namely, in March, May, July, and September, at each season laying fifty eggs; in other words, producing two hundred young in the space of a year. At the age of eleven weeks the young bugs have arrived at maturity, and are ready to become parents in turn. With this data, the following calculation may be made:—Suppose one female bug is allowed to enter a house just before laying time in spring, it will produce 50 young in March, of which 25 may be females. In May, the 26 females (that is, including the mother) will produce 1300 young; take 750 of these as females, we have in July 35,500 young; take 15,750 of these as females, along with the former 750, that will be 16,500 females, which in September will bring forth 825,000 young; take 412,500 of these as females, along with the former, 16,500 females, that will make 429,000, which in the ensuing March will produce 21,450,000; add to these the 429,025 males not reckoned, there is a total of 21,909,025, or very nearly twenty-two millions of bugs, all from a single parent in the course of twelve months. If a knowledge of this fact will not induce activity in extirpating the first bug which makes its appearance in a dwelling, we do not know what will.

[2] The *Bed Bug.*—It is supposed to have been introduced into this country in the fir timber that was brought over for the purpose of rebuilding London, after it had suffered by the great fire. For it is generally said that bugs were not known in England before that time; and many of them were found almost immediately afterwards in the new-built houses. Their most favourite food is blood, dried paste, size, deal, beech, osier, and some other kinds of timber, the sap of which they suck; and on any of these they are able to exist. They will not feed on oak, walnut, cedar, or mahogany; for several pairs which, for the sake of experiment, were confined with these kinds of wood, soon died, whilst those kept with the other continued to thrive through the whole year.

Bugs appear to have been favourite ingredients among

beds, particularly in their inns, swarm with them; and every piece of furniture seems to afford them a retreat. They grow larger also with them than with us, and bite with more cruel appetite.

This animal, if examined minutely, appears to consist of three principal parts; the head, the corselet, and the belly. It has two brown eyes, that are very small, and a little prominent, besides two feelers, with three joints; underneath these there is a crooked trunk, which is its instrument of torture, and which, when in motion, lies close upon the breast. The breast is a kind of ring, in which are placed the two first pair of legs. The belly consists of nine rings; under which are placed two pair of legs more, making six in all. Each leg has three joints, which form the thigh, the leg, and the foot, which is armed with a crooked claw, like a hook. The body is smooth, except a few short hairs, that may be seen by the microscope, about the vent, and on the two last rings. Its motion is slow and unwieldy; yet its sight is so exquisite, that the instant it perceives the light, it generally makes good its retreat; and they are seldom caught, though the bed swarms with them.

If we examine this insect internally, we shall find the great artery, which in all insects performs the functions of the heart; we shall find the apertures of the lungs on the right side and the left, through which the animal breathes; we shall find a stomach and intestines, which, as in other animals, run from the mouth to the anus. If the insect has been long kept fasting, there will be a mucus found in its body, like the white of an egg; but if crushed after a full meal, the human blood which it has sucked in will appear a little darkened, by having passed through the insect's body.

The male and female of these animals are plainly distinguishable from each other; and the parts of generation are obvious enough. They are often found coupling tail to tail; and in this state are very easily destroyed. The female has an ovary filled with eggs, joined together like a bunch of grapes; each egg being an oblong, almost cylindrical, inclining to white, and pretty transparent. In about two days after impregnation by the male, she deposits her eggs to the number of about a hundred and fifty, in some convenient place where they are likely to receive no disturbance. There they continue for some months; during which time, neither cold nor heat, neither moisture nor fumigation, can in the least retard their exclusion; but they come forth active, and ready for mischief.[1] It is this hardiness in the shell that seems to continue the breed; as the old ones die every winter, or are easily destroyed by any fumigation that is used for that purpose. But the eggs seem incapable of destruction; even those men who make a livelihood by killing these nauseous insects, though they can answer for the parent, can never be sure of the egg. For this reason they usually pay those houses to which they are called a second or a third visit, and at last exterminate them by perseverance.

The manner of destroying them seems rather the effects of assiduity than antidote; for the men called in upon this occasion, take every part of the furniture asunder, brush every part of it with great assiduity, anoint it with a liquid which I take to be a solution of corrosive sublimate, and having performed this operation twice or thrice, the vermin are most usually destroyed.

Cleanliness, therefore, seems to be the best antidote to remove these nauseous insects; and wherever that is wanting, their increase seems but a just punishment. Indeed, they are

---

the medicaments of ancient doctors. They were prescribed in wine for colic, and an ancient writer says, "It is no new remedy, and it is a certain cure: it once helped a governor of Zurich, so that he had like to have written a commendation in favour of them."

The *Leek-Green Bug*.—The leek-green bug is to be found in Great Britain, as well as in many other parts of Europe. Its body is green, without spots; the abdomen black above, the margin spotted with yellow; the body beneath of a yellowish green; with six yellow legs. The antennæ sometimes entirely reddish brown; their last joints are tipt with black.

The Harvest Bug.—This is one of the most teasing little animals in nature. Though bred and intended, like its congener, the red spider, to live on vegetables, as currents, rasp-berries, and French beans, yet it will desert these, whether by accident or design, to live on and annoy the most delicate and sensitive portion of the human race. These insects are so minute, that they are only visible to the keenest eyes, and then only when placed on any very smooth white surface; in course, they are only known by their effects. Ladies and children are the first to complain of their attacks; and chiefly where any part of the dress fits closely to the skin. There they seat themselves at the intersection of the lines, and lay such firm hold with their feet and jaws, that they cannot be displaced by rubbing, nor by washing, unless a powerful spirit or acid be used. A microscope readily detects them; and, by its assistance, they may be dislodged with the point of a muslin needle, and, if placed on writing-paper, will be seen to have eight legs, two tentacula or feelers, and an abdomen something egg-shaped; colour livid red; and in size no bigger than the point of a small needle. They lacerate the epidermis in some way or other, as a small hole is observable where they have been seated; and cause extreme itching and considerable inflammation of the part.—*Magazine Nat. Hist.*

[1] The female bug (as we have stated in a previous note) generally lays about fifty eggs at a time, which are white, and when protruded are covered with a viscous matter, which afterwards hardening sticks them firmly to the place where they are deposited. These are usually hatched in about three weeks. The young, for some time after they first escape from the egg, are perfectly white, but they generally become brown in the course of about three weeks. In eleven weeks they are at full growth.

sometimes found in such numbers among old furniture and neglected chambers, exposed to the south, that, wanting other sustenance, they devour each other. They are also enemies to other vermin, and destroy fleas very effectually; so that we seldom have the double persecution of different vermin in the same bed. Of the bug kind Linnæus reckons up forty.

CHAP. VII.

OF THE WOOD-LOUSE AND ITS VARIETIES.

The common wood-louse is seldom above half an inch long, and a quarter of an inch broad. The colour is of a livid black, especially when found about dunghills, and on the ground; but those that are to be met with under tiles, and in drier places, are of the colour of the hair of an ass.—It has fourteen feet, seven on each side; and they have only one joint each, which is scarcely perceivable. It has two short feelers, and the body is of an oval shape. When it is touched it rolls itself up into a sort of ball; and the sides near the feet are dentated like a saw. It is often found among rotten timber, and on decayed trees: in winter it lies hid in the crevices of walls and all sorts of buildings. The male is easily distinguishable from the female, being less and more slender. The eggs they lay are white and shining, like seed-pearls, and are very numerous: however, more properly speaking, although, when excluded, the young have all the appearance of an egg, yet they are alive, and, without throwing off any shell, stir and move about with great vivacity; so that this animal may properly be said to be viviparous. The little worms at first seem scarcely able to stir; but they soon feed, and become very brisk. These animals are of great use in medicine, being impregnated with a saline quality, which is diuretic and stimulating. Of this insect, Linnæus makes three species.

CHAP. VIII.

OF THE MONOCULUS; OR, ARBORESCENT WATER-FLEA.

This animal, which is of the size of a flea, appears to the sight, unassisted by the microscope, to have but one eye; for the eyes, by reason of the smallness of the head, seem to be joined to each other: they are situated in the trunk of this insect, and the beak is likewise very small and sharp-pointed. The structure of the eye is seen, by the microscope, to be reticulated, or made like a net; and the trunk of this insect, by which it feeds, is not only small and sharp, but also transparent. The insects are of a blood-red colour; and sometimes are seen in such multitudes on the surface of standing waters, as to make them appear all over red, whence many fanciful people have thought the water to be turned into blood.

Swammerdam tells us of a celebrated professor at Leyden, who was at first astonished by an appearance of this kind. Being once intent upon his studies, he heard a noise, of which, as it increased by degrees, he was desirous to know the cause. The maid-servant attending to his summons, appeared quite petrified with fear, and told him with a tremulous voice, that all the waters of Leyden were turned into blood! Upon this he went directly, in a small bark, to the place where the water was thus changed, and put some of the bloody water into a glass; but upon viewing it with attention, he observed, that it abounded with infinite numbers of these little red insects, which tinged the whole body of the fluid with that seemingly formidable colour. Thus his sudden fright was changed into lasting admiration.[1]

Of all parts of this animal, its branching arms, and the motion it makes with them in the water, deserve our greatest attention. By these the little creature can move in a straight line; waving its arms, as a bird does its wings in the air, sometimes upward, sometimes downward, sometimes to the right, sometimes to the left, yet still continuing to proceed in a right line. By striking the water with its arms, it can ascend with great velocity; and by striking it in a contrary direction, it dives with equal ease. As these motions are very rapid, the little animal appears to jump in the water, its head always tending to the surface, and its tail stretched downward. This insect is produced from an egg, which, when excluded, is

[1] The *Cancroid Monoculus*.—This curious little animal has a convex shell rounded in front, and truncated behind; the tail is furnished with two bristle-shaped processes. This insect is by far the largest of the European monoculi; exhibiting with great distinctness the numerous brachial and other parts, which in the smaller species are only to be viewed by the assistance of the microscope. The Linnæan genus monoculus has, by Fabricius Muller, been subdivided into different distinct genera, on account of the disposition of the eyes, which in some species are approximated, so as to appear as if single, while in others they are remote from each other.

The *Four-horned Monoculus*.—This may be considered as one of the most common of the genus to which it belongs, occuring during the whole year in the clearer ponds of stagnant waters, wells, &c. In the size of the body it scarcely exceeds a large mite, but if measured from the extremities of its limbs, will sometimes be found to equal the eighth of an inch in length. The female is, in general, distinguished by the remarkable appearance of the ovaries, which bear a resemblance to a double cluster of grapes in miniature.

carried on the back of the female, and soon is seen floating in the water round her. Its appearance at first is that of a very small whitish insect, endued with a very nimble motion. Except in colour, it suffers no change, only continuing to grow larger and redder as it grows old. They sometimes remain several days on the surface of the water; and sometimes are seen at the bottom only; but they are never at rest. They change their skin, like most other insects; and the cast skin resembles the insect itself so exactly, that one might mistake the mask for the animal.

CHAP. IX.

OF THE SCORPION AND ITS VARIETIES.[1]

There is scarcely an insect without wings that is not obnoxious to man: the smallest have the power of annoying him, either by biting or stinging him; and though each is in itself contemptible, they become formidable from their numbers. But of all this class, there is none so terrible as the Scorpion, whose shape is hideous, whose size among the insect tribe is enormous, and whose sting is generally fatal. Happy for England, the scorpion is entirely a stranger among us! In several parts of the continent of Europe it is but too well known, though it seldom grows above four inches long: but in the warm tropical climates it is seen a foot in length, and in every respect as large as a lobster.

The scorpion is one of the largest of the insect tribe, and not less terrible from its size than its malignity. It resembles a lobster somewhat in shape, but is infinitely more hideous. There have been enumerated nine different kinds of this dangerous insect, chiefly distinguished by their colour, there being scorpions yellow, brown, and ash coloured; others that are the colour of rusty iron, green, pale yellow, black, claret-colour, white, and gray.

There are four principal parts distinguishable in this animal; the head, the breast, the belly, and the tail. The scorpion's head seems, as it were, jointed to the breast; in the middle of which are seen two eyes; and a little more forward, two eyes more, placed in the fore-part of the head: these eyes are so small, that they are scarcely perceivable; and it is probable the animal has but little occasion for seeing. The mouth is furnished with two jaws; the undermost is divided into two, and the parts notched into each other, which serve the animal as teeth, and with which it breaks its food, and thrusts it into its mouth: these the scorpion can at pleasure pull back into its mouth, so that no part of them can be seen. On each side of the head are two arms, each composed of four joints; the last of which is large, with strong muscles, and made in the manner of a lobster's claw. Below the breast are eight articulated legs, each divided into six joints; the two hindmost of which are each provided with two crooked claws, and here and there covered with hair. The belly is divided into seven little rings; from the lowest of which is continued a tail composed of six joints, which are bristly, and formed like little globes, the last being armed with a crooked sting. This is that fatal instrument which renders this insect so formidable: it is long, pointed, hard, and hollow; it is pierced near the base by two small holes, through which, when the animal stings, it ejects a drop of poison, which is white, caustic, and fatal. The reservoir in which this poison is kept, is in a small bladder near the tail, into which the venom is distilled by a peculiar apparatus. If this bladder be gently pressed, the venom will be seen issuing out through the two holes above-mentioned; so that it appears, that when the animal stings, the bladder is pressed, and the venom issues through the two apertures into the wound.

There are few animals more formidable, or more truly mischievous, than the scorpion. As it takes refuge in a small place, and is generally found sheltering in houses, so it cannot be otherwise than that it must frequently sting those among whom it resides. In some of the towns of Italy, and in France, in the province of Languedoc, it is one of the greatest pests that torment mankind: but its malignity in Europe is trifling, when compared to what the natives of Africa and the East are known to experience. In Batavia, where they grow twelve inches long, there is no removing any piece of furniture, without the utmost danger of being stung by them. Bosman assures us, that, along the Gold Coast, they are often found larger than a lobster; and that their sting is inevitably fatal. In Europe, however, they are by no means so large, so venomous, or so plentiful. The general size of this animal does not exceed two or three inches; and its sting is very seldom found to be fatal. Maupertuis, who made several experiments on the scorpion of Languedoc, found it by no means so invariably dangerous as had till then been represented. He provoked one of them to sting a dog, in three places of the belly, where the animal was without hair: in about an hour after, the poor animal seemed greatly swollen, and became very sick; he then cast up whatever he had in his bowels; and for about three hours continued vomiting a whitish liquid. The belly was always

[1] The Scorpion is placed by naturalists among the *Arachnides* or Spiders.

greatly swollen, when the animal began to vomit; but this operation always seemed to abate the swelling; which alternately swelled, and was thus emptied, for three hours successively. The poor animal, after this, fell into convulsions, bit the ground, dragged himself along upon his fore-feet, and at last died, five hours after being bitten. He was not partially swollen round the place which was bitten, as is usual after the sting of a wasp or a bee; but his whole body was inflated, and there only appeared a red spot on the places where he had been stung.

Some days after, however, the same experiment was tried upon another dog, and even with more aggravated cruelty; yet the dog seemed no way affected by the wounds, but howling a little when he received them, continued alert and well after them; and soon after was set at liberty, without showing the smallest symptoms of pain. So far was this poor creature from being terrified at the experiment, that he left his own master's house, to come to that of the philosopher, where he had received more plentiful entertainment. The same experiment was tried by fresh scorpions, upon seven other dogs, and upon three hens; but not the smallest deadly symptom was seen to ensue. From hence it appears that many circumstances, which are utterly unknown, must contribute to give efficacy to the scorpion's venom. Whether its food, long fasting, the season, the nature of the vessels it wounds, or its state of maturity, contribute to, or retard its malignity, is yet to be ascertained by succeeding experiment. In the trials made by our philosopher, he employed scorpions of both sexes, newly caught and seemingly vigorous and active. The success of this experiment may serve to show, that many of those boasted antidotes which are given for the cure of the scorpion's sting, owe their success rather to accident than their own efficacy. They only happened to cure, when the sting was no way dangerous; but in cases of actual malignity, they might probably be utterly unserviceable.

The scorpion of the tropical climates being much larger than the former, is probably much more venomous. Helbigius, however, who resided for many years in the East, assures us, that he was often stung by the scorpion, and never received any material injury from the wound: a painful tumor generally ensued; but he always cured it, by rubbing the part with a piece of iron or stone, as he had seen the Indians practise before him, until the flesh became insensible. Seba, Moore, and Bosman, however, give a very different account of the scorpion's malignity; and assert, that, unless speedily relieved, the wound becomes fatal.[1]

It is certain that no animal in the creation seems endued with such an irascible nature. I have often seen them taken and put into a place of security, exerting all their rage against the sides of the glass vessel that contained them. I have seen them attempt to sting a stick, when put near them; and attack a mouse or a frog, while those animals were far from offering any injury. Maupertuis put three scorpions and a mouse into the same vessel together, and they soon stung the little animal in different places. The mouse, thus assaulted, stood for some time upon the defensive, and at last killed them all, one after another. He tried this experiment, in order to see whether the mouse, after it had killed, would eat the scorpions; but the little quadruped seemed entirely satisfied with the victory, and even survived the severity of the wounds it had received. Wolkamer tried the courage of the scorpion against the large spider, and enclosed several of both kinds in glass vessels for that purpose.[2] The success of this combat was very remarkable. The spider at first used all its efforts to immesh the scorpion in its web, which he immediately began spinning; but the scorpion rescued itself from the danger, by stinging its adversary to death: it soon after cut off, with its claws, all the legs of the spider, and then sucked all the internal parts at its leisure. If the scorpion's skin had not been so hard, Wolkamer is of opinion that the spider would have obtained the victory; for he had often seen one of these spiders destroy a toad.

The fierce spirit of this animal is equally dangerous to its own species; for scorpions are

[1] Many experiments have been made to ascertain the strength of the poison; and in warm climates it has uniformly been found fatal to the smaller animals. To man the wound is extremely painful. The place becomes inflamed, and the surrounding parts often turn livid, and require to be carefully dressed in order to prevent mortification.

A French physician, who paid great attention to the habits of these animals, has related many particulars respecting them. The care with which the female attended upon her young, and, by degrees, instructed them in the mode of hollowing out their burrow or nest, particularly attracted his attention. He made also many curious experiments on the effects of their poison; by allowing himself to be frequently stung, he discovered that these effects became less and less painful at every repetition, so that, by degrees, he became almost proof against their venom. He describes the part affected as becoming much swollen, and extremely painful, immediately after the infliction of the injury; and, according to the constitution of the individual, this painful feeling continued from twenty-four to forty-eight hours, or even as much as three days. But the most peculiar effect is a sudden and complete prostration of strength, to such an extent that the patient becomes at once deprived of the power of supporting himself. This curious symptom induced the doctor even to propose the use of the sting of the scorpion in medicine, in cases where it became necessary suddenly to reduce the pulsations of the heart.

[2] Ephemerides, Dec. 2, 1687, Observ. 224.

the cruelest enemies to each other. Maupertuis put about a hundred of them together in the same glass; and they scarce came into contact, when they began to exert all their rage in mutual destruction: there was nothing to be seen but one universal carnage, without any distinction of age or sex; so that in a few days there remained only fourteen, which had killed and devoured all the rest.

But their unnatural malignity is still more apparent in their cruelty to their offspring. He enclosed a female scorpion, big with young, in a glass vessel, and she was seen to devour them as fast as they were excluded: there was but one only of the number that escaped the general destruction, by taking refuge on the back of its parent; and this soon after revenged the cause of its brethren, by killing the old one in its turn.

Such is the terrible and unrelenting nature of this insect, which neither the bonds of society nor of nature can reclaim: it is even asserted that, when driven to an extremity, the scorpion will often destroy itself. The following experiment was ineffectually tried by Maupertuis: but I am so well assured of it by many eye-witnesses, who have seen it both in Italy and America, that I have no doubt remaining of its veracity. A scorpion, newly caught, is placed in the midst of a circle of burning charcoal, and thus an egress prevented on every side: the scorpion, as I am assured, runs for about a minute round the circle, in hopes of escaping: but finding that impossible, it stings itself on the back of the head, and in this manner the undaunted suicide instantly expires.

It is happy for mankind that these animals are thus destructive to each other; since otherwise they would multiply in so great a degree as to render some countries uninhabitable. The male and female of this insect are very easily distinguishable; the male being smaller and less hairy. The female brings forth her young alive, and perfect in their kind.[1] Rhedi having brought a quantity of scorpions, selected the females, which by their size and roughness were easily distinguishable from the rest, and putting them in separate glass vessels, he kept them for some days without food. In about five days one of them brought forth thirty-eight young ones, well shaped, and of a milk-white colour, which changed every day more and more into a dark rusty hue. Another female, in a different vessel, brought forth twenty-seven of the same colour: and the day following the young ones seemed all fixed to the back and belly of the female. For near a fortnight all these continued alive and well: but afterwards some of them died daily; until, in about a month, they all died except two.

Were it worth the trouble, these animals might be kept living as long as curiosity should think proper. Their chief food is worms and insects; and upon a proper supply of these, their lives might be lengthened to their natural extent. How long that may be, we are not told; but if we may argue from analogy, it cannot be less than seven or eight years; and perhaps, in the larger kind, double that duration. As they have somewhat the form of the lobster, so they resemble that animal in casting their shell, or more properly their skin; since it is softer by far than the covering of the lobster, and set with hairs, which grow from it in great abundance, particularly at the joinings. The young lie in the womb of the parent each covered up in its own membrane, to the number of forty or fifty, and united to each other by an oblong thread, so as to exhibit altogether the form of a chaplet.

Such is the manner in which the common scorpion produces its young; but there is a scorpion of America, produced from the egg, in the manner of the spider. The eggs are no larger than pin-points; and they are deposited in a web, which they spin from their bodies, and carry about with them till they are hatched. As soon as the young ones are excluded from the shell, they get upon the back of the parent, who turns her tail over them, and defends them with her sting. It seems probable, therefore, that captivity produces that unnatural disposition in the scorpion, which induces it to destroy its young; since, at liberty, it is found to protect them with such unceasing assiduity.[2]

[1] All the scorpion tribe are produced from eggs, of which one female lays a considerable number. After their escape from the egg, they undergo no farther transformation, except occasionally casting their skin like the spider.

CHAP. X.

OF THE SCOLOPENDRA AND GALLY-WORM.

Of these hideous and angry insects we know little, except the figure and the noxious quali-

[2] *Black Scorpion.*—The black Scorpion of Ceylon is a very dangerous insect, and its sting is frequently mortal. This species is about four inches long, and from one to two broad over the middle of the body. When running, or disturbed, their tail is usually carried on their backs. They bite with their fangs, or forceps, and instantly dart the sting, which lies in their tail, into the place they have bitten. Their sting emits a poison resembling milk, but not altogether so white. When these scorpions are attacked by their inveterate enemy the ant, and cannot get rid of him, they sting themselves to death.

The African Scorpion.—The general colour of this animal is a deep brown, nearly approaching in some specimens to black. It grows to a very large size, sometimes nearly a foot long.

ties. Though with us there are insects somewhat resembling them in form, we are placed at a happy distance from such as are really formidable. With us they seldom grow above an inch long; in the tropical climates they are often found above a quarter of a yard.

The Scolopendra is otherwise called the Centipes, from the number of its feet; and it is very common in many parts of the world, especially between the tropics. Those of the East Indies, where they grow to the largest size, are about six inches long, of a ruddy colour, and as thick as a man's finger: they consist of many joints; and from each joint is a leg on each side: they are covered with hair, and seem to have no eyes; but there are two feelers on the head, which they make use of to find out the way they are to pass: the head is very round, with two small sharp teeth, with which they inflict wounds that are very painful and dangerous. A sailor that was bit by one on board a ship, felt an excessive pain, and his life was supposed to be in danger: however, he recovered by the application of three roasted onions to the part, and was soon quite well. Of this animal there are different kinds; some living, like worms, in holes in the earth; others under stones, and among rotten wood; so that nothing is more dangerous than removing those substances, in the places where they breed.[1]

The Gally-worm differs from the scolopendra, in having double the number of feet; there being two on each side, to every joint of the body. Some of them are smooth, and others hairy; some are yellow, some black, and some brown. They are found among decayed trees, between the wood and the bark; as also among stones that are covered with moss. They all, when touched, contract themselves, rolling themselves up like a ball. Whatever may be their qualities in the tropical parts of the world, in Europe they are perfectly harmless; having been often handled and irritated, without any vindictive consequences.

All these, as well as the scorpion, are supposed to be produced perfect from the parent, or the egg; and to undergo no changes after their first exclusion. They are seen of all sizes; and this is a sufficient inducement to suppose, that they preserve their first appearance through the whole of their existence. It is probable, however, that, like most of this class, they often change their skins; but of this we have no certain information.

CHAP. XI.

OF THE LEECH.[2]

The last of this wingless tribe that I shall mention is the Leech, which, like all the for-

[1] *The Great Centipede.*—None of the insect tribe, the scorpions excepted, are so formidable in appearance as the centipede or great scolopendra. It is found in the East and West Indies, and in various parts of Africa, inhabiting chiefly the woods, where it is preyed upon by the different species of snakes. It is, however, sometimes found in houses, and is said to be so common in particular districts, that the inhabitants are obliged to have the feet of their beds placed in vessels of water, in order to prevent their being annoyed during night by these horrible reptiles.

The scolopendræ vary greatly both in size and colour. Some of them are of a deep reddish brown; others of a yellow ochre colour, livid yellow, or tinged with red; and are sometimes seen about a foot in length: they are, however, generally much less. Their legs terminate in very sharp hooks, or nails, of a shining black colour; and all the other legs are furnished with smaller ones of the same kind.

Gronovius says, that all the legs of this detestable animal are venomous; but its most formidable weapons are the two sharp and hooked instruments that are placed under its mouth, with which it destroys its prey. At the extremity of each of these there is a small opening, and from thence extends a tube, through which it is supposed the centipede emits the poisonous fluid into the wound inflicted by these fangs.

Leeuwenhock, desirous of ascertaining the influence of the poison, placed a large fly within reach of a centipede. He seized it between a pair of the middle feet, then passed it from one pair to the next, till it was brought under the fangs, which were plunged into its body, and it died instantly. St Pierre says, that in the Isle of France his dog was bitten by one of them which was upwards of six inches in length, and that the wound turned to a kind of ulcer, which was three weeks in healing. He was highly diverted in observing one of them overcome by a vast number of ants, that attacked it in conjunction, and, after seizing it by all its legs, bore it along as workmen would do a large piece of timber. Its poison is not more injurious than that of the scorpion, and seldom proves fatal to the larger animals.

[2] Cuvier classes leeches with worms, among the Annclida, or invertebrated animals with red blood.

The *Medicinal Leech*, (*Hirudo medicinalis*), may be known by having six yellowish lines, or striæ, on its back, while the under part is of a grayish hue, spotted with black; but, as we shall presently see, these markings are not uniformly found. The medicinal leech is common throughout the whole of Europe, but is much more abundant in the southern parts; it is generally about three inches in length. Formerly it was very abundant in Great Britain, but the improvements in agriculture, and the consequent drainage of the land, together with the great use made of it in medicine, have of late years rendered it of less frequent occurrence. On this account great quantities of leeches are imported; these chiefly come from Bourdeaux and Lisbon. The prevailing colour of the medicinal leech appears to vary according to the nature of the soil on which it is found. In winter the leech retires to waters of considerable depth, and seeks shelter in the mud at the bottom; but in the summer it appears to delight in shallow pools, basking, as it were, in the warmth of the sun: but if the water it frequents is in danger of being dried up by the summer heat, the leech buries itself in the mud at a considerable depth. Just before a thunder-storm, leeches appear much agitated, and rise frequently to the surface of the water; this, therefore, is considered by the *leech-*

mer, undergoes no varieties of transformation; but when once excluded from the body of the parent, preserves its first figure to the end. I place the history of the Leech among the first class of insects; while I have degraded the earth-worm, the Tænia, and the Polypus, into the class of zoophytes, or that imperfect tribe which serves to make the shade between animal and vegetable nature. Not but that the earth-worm or the polypus have their motions, their appetites, and their vital principles, as complete as the leech, and, to a cursory view, appear every way as complete animals. But there is one circumstance that lays the line between them; that exalts the one, and degrades the other. The earth-worm and the polypus may be cut into pieces, and each piece will produce a new and perfect animal: the leech cannot suffer this dissection, but dies when cut in two; an evident instance that it is possessed of a more perfect organization than those animals which it otherwise very much resembles.

The leech, from its uses in medicine, is one of those insects that man has taken care to provide; but, of a great variety, one kind only is considered as serviceable. The horse-leech, which is the largest of all, and grows to four inches in length, with a glossy black surface, is of no use, as it will not stick to the skin; the snail-leech is but an inch in length; and though it will stick, is not large enough to extract a sufficient quantity of blood from the patient; the broad-tailed leech, which grows to an inch and a half in length, with the back raised into a sort of ridge, will stick but on very few occasions: it is the large brown leech, with a whitish belly, that is made use of in medicine, and whose history best merits our curiosity.

The leech has the general figure of a worm, and is about as long as one's middle finger. Its skin is composed of rings, by means of which it is possessed of its agility, and swims in water. It contracts itself, when out of water, in such a manner, that when touched it is not above an inch long. It has a small head, and a black skin, edged with a yellow line on each side, with some yellowish spots on the back. The belly also, which is of a reddish colour, is marked with whitish yellow spots. But the most remarkable part of this animal is the mouth, which is composed of two lips, that take whatever form the insect finds convenient. When at rest, the opening is usually triangular; and within it are placed three very sharp teeth, capable of piercing not only the human skin, but also that of a horse or an ox. Still deeper in the head is discovered the tongue, which is composed of a strong fleshy substance, and which serves to assist the animal in sucking, when it has inflicted its triple wound; for no sooner is this voracious creature applied to the skin, than it buries its teeth therein, then closes its lips round the wounds which it has made; and thus, in the manner of a cupping-glass, extracts the blood as it flows to the different orifices.

In examining this animal's form farther towards the tail, it is seen to have a gullet and an intestinal canal, into which the blood flows in great abundance. On each side of this are seen running along several little bladders, which, when the animal is empty, seem to be filled with nothing but water; but when it is gorging blood, they seem to communicate with the intestines, and receive a large portion of the blood which flows into the body. If these bladders should be considered as so many stomachs, then every leech will be found to have twenty-four. But what is most extraordinary of all in this animal's formation is, that though it takes so large a quantity of food, it has no anus or passage to eject it from the body when it has been digested. On the contrary, the blood which the leech has thus sucked remains for several months clotted within its body, blackened a little by the change, but no way putrified, and very little altered in its texture or consistence. In what manner it passes through the animal's body, or how it contributes to its nourishment, is not easily accounted for. The water in which they are kept is very little discoloured by their continuance; they cannot be supposed to return the blood by the same passage through which it was taken in: it only remains, therefore, that it goes off through the pores of the body, and that these are sufficiently large to permit its exclusion.

But it is not in this instance alone that the leech differs from all other insects. It was remarked in a former chapter, that the whole insect tribe had the opening into their lungs placed in their sides, and that they breathed through those apertures as other animals through the mouth. A drop of oil poured on the sides of a wasp, a bee, or a worm, would quickly suffocate them, by stopping up the passages through which they breathe: but it is otherwise with the leech, for this animal may be immersed in oil without injury; nay, it will live therein; and the only damage it

---

gatherers as a favourable time for collecting them. The property by which a leech anticipates thunder, has induced some persons to employ it as a species of barometer; but its indications are very uncertain.

The *Horse-Leech*, (*Hirudo sanguisuga*), is much larger than the medicinal leech, and altogether of a greenish black. It is said to be dangerous, from the wounds which it inflicts; but much difference of opinion exists, even among learned naturalists, as to its power of drawing blood.

Leeches prey on worms, tadpoles, &c., which they devour with avidity.

will sustain is, that, when taken out, it will be seen to cast a fine pellucid skin exactly of the shape of the animal, after which it is as alert and vigorous as before. It appears from hence that the leech breathes through the mouth; and, in fact, it has a motion that seems to resemble the act of respiration in more perfect animals: but concerning all this we are much in the dark.

This animal seems to differ from all others in several respects: the rest of the reptile tribe are brought forth from eggs; the leech is viviparous, and produces its young one after the other, to the number of forty or fifty at a birth.[1] It is probable that, like the snail, each insect contains the two sexes, and that it impregnates and is impregnated in the same manner. The young ones are chiefly found in the month of July, in shallow running waters, and particularly when they are tepified by the rays of the sun. The large ones are chiefly sought after; and being put into a glass vessel filled with water, they remain for months, nay, for years, without taking any other subsistence. But they never breed in this confinement; and, consequently, what regards that part of their history still remains obscure.

[1] It was long a matter of dispute as to whether leeches were produced from eggs or born alive, but it is now ascertained that the ova are developed in a singular case, having some resemblance to the cocoon of a silk-worm. This cocoon is formed by the parent animal, and by it deposited in the mud or clay which composes the bed of the pool it inhabits.

The fact of the young leech being produced from these cocoons, although only latterly ascertained by naturalists, was long since well known to the dealers in leeches on the French coast, who avail themselves of this knowledge of their habits, to multiply them for the purpose of sale. It was by these means the leech-dealers of Bretagne, and particularly in Finisterre, replenished the ponds in which they preserved those leeches which were intended for the Paris market.

About the month of April or May, according to the nature of the season, they send out labourers, provided with spades and baskets, to the little muddy marshes, where they are known to exist in abundance. These workmen then set about removing those portions of mud that are known to contain cocoons, which are afterwards deposited in sheets of water previously prepared for their reception; here the young leeches quit the cocoons, and are allowed to remain six months, when they are removed to larger ponds.

In this part of the world they seldom grow to above four inches; but in America and the East they are found from six to seven. The pools there abound with them in such numbers that it would be dangerous bathing, if for no other consideration. Our sailors and soldiers, who the last war were obliged to walk in those countries through marshy grounds, talk with terror of the number of leeches that infested them on their march. Even in some parts of Europe they increase so as to become formidable. Sedelius, a German physician, relates, that a girl of nine years old, who was keeping sheep near the city of Bomist in Poland, perceiving a soldier making up to her, went to hide herself in a neighbouring marsh among some bushes; but the number of leeches was so great in that place, and they stuck to her so close, that the poor creature expired from the quantity of blood which she lost by their united efforts. Nor is this much to be wondered at, since one of those insects which, when empty, generally weighs but a scruple, will, when gorged, weigh more than two drachms.

When leeches are to be applied, the best way is to take them from the water in which they are contained about an hour before, for they thus become more voracious, and fasten more readily. When saturated with blood, they generally fall off of themselves; but if it be thought necessary to take them from the wound, care should be used to pull them very gently, or even to sprinkle them with salt if they continue to adhere: for if they be plucked rudely away, it most frequently happens that they leave their teeth in the wound, which makes a very troublesome inflammation, and is often attended with danger. If they be slow in fixing to the part, they are often enticed by rubbing it with milk or blood, or water mixed with sugar. As salt is a poison to most insects, many people throw it upon the leech when it has dropped from the wound, by which means it disgorges the blood it has swallowed, and it is then kept for repeated application. They seldom, however, stick after this operation; and as the price is but small, fresh leeches should always be applied whenever such application is thought necessary.

HISTORY OF INSECTS, &c.

BOOK II.

INSECTS OF THE SECOND ORDER.

CHAP. I.

OF THE SECOND ORDER OF INSECTS.

In the former part we gave a concise history of the most considerable insects that, without wings, were produced in a perfect state; either from the body of the parent alive, like quadrupeds, or from the egg, in the manner of birds. We come now to a second order of insects, that are produced from the egg, like the former, but not in a perfect state; for when first excluded, they are without wings. This, however, does not hinder the exercise of their animal functions; the insect, although not yet come to perfection, walks, leaps, and eats; nor is it ever deprived of motion, only that it rests a little when it is about to cast that part of its skin previous to its state of perfection. It is then seen to assume two wings, which, like a budding flower, burst through the case that contained them, and the animal becomes a winged insect in its state of highest perfection. To this order we may refer the Libella, or Dragon-Fly; the Formica Leo, or Lion-Ant; the Grasshopper; the Locust; the Cricket, the Wood-Cricket; the Mole-Cricket; the Flea-Locust; the Flying-Bug; the Tipula; the Water-scorpion; the Notonect, or Water-Fly; and many others.

CHAP. II.

OF THE LIBELLA, OR DRAGON-FLY.

Of all the flies which adorn or diversify the face of nature, these are the most various and the most beautiful: they are of all colours; green, blue, crimson, scarlet, white: some unite a variety of the most vivid tints, and exhibit in one animal more different shades than are to be found in the rainbow. They are called, in different parts of the kingdom, by different names; but none can be at a loss to know them, as they are distinguished from all other flies by the length of their bodies, by the largeness of their eyes, and the beautiful transparency of their wings, which are four in number. They are seen in summer flying with great rapidity near every hedge, and by every running brook; they sometimes settle on the leaves of plants, and sometimes keep for hours together on the wing.

Dragon-flies, though there are three or four different kinds, yet agree in the most striking parts of their history, and one account may serve for all. The largest sort are generally found from two to three inches long; their tail is forked; their body divided into eleven rings; their eyes are large, horny, and transparent, divided by a number of intersections; and their wings, that always lie flat when they are at rest, are of a beautiful glossy transparency; sometimes shining like silver and sometimes glistening like gold. Within the mouth are to be seen two teeth covered with a beautiful lip: with these the creatures bite fiercely when they are taken; but their bite is perfectly harmless, as I have experienced more than once.

These insects, beautiful as they are, are produced from eggs, which are deposited in the water, where they remain for some time without seeming life or motion. They are ejected by the female into the water in clusters, like a bunch of grapes, where they sink to the bottom by their natural weight, and continue in that state till the young ones find strength enough to break the shell, and to separate from each other. The form in which

they first show life, is that of a worm with six legs, bearing a strong resemblance to the dragon-fly in its winged state, except that the wings are yet concealed within a sheath peculiar to this animal. The rudiments of these appear in bunches on the back, within which the wings are folded up into each other, while all colours and varieties of painting appear transparent through the skin. These animals, upon quitting the egg, still continue in the water, where they creep and swim, but do not move swiftly. They have likewise a sharp sight, and immediately sink to the bottom, if any one come to the places wherein they live, or whenever they perceive the least uncommon object. Their food at that time is soft mud and the glutinous earthy substances that are found at the bottom.

When these animals prepare to change from their reptile to their flying state, they then move out of the water to a dry place, as into grass; to pieces of wood, stone, or any thing else they meet with. They there firmly fix their acute claws; and, for a short time, continue quite unmovable, as if meditating on the change they are to undergo. It is then observed, that the skin first opens on the head and back; and out of this opening they exhibit their real head and eyes, and at length their six legs; whilst, in the mean time, the hollow and empty skin, or slough of their legs, remains firmly fixed in its place. After this, the enclosed creature creeps forward by degrees; and by this means draws first its wings and then its body out of the skin; and proceeding a little farther, sits at rest for some time, as if immovable. During this time, the wings, which were moist and folded, begin by degrees to expand themselves, and to make smooth and even all those plaits which were laid against each other, like a closed fan. The body is likewise insensibly extended, until all the limbs have obtained their proper size and dimensions. All these surprising and difficult operations are accomplished by the force of the blood and the circulating humours. The creature cannot at first make use of its new wings, and therefore is forced to stay in the same place until all its limbs are dried by the circumambient air. It soon, however, begins to enter upon a more noble life than it had hitherto led in the bottom of the brook; and from creeping slowly and living accidentally, it now wings the air, and makes choice from amidst the variety of its provisions.

Indeed, no animal is more amply fitted for motion, subsistence, and enjoyment. As it hunts and seeks after its food flying in the air, Nature has provided it with two large eyes, which make almost the whole head, and which resemble glittering mother-of-pearl. It has also four expansive silver-coloured wings, with which, as with oars, it can turn itself with prodigious velocity; and to assist these, it is furnished with a very long body, which, like a rudder, directs its motions. As the wings are long, and the legs short, they seldom walk, but are ever seen either resting or flying. For this reason, they always choose dry branches of trees or shrubs to remain on; and when they have refreshed themselves a little, they renew their flight. Thus they are seen adorning the summer with a profusion of beauty, lightly traversing the air in a thousand directions, and expanding the most beautiful colours to the sun. The garden, the forest, the hedges, and the rivulets, are animated by their sports; and there are few who have been brought up in the country, who have not employed a part of their childhood in the pursuit.

But while these beautiful flies appear to us so idly and innocently employed, they are in fact the greatest tyrants of the insect tribe; and, like the hawk among birds, are only hovering up and down to seize their prey. They are the strongest and the most courageous of all winged insects; nor is there one, how large soever, that they will not attack and devour. The blue-fly, the bee, the wasp, and the hornet, make their constant prey; and even the butterfly, that spreads so large a wing, is often caught and treated without mercy. Their appetite seems to know no bounds; they spend the whole day in the pursuit, and have been seen to devour three times their own size in the capture of a single hour. They seize their prey flying with their six claws, and tear it easily to pieces with their teeth, which are capable of inflicting troublesome wounds.

But the males are upon the wing for another purpose beside that of food, as they are very salacious, and seek the females with great ardour. The sun no sooner begins to warm the fields, than the males are found assiduously employed each in seeking its mate; and no sooner does a female appear, but two or three males are seen pursuing, and endeavouring to seize her with all their arts and agility. The instrument of generation in the male is placed very different from that of any other insect, being not at the end of the tail, as in others, but immediately under the breast, and consequently, at first view, incapable of being united to the sexual part of the female: which, as in order insects, lies in the tail. To perform this junction, Nature has provided the male with a very peculiar manner of proceeding. As soon as he perceives the female, and finds himself sufficiently near, he seizes upon the back of her head by surprise, and fastening his claws upon her, turns round his forky tail, which he fastens round her neck, and in this manner fixes himself so closely and firmly, that no efforts can remove him. It is in vain

that she flies from one branch to another, and settles upon them, he still keeps fixed, and often continues in this situation for three or four hours successively. When he flies, she is obliged to fly with him; but he still directs the way: and though she moves her wings, she seems entirely guided by his motion. As yet, however, the business of impregnation is not performed; for to this the female must contribute; and she at last seems, by the continuance of her constraint, to comply; for, turning up the end of her tail to that part of the breast of the male in which lies the part proper for generation, both instruments meet, and the eggs of the female receive the necessary fecundation. An hour or two after this she flies to some neighbouring pool, where she deposits her eggs, as was already mentioned. There they continue in a reptile state for a year; and then are changed into a beautiful fly, resembling the parent.[1]

CHAP. III.

OF THE FORMICA LEO, OR LION-ANT.

Although this animal properly belongs to no order of insects, yet as it is changed into a fly very much resembling that described in the preceding chapter, it may not be improper to give its history here. If we consider the life of this animal, in its different stages of existence, we shall find it equally wonderful in all; but as it changes to a dragon-fly, what we have said of that animal above, need not be repeated here. The lion-ant, when it becomes an inhabitant of air, in every respect resembles that which has been already described; its glossy wings, its voracious appetites, its peculiar manner of generation, are entirely the same. It is in its reptile state that it differs from all other insects; and in that state it will be amusing to pursue its history.

The lion-ant, in its reptile state, is of the size of a common wood-louse, but somewhat broader. It has a pretty long head and a roundish body, which becomes a little narrower towards the tail. The colour is a dirty gray, speckled with black, and the body is composed of several flat rings, which slip one upon another. It has six feet, four of which are fixed to the breast, and two to the neck. The head is small and flat, and before there are two little smooth horns or feelers, which are hard, about a quarter of an inch long, and crooked at the ends. At the basis of the feelers there are two small black lively eyes, by which it can see the smallest object, as it is easily discovered by its starting from every thing that approaches.

To a form so unpromising, and so ill provided for the purposes of rapacity, this animal unites the most ravenous appetites in nature; but to mark its imbecility still stronger, as other animals have wings or feet to enable them to advance towards their prey, the lion-ant is unprovided with such assistance from either. It has legs, indeed; but these only enable it to run backward, so that it could as soon die as make the smallest progressive motion. Thus famished and rapacious as it ever seems, its prey must come to it, or rather into the snare provided for it, or the insidious assassin must starve.

But Nature, that has denied it strength or swiftness, has given it an equivalent in cunning, so that no animal fares more sumptuously, without ever stirring from its retreat. For this purpose, it chooses a dry sandy place at the foot of a wall, or under some shelter, in order to preserve its machinations from the rain. The driest and most sandy spot is the most proper for it; because a heavy clogged earth would defeat its labour. When it goes about to dig the hole where it takes its prey, it begins to bend the hinder part of its body, which is pointed, and thus works backward; making, after several attempts, a circular furrow, which serves to mark out the size of the hole it intends making, as the ancients marked out the limits of a city with a plough.

---

[1] During the grub-state of the dragon-fly, it preys with the most savage ferocity on all aquatic insects. It is, likewise, at this period, furnished with an apparatus at the end of the body, by which it can suck up and eject water with such considerable force, that the stream is perceptible to the distance of two or three inches from their bodies. If they are kept some time out of water, the desire or necessity of respiration is augmented: and accordingly, when replaced in a vessel filled with water, inspirations and respirations are repeated with unusual force and frequency.

The *Depressed Dragon-fly*.—This beautiful insect, the general manners or habits of which resemble those of its cogenera, is of so different a colour in the different sexes, that the shape is the chief criterion of the species. The body of the male is of a bright blue, with brown marginal variegations, while that of the female, on the contrary, is of a bright yellow, with similar marginal markings. Like the libellula grandis, this species is principally seen towards the decline of summer, and flies with great rapidity about the neighbourhood of brooks and stagnant waters. It differs much from other species of this genus, from the body being much flattened.

The *Black-winged Dragon-fly*.—This is one of the most common species in this country, and is generally seen flying, during the morning hours, about the banks of rivers or stagnant waters. The general colour of the body is deep blue-green, while the wings are marked in the middle by a very large patch or area of bluish black. The insect varies, however, in point of colour, more than any other species, and is sometimes seen with the wings perfectly plain or unmarked, and sometimes, on the contrary, entirely blue-black: the tinge of the body also varies in a similar manner, being either bright golden-green, deep livid blue, or sometimes brown.

Within this first furrow it digs a second, then a third, and afterwards others, which are always less than the preceding. Then it begins to deepen its hole, sinking lower and lower into the sand, which it throws with its horns and feelers towards the edges, as we see men throw up sand in a gravel-pit. Thus, by repeating its labours all round, the sand is thrown up in a circle about the edge of the pit, until the whole is quite completed. This hole is always formed in a perfect circle; and the pit itself resembles the inside of an inverted funnel.[1] When this insect first leaves the egg and is newly hatched, the first pit it makes is very small; but as it grows bigger, it makes a larger hole; which is destined, like a pitfall, to entrap its prey. It is generally about two inches deep, and as much in diameter.

[1] *The Ant-Lion.*—The observations of the continental naturalists have made known to us a pitfall constructed by an insect, the details of whose operations are exceedingly curious—we refer to the grub of the ant-lion (*Myrmeleon formicarius*), which, though marked by Dr Turton and Mr Stewart as British, has not (at least of late years) been found in this country. As it is not, however, uncommon in France and Switzerland, it is probable it may yet be discovered in some spot hitherto unexplored.

The ant-lion grub being of a gray colour, and having its body composed of rings, is not unlike a wood-louse (*Oniscus*), though it is larger, more triangular, has only six legs, and most formidable jaws, in form of a reaping-hook, or a pair of calliper compasses. These jaws, however, are not for masticating, but are perforated and tubular, for the purpose of sucking the juices of ants upon which it feeds. Vallisnieri was, therefore, mistaken, as Réaumur well remarks, when he supposed that he had discovered its mouth. Its habits require that it should walk backwards, and this is the only species of locomotion which it can perform. Even this sort of motion it executes very slowly; and were it not for the ingenuity of its stratagems, it would fare but sparingly, since its chief food consists of ants, whose activity and swiftness of foot would otherwise render it impossible for it to make a single capture. Nature, however, in this, as in nearly every other case, has given a compensating power to the individual animal, to balance its privations. The ant-lion is slow—but it is extremely sagacious;—it cannot follow its prey, but it can entrap it.

Grub of the Ant-Lion magnified, with one perfect Trap, and another begun.

The snare which the grub of the ant-lion employs, consists of a funnel-shaped excavation formed in loose sand, at the bottom of which it lies in wait for the ants that chance to stumble over the margin, and cannot, from the looseness of the walls, gain a sufficient footing to effect their escape. When the pitfall is intended to be small, it only thrusts its body backwards into the sand as far as it can, throwing out at intervals the particles which fall in upon it, till it is rendered of the requisite depth.

By shutting up one of these grubs in a box with loose sand, it has been repeatedly observed constructing its trap of various dimensions, from one to three inches in diameter, according to circumstances. When it intends to make one of considerable diameter, it proceeds as methodically as the most skilful architect or engineer amongst ourselves. It first examines the nature of the soil, whether it be sufficiently dry and fine for its purpose, and if so, it begins by tracing out a circle, where the mouth of its funnel-trap is intended to be. Having thus marked the limits of its pit, it proceeds to scoop out the interior. Getting within the circle, and using one of its legs as a shovel, it places therewith a load of sand on the flat part of its head, and it throws the whole with a jerk some inches beyond the circle. It is worthy of remark that it only uses one leg in this operation—the one, namely, which is nearest the centre of the circle. Were it to employ the others in digging away the sand, it would encroach upon the regularity of its plan. Working with great industry and adroitness in the manner we have just described, it quickly makes the round of its circle, and as it works backwards it soon arrives at the point where it had commenced. Instead, however, of proceeding from this point in the same direction as before, it wheels about and works a round in the contrary direction, and in this way it avoids throwing all the fatigue of the labour on one leg, alternating them every round of the circle.

Were there nothing to scoop out but sand or loose earth, the little engineer would have only to repeat the operations we have described, till it had completed the whole. But it frequently happens in the course of its labours, sometimes even when they are near a close, that it will meet with a stone of some size which would, if suffered to remain, injure materially the perfection of its trap. But such obstacles as this do not prevent the insect from proceeding: on the contrary, it redoubles its assiduity to remove the obstruction, as M. Bonnet repeatedly witnessed. If the stone be small, it can manage to jerk it out in the same manner as the sand; but when it is two or three times larger and heavier than its own body, it must have recourse to other means of removal. The larger stones it usually leaves till the last, and when it has removed all the sand which it intends, it then proceeds to try what it can do with the less manageable obstacles. For this purpose, it crawls backwards to the place where a stone may be, and thrusting its tail under it, is at great pains to get it properly balanced on its back, by an alternate motion of the rings composing its body. When it has succeeded in adjusting the stone, it crawls up the side of the pit with great care and deposits its burden on the outside of the circle. Should the stone happen to be round, the balance can be kept only with the greatest difficulty, as it has to travel with its load upon a slope of loose sand which is ready to

The work being thus, with great labour, finished, the insidious insect places itself in ambush, hiding itself in the bottom under the sand, in such a manner that its two horns encircle the bottom of the pit. All the sides of this pit-fall are made of the most loose and crumbling materials; so that scarce any insect can climb up that has once got down to the bottom. Conscious of this, the lion-ant remains in patient expectation, ready to profit by that accident which throws some heedless little animal into its den. If then, by misfortune, an ant, a wood-louse, or a small caterpillar, walks too near the edge of the precipice, the sand gives way beneath them, and they fall to the bottom of the pit, where they meet inevitable destruction. The fall of a single grain of sand gives the murderer notice at the bottom of its cave; and it never fails to sally forth to seize upon its prey. It happens sometimes, however, that the ant or the wood-louse is too nimble, and runs up the sides of the pit-fall before the other can make ready to seize it. The lion-ant has then another contrivance, still more wonderful than the former; for, by means of its broad head and feelers, it has a method of throwing up a shower of sand, which falls upon the struggling captive with tremendous weight, and once more crushes it down to the bottom. When the insect is once fallen thus low, no efforts can retrieve or release it; the lion-ant seizes it with its feelers, which are hollow, and darting them both into its body, sucks out all the little animal's juices with the utmost rapacity.

When the prey is thus reduced to a husk, and nothing but the external form remains, the next care of the murderer is to remove the body from its cell; since the appearance of dead carcases might forewarn other insects of

give way at every step; and often when the insect has carried it to the very brink it rolls off its back and tumbles down to the bottom of the pit. This accident, so far from discouraging the ant-lion, only stimulates it to more persevering efforts. Bonnet observed it renew these attempts to dislodge a stone, five or six times. It is only when it finds it utterly impossible to succeed, that it abandons the design and commences another pit in a fresh situation. When it succeeds in getting a stone beyond the line of its circle, it is not contented with letting it rest there; but to prevent it from again rolling in, it goes on to push it to a considerable distance.

The pitfall, when finished, is usually about three inches in diameter at the top, about two inches deep, and gradually contracting into a point in the manner of a cone or funnel. In the bottom of this pit the ant-lion stations itself to watch for its prey. Should an ant or any other insect wander within the verge of the funnel, it can scarcely fail to dislodge and roll down some particles of sand, which will give notice to the ant-lion below to be on the alert. In order to secure the prey, Réaumur, Bonnet, and others have observed the ingenious insect throw up showers of sand by jerking it from his head in quick succession, till the luckless ant is precipitated within reach of the jaws of its concealed enemy. It feeds only on the blood or juice of insects; and as soon as it has extracted these, it tosses the dry carcase out of its den. Its next care is to mount the sides of the pitfall and repair any damage it may have suffered; and when this is accomplished, it again buries itself among the sand at the bottom, leaving nothing but its jaws above the surface, ready to seize the next victim.

When it is about to change into a pupa, it proceeds in nearly the same manner as the caterpillar of the water-betony moth (*Cucullia scrophulariæ*). It first builds a case of sand, the particles of which are secured by threads of silk, and then tapestries the whole with a silken web. Within this it undergoes its transformation into a pupa, and in due time, it emerges in form of a four-winged fly, closely resembling the dragon-flies (*Libellulæ*), vulgarly and erroneously called *horse-stingers*.

The instance of the ant-lion naturally leads us to consider the design of the Author of Nature in so nicely adjusting, in all animals, the means of destruction and of escape. As the larger quadrupeds of prey are provided with a most ingenious machinery for preying on the weaker, so are these furnished with the most admirable powers of evading their destroyers. In the economy of insects, we constantly observe, that the means of defence, not only of the individual creatures, but of their larvæ and pupæ, against the attacks of other insects, and of birds, is proportioned, in the ingenuity of their arrangements, to the weakness of the insect employing them. Those species which multiply the quickest have the greatest number of enemies. Bradley, an English naturalist, has calculated that two sparrows carry, in the course of a week, above three thousand caterpillars to the young in their nests. But though this is, probably, much beyond the truth, it is certain that there is a great and constant destruction of individuals going forward; and yet the species is never destroyed. In this way a balance is kept up, by which one portion of animated nature cannot usurp the means of life and enjoyment which the world offers to another portion. In all matters relating to reproduction, Nature is prodigal in her arrangements. Insects have more stages to pass through before they attain their perfect growth than other creatures. The continuation of the species is, therefore, in many cases, provided for by a much larger number of eggs being deposited than ever become fertile. How many larvæ are produced, in comparison with the number which pass into the pupa state; and how many pupæ perish before they become perfect insects! Every garden is covered with caterpillars; and yet how few moths and butterflies, comparatively, are seen, even in the most sunny season! Insects which lay few eggs are, commonly, most remarkable in their contrivances for their preservation. The dangers to which insect life is exposed are manifold; and therefore are the contrivances for its preservation of the most perfect kind, and invariably adapted to the peculiar habits of each tribe. The same wisdom determines the food of every species of insect; and thus some are found to delight in the rose-tree, and some in the oak. Had it been otherwise, the balance of vegetable life would not have been preserved. It is for this reason that the contrivances which an insect employs for obtaining its food are curious, in proportion to the natural difficulties of its structure. The ant-lion is carnivorous, but he has not the quickness of the spider, nor can he spread a net over a large surface, and issue from his citadel to seize a victim which he has caught in his outworks. He is therefore taught to dig a trap, where he sits, like the unwieldy giants of fable, waiting for some feeble one to cross his path. How laborious and patient are his operations—how uncertain the chances of success! Yet he never shrinks from them, because his instinct tells him that by these contrivances alone can he preserve his own existence, and continue that of his species.—*Insect Architecture.*

the danger of the place. The insect, therefore, takes up the wasted trunk with its feelers, and throws it, with wonderful strength, at least six inches from the edge of its hole; and then patiently sets about mending the breaches which its fortifications had received in the last engagement. Nothing can abate its industry, its vigilance, its patience, or its rapacity. It will work for a week together to make its pit-fall; it will continue upon the watch for more than a month, patiently expecting the approach of its prey; and if it comes in greater quantities than is needful, yet still the little voracious creature will quit the insect it has newly killed, and leave it half eaten, to kill and attack any other that happens to fall within the sphere of its malignity: though so voracious, it is suprisingly patient of hunger; some of them having been kept in a box with sand for six months and upwards, without feeding at all.

When the lion-ant attains a certain age, in which it is to change into another form, it then leaves off its usual rapacious habits, but keeps on its industry. It no longer continues to make pits, but furrows up the sand all around in an irregular manner; testifying those workings and violent agitations which most insects exhibit previous to their transformation. These animals are produced in autumn, and generally live a year, and perhaps two, before they assume a winged form. Certain it is, that they are found at the end of winter of all sizes; and it would seem that many of the smaller kinds had not yet attained sufficient maturity for transformation. Be this as it may, when the time of change approaches, if the insect finds its little cell convenient, it seeks no other; if it is obliged to remove, after furrowing up the sand, it hides itself under it, horns and all.—It there spins a thread, in the manner of the spider; which being made of a glutinous substance, and being humid from the moisture of its body, sticks to the little particles of sand among which it is spun; and in proportion as it is thus excluded, the insect rolls up its web, sand and all, into a ball, of which itself is the centre. This ball is about half an inch in diameter; and within it the insect resides, in an apartment sufficiently spacious for all its motions. The outside is composed of sand and silk; the inside is lined with silk only, of a fine pearl-colour, extremely delicate, and perfectly beautiful. But though the work is so curious within, it exhibits nothing to external appearance but a lump of sand; and thus escapes the search of birds that might otherwise disturb the inhabitant within. The insect continues thus shut up for six weeks or two months; and gradually parts with its eyes, its feelers, its feet, and its skin; all which are thrust into a corner of the inner apartment, like a rag. The insect then appears almost in its winged state, except that there is a thin skin which wraps up the wings, and that appears to be nothing else but a liquor dried on their outside. Still, however, the little animal is too delicate and tender to venture from its retreat; but continues enclosed for sometime longer: at length, when the members of this new insect have acquired the necessary consistence and vigour, it tears open its lodging, and breaks through its wall. For this purpose it has two teeth, like those of grasshoppers, with which it eats through, and enlarges the opening, till it gets out. Its body, which is turned like a screw, takes up no more than the space of a quarter of an inch; but when it is unfolded, it becomes half an inch in length; while its wings, that seemed to occupy the smallest space, in two minutes' time unfold, and become longer than the body. In short, it becomes a large and beautiful fly, of the libellula kind, with a long slender body, of a brown colour; a small head, with large bright eyes, long slender legs, and four large transparent reticulated wings. The rest of its habits resemble that insect whose form it bears; except, that instead of dropping its eggs in the water, it deposits them in sand, where they are soon hatched into that rapacious insect so justly admired for its method of catching its prey.

CHAP. VI.

OF THE GRASSHOPPER, THE LOCUST, THE CICADA, THE CRICKET, AND THE MOLE-CRICKET.

Belonging to the second order of insects, we find a tribe of little animals, which, though differing in size and colour, strongly resemble each other in figure, appetites, nature, and transformation. But though they all appear of one family, yet man has been taught to hold them in different estimation; for while some of this tribe amuse him with their chirpings, and banish solitude from the fields, others come in swarms, eat up every thing that is green, and in a single night convert the most delightful landscape into a dreary waste. However, if these animals be separately considered, the devouring locust is not in the least more mischievous than the musical grasshopper; the only difference is, that one species comes for food in a swarm, the other feeds singly.

That animal which is called the grasshopper with us, differs greatly from the cicada of antiquity; for as our insect is active enough in hopping through the long grass, from whence it has taken its name, the cicada had

not this power, but either walked or flew.[1] The little hissing note also of our grasshopper is very different from the song of the cicada, which was louder and far more musical. The manner in which this note is produced by the two animals is very different; for the cicada makes it by a kind of buckler, which the male has beneath its belly; the grasshopper by a

1 The *Cicada* is celebrated for its song, by the ancient Greek poets, under the name of Τεττιξ. The Romans called it *Cicada*, which we sometimes, but erroneously, translate "grasshopper;" for the grasshoppers belong to an entirely different order of insects. We shall, therefore, (says Mr Rennie) take the liberty of calling the Cicadæ, *Tree-hoppers*, to which the cuckoo-spit insect (*Tettigonia spumaria*, Oliv.) is allied; but there is only one of the true cicadæ hitherto ascertained to be British, namely, the *Cicada hæmatodes* (Linn.) which was taken in the New Forest, Hampshire, by Mr Daniel Bydder.

M. Reaumur was exceedingly anxious to study the economy of those insects; but they not being indigenous in the neighbourhood of Paris, he commissioned his friends to send him some from more southern latitudes, and he procured in this way specimens not only from the South of France and from Italy, but also from Egypt. From these specimens he has given the best account of them yet published; for though, as he tells us, he had never had the pleasure of seeing one of them alive, the more interesting parts of their structure can be studied as well in dead as in living specimens. We ourselves possess several specimens from New Holland, upon which we have verified some of the more interesting observations of Reaumur.

Virgil tells us, that in his time "the cicadæ burst the very shrubs with their querulous music;" but we may well suppose that he was altogether unacquainted with the singular instrument by means of which they can actually (not poetically) cut grooves in the branches they select for depositing their eggs. It is the male, as in the case of birds, which fills the woods with his song; while the female, though mute, is no less interesting to the naturalist on account of her curious ovipositor. This instrument, like all those with which insects are furnished by nature for cutting, notching, or piercing, is composed of a horny substance, and is also considerably larger than the size of the tree-hopper would proportionally indicate. It can on this account be partially examined without a microscope, being, in some of the larger species, no less than five lines * in length.

The ovipositor or auger *(tariere)* as Reaumur calls it, is lodged in a sheath which lies in a groove of the terminating ring of the belly. It requires only a very slight pressure to cause the instrument to protrude from its sheath, when it appears to the naked eye to be of an equal thickness throughout except at the point, where it is somewhat enlarged and angular, and on both sides finely indented with teeth. A more minute examination of the sheath demonstrates that it is composed of two horny pieces slightly curved, and ending in the form of an elongated spoon, the concave part of which is adapted to receive the convex end of the ovipositor.

When the protruded instrument is further examined with a microscope, the denticulations, nine in number on each side, appear strong, and arranged with great symmetry, increasing in fineness towards the point, where there are three or four very small ones, beside the nine that are more obvious. The magnifier also shows that the instrument itself, which appeared simple to the naked eye, is in fact composed of three different pieces, two exterior armed with the teeth before-mentioned, denominated by Reaumur files, *(limes)*, and another pointed like a lancet, and not denticulated. The denticulated pieces moreover are capable of being moved forwards and backwards, while the centre one remains stationary, and as this motion is effected by pressing a pin or the blade of a knife over the muscles on either side at the origin of the ovipositor, it may be presumed that those muscles are destined for producing similar movements when the insect requires them. By means of a finely pointed pin carefully introduced between the pieces, and pushed very gently downwards, they may be, with no great difficulty, separated in their whole extent.

* A line is about the twelfth part of an inch.

The contrivance by which those three pieces are held united, while at the same time the two files can be easily put in motion, are similar to some of our own mechanical inventions, with this difference, that no human workman could construct an instrument of this description so small, fine, exquisitely polished, and fitting so exactly. We should have been apt to form the grooves in the central piece, whereas they are scooped out in the handles of the files, and play upon two projecting ridges in the central piece, by which means this is rendered stronger. M. Reaumur discovered that the best manner of showing the play of this extraordinary instrument is to cut it off with a pair of scissors near its origin, and then, taking it between the thumb and the finger at the point of section, work it gently to put the files in motion.

Beside the muscles necessary for the movement of the files, the handle of each is terminated by a curve of the same hard horny substance as itself, which not only furnishes the muscles with a sort of lever, but serves to press, as with a spring, the two files close to the central piece, as is shown in the lower figure.

M. Pontedera, who studied the economy of the tree-hoppers with some care, was anxious to see the insect itself make use of the ovipositor in forming grooves in wood, but found that it was so shy and easily alarmed, that it took to flight whenever he approached; a circumstance of which Reaumur takes advantage to soothe his regret that the insects were not indigenous in his neighbourhood. But of their workmanship when completed, he had several specimens sent to him from Provence and Languedoc by the Marquis de Caumont.

The gall-flies, when about to deposit their eggs, select growing plants and trees; but the tree-hoppers, on the contrary, make choice of dead, dried branches, for the mother seems to be aware that moisture would injure her progeny. The branch, commonly a small one, in which eggs have been deposited, may be recognised by being covered with little oblong elevations caused by small splinters of the wood, detached at one end, but left fixed at the other by the insect. These elevations are for the most part in a line, rarely in a double line, nearly at equal distances from each other, and form a lid to a cavity in the wood about four lines in length, containing from four to ten eggs. It is to be remarked, that the insect always selects a branch of such dimensions, that it can get at the pith, not because the pith is more easily bored, for it does not penetrate into it at all, but to form a warm and safe bed for the eggs. M. Pontedera says, that when the eggs have been deposited, the insect closes the mouth of the hole with a gum capable of protecting them from the weather; but M. Reaumur thinks this only a fancy, as out of a great number which he examined, he could discover nothing of the kind. Neither is such a protection wanted; for the woody splinters above mentioned furnish a very good covering.

The grubs hatched from these eggs (of which, M. Pontedera says, one female will deposit from five to seven hundred) issue from the same holes through which the eggs have been introduced, and betake themselves to the ground to feed on the roots of plants. They are not transformed into chrysalides, but into active nymphs, remarkable for their fore limbs, which are thick, strong, and furnished with prongs for digging; and when we are

transparent membrane that covers a hole at the base of its wings. There is still a greater variety in all these with regard to shape and colour. Some are green, some black, some livid, and some variegated; but many of them do not show all their colours till they fly. Some have long legs, some short, some with more joints, others with fewer. Some sing, others are mute: some are innocent, doing no damage to the husbandman; while others do such prodigious mischief, that they are looked upon in some countries as one of the terrible scourges of the incensed Divinity.

Of this variegated tribe, the little grasshopper that breeds in such plenty in every meadow, and that continues its chirping through the summer, is best known to us; and by having its history, we shall be possessed of that of all the rest. This animal is of the colour of green leaves, except a line of brown which streaks the back, and two pale lines under the belly and behind the legs. It may be divided into the head, the corselet, and the belly. The head is oblong, regarding the earth, and bearing some resemblance to that of a horse. Its mouth is covered by a kind of round buckler jutting over it, and armed with teeth of a brown colour, hooked at the points. Within the mouth is perceivable a large reddish tongue, and fixed to the lower jaw. The feelers or horns are very long, tapering off to a point; and the eyes are like two black specks, a little prominent. The corselet is elevated, narrow, armed above and below by two serrated spines. The back is armed with a strong buckler, to which the muscles of the legs are firmly bound, and round these muscles are seen the vessels by which the animal breathes, as white as snow. The last pair of legs are much longer and stronger than the first two pair, fortified by thick muscles, and very well formed for leaping. It has four wings; the anterior one springing from the second pair of legs, the posterior from the third pair. The hinder wings are much finer and more expansive than the foremost, and are the principal instruments of its flight. The belly is considerably large, composed of eight rings, and terminated by a forky tail, covered with down, like the tail of a rat. When examined internally, besides the gullet, we discover a small stomach; and behind that a very large one, wrinkled and furrowed within side: lower down there is still a third; so that it is not without reason that all the animals of this order are said to chew the cud, as they so much resemble ruminant animals in their internal conformation.

A short time after the grasshopper assumes its wings, it fills the meadow with its note; which, like that among birds, is a call to courtship. The male only of this tribe is vocal; and, upon examining at the base of the wings, there will be found a little hole in its body, covered with a fine transparent membrane. This is thought, by Linnæus, to be the instrument it employs in singing: but others are of opinion the sound is produced by rubbing its hinder legs against each other: however this be, the note of one male is seldom heard, but it is returned by another; and the two little animals, after many mutual insults of this kind, are seen to meet and fight desperately. The female is generally the reward of victory; for, after the combat, the male seizes her with his teeth behind the neck, and thus keeps her for several hours till the business of fecundation is performed. They are at that time so strongly united, that they can scarcely be separated without tearing asunder. Towards the latter end of autumn the female prepares to deposit her burden; and her body is then seen greatly distended with her eggs, which she carries to the number of an hundred and fifty. In order to make a proper lodgment in the earth for them, Nature has furnished her with an instrument at her tail, somewhat resembling a two-edged sword, which she can sheathe and unsheathe at pleasure: with this she pierces the earth as deep as she is able; and into the hole which her instrument has made, she deposits her eggs, one after the other.

Having thus provided for the continuation of her posterity, the animal herself does not long survive; but as the winter approaches, she dries up, seems to feel the effects of age, and dies from total decay. Some, however, assert, that she is killed by the cold: and others, that she is eaten by worms: but certain it is, that neither the male nor female are ever seen to survive the winter. In the meantime the eggs which have been deposited continue unaltered, either by the severity of the season or the retardation of the spring. They are of an oval figure, white, and of the consistence of horn; their size nearly equals that of a grain of anise: they are enveloped in the body within a covering, branched all over with veins and arteries; and when excluded they crack, on being pressed between the fingers; their substance within is a whitish, viscous, and transparent fluid. In this manner they remain deposited beneath the surface of the earth during the whole winter; till the genial return of spring begins to vivify and hatch them. The sun, with its warmth, beginning to animate all nature, the insect eggs feel its benign influence; and generally, about the beginning of May, every egg produces an insect about the size of a flea. These, at first, are of a whitish colour; at the end of two or three days

told by Dr Le Fevre, that they make their way easily into hard stiff clay, to the depth of two or three feet, we perceive how necessary to them such a conformation must be.—*Insect Architecture.*

they turn black; and soon after they become of a reddish brown.

They appear, from the beginning, like grasshoppers, wanting wings; and hop among the grass, as soon as excluded, with great agility.

Yet still they are by no means arrived at their state of full perfection, although they bear a strong resemblance to the animal in its perfect form. They want, or seem to want, the wings, which they are at last seen to assume; and can only hop among the grass, without being able to fly. The wings, however, are not wanting, but are concealed within four little bunches, that seem to deform the sides of the animal: there they lie rolled up in a most curious manner; and occupying a smaller space than one could conceive who saw them extended. Indeed, all insects, whatever transmutations they seem to undergo, are yet brought forth with those very limbs, parts, and wings, which they afterwards seem to acquire. In the most helpless caterpillar there is still to be seen the rudiments of that beautiful plumage which it afterwards expands when a butterfly: and though many new parts seem unfolded to the view, the animal acquires none but such as it was from the beginning possessed of. The grasshopper, therefore, though seemingly without wings, is, in reality, from the first, possessed of those instruments, and only waits for sufficient force to break the bonds that hold them folded up, and to give them their full expansion.

The grasshopper, that, for above twenty days from its exclusion, has continued without the use of its wings, which were folded up to its body, at length prepares for its emancipation, and for a life of greater liberty and pleasure. To make the proper dispositions for the approaching change, it ceases from its grassy food, and seeks about for a convenient place beneath some thorn or thistle, that may protect it from an accidental shower. The same laborious writhings and workings, heavings and palpitations, which we have remarked in every other insect upon an approaching change, are exhibited in this. It swells up its head and neck; it then seems to draw them in again; and thus alternately, for some time it exerts its powers to get free. At length, the skin covering the head and breast is seen dividing above the neck; the head is seen issuing out first from the bursting skin; the efforts still continuing, the other parts follow successively; so that the little animal, with its long feelers, legs and all, works its way from the old skin, that remains fixed to the thistle or the thorn. It is, indeed, inconceivable how the insect can thus extricate itself from so exact a sheath as that which covereth every part of its body.[1]

The grasshopper, thus disengaged from its outer skin, appears in its perfect form; but then so feeble, and its body so soft and tender, that it may be moulded like wax. It is no longer of that obscure colour which it exhibited before, but of a greenish white, which becomes more vivid as the moisture on the surface is dried away. Still, however, the animal continues to show no signs of life, but appears quite spent and fatigued with its labour for more than an hour together. During this time, the body is drying, and the wings unfolding to their greatest expansion; and the curious observer will perceive them, fold after fold, opening to the sun, till at last they become longer than the two hinder legs. The insect's body also is lengthened during this operation, and it becomes much more beautiful than before.

These insects are generally vocal in the midst of summer, and they are heard at sunsetting much louder than during the heats of the day. They are fed upon grass; and, if their belly be pressed, they will be seen to return the juices of the plants they have last fed upon. Though unwilling to fly, and slow in flight, particularly when the weather is moist or cool, they are sometimes seen to fly to considerable distances. If they are caught by one of the hinder legs, they quickly disengage themselves from it, and leave the leg behind them. This, however, does not grow again, as with crabs or spiders; for as they are animals but of a single year's continuance, they have not sufficient time for repairing those accidental misfortunes. The loss of their leg also prevents them from flying; for being unable to lift themselves in the air, they have not room upon the ground for the proper expansion of their wings. If they be handled roughly, they will bite very fiercely; and when they fly, they make a noise with their wings. They generally keep in the plain, where the grass

[1] A curious circumstance regarding the grasshopper is related in the *American Quarterly Review*. The large winged grasshopper, which flutters with so much vivacity through our meadows during the autumn, feeds upon vegetable matter, and deposits its eggs upon vegetables, for the purpose of being supported until matured. Before the grasshopper takes wing another insect, the ichneumon, lights upon its body, and thrusts under its skin a number of its eggs, by means of a tubular awl-shaped oviduct. Those eggs slowly acquire perfection, become living worms, and feed upon the body of the hapless grasshopper, until themselves are ready to take wing. So admirably do they perform their office, that they do not injure the vital organs of the insect they are internally devouring, until they are just ready to change their state: and at the proper season, hundreds of grasshoppers, in this condition, have just strength enough remaining to flutter to a tree or fence, and with a dying effort fix their hooked feet so firmly as to retain their position long after death. Examine their bodies at this season, and you will find an empty shell or one filled with large and active worms, just ready to burst their coverings and become winged insects.

is luxuriant, and the ground rich and fertile: there they deposit their eggs, particularly in those cracks which are formed by the heat of the sun.

Such are the habits and nature of those little vocal insects that swarm in our meadows, and enliven the landscape. The larger kinds only differ from them in size, in rapidity of flight, and the powers of injuring mankind, by swarming upon the productions of the earth. The quantity of grass which a few grasshoppers that sport in the fields can destroy is trifling; but when a swarm of locusts, two or three miles long, and several yards deep, settle upon a field, the consequences are frightful. The annals of every country are marked with the devastation which such a multitude of insects produces; and though they seldom visit Europe in such dangerous swarms as formerly, yet, in some of the southern kingdoms, they are still formidable. Those which have, at uncertain intervals, visited Europe, in our memory, are supposed to have come from Africa, and the animal is called the Great Brown Locust. It was seen in several parts of England in the year 1748, and many dreadful consequences were apprehended from its appearance. This insect is about three inches long; and has two horns or feelers, an inch in length. The head and horns are of a brownish colour; it is blue about the mouth, as also on the inside of the larger legs. The shield that covers the back is greenish; and the upper side of the body brown, spotted with black, and the under side purple. The upper wings are brown, with small dusky spots, with one larger at the tips; the under wings are more transparent, and of a light brown, tinctured with green, but there is a dark cloud of spots near the tips. This is that insect that has threatened us so often with its visitations; and that is so truly terrible in the countries where it is bred. There is no animal in the creation that multiplies so fast as these, if the sun be warm, and the soil in which their eggs are deposited be dry. Happily for us, the coldness of our climate, and the humidity of our soil, are no way favourable to their production; and as they are but the animals of a year, they visit us and perish.

The Scripture, which was written in a country where the locust made a distinguished feature in the picture of nature, has given us several very striking images of this animal's numbers and rapacity. It compares an army, where the numbers are almost infinite, to a swarm of locusts: it describes them as rising out of the earth, where they are produced; as pursuing a settled march to destroy the fruits of the earth, and co-operate with divine indignation.

When the locusts take the field, as we are assured, they have a leader at their head, whose flight they observe, and pay a strict attention to all his motions. They appear, at a distance, like a black cloud, which, as it approaches, gathers upon the horizon, and almost hides the light of the day. It often happens that the husbandman sees this imminent calamity pass away without doing him any mischief; and the whole swarm proceeds onward, to settle upon the labours of some less fortunate country. But wretched is the district upon which they settle: they ravage the meadow and the pasture ground; strip the trees of their leaves, and the garden of its beauty: the visitation of a few minutes destroys the expectations of a year; and a famine but too frequently ensues. In their native tropical climates they are not so dreadful as in the more southern parts of Europe. There, though the plain and the forest be stripped of their verdure, the power of vegetation is so great, that an interval of two or three days repairs the calamity: but our verdure is the livery of a season; and we must wait till the ensuing spring repairs the damage. Besides, in their long flights to this part of the world, they are famished by the tediousness of their journey, and are, therefore, more voracious wherever they happen to settle. But it is not by what they devour that they do so much damage as by what they destroy. Their very bite is thought to contaminate the plant, and to prevent its vegetation. To use the expression of the husbandman, they burn whatever they touch, and leave the marks of their devastation for two or three years ensuing. But if they be noxious while living, they are still more so when dead; for wherever they fall, they infect the air in such a manner, that the smell is unsupportable. Orosius tells us, that, in the year of the world 3800, there was an incredible number of locusts which infected Africa; and, after having eaten up every thing that was green, they flew off, and were drowned in the African sea: where they caused such a stench, that the putrefying bodies of hundreds of thousands of men could not equal it.

In the year 1690, a cloud of locusts was seen to enter Russia in three different places; and from thence to spread themselves over Poland and Lithuania, in such astonishing multitudes, that the air was darkened, and the earth covered with their numbers. In some places they were seen lying dead, heaped upon each other four feet deep; in others, they covered the surface like a black cloth: the trees bent beneath their weight; and the damage which the country sustained exceeded computation. In Barbary their numbers are formidable, and their visits are frequent. In the year 1724, Dr Shaw was a witness, in that country, of their devastations. Their first ap-

pearance was about the latter end of March, when the wind had been southerly for some time. In the beginning of April, their numbers were so vastly increased, that, in the heat of the day they formed themselves into large swarms, which appeared like clouds, and darkened the sun. In the middle of May they began to disappear, retiring into the plains to deposit their eggs. In the next month, being June, the young brood began to make their appearance, forming many compact bodies of several hundred yards square; which afterwards marching forward, climbed the trees, walls, and houses, eating every thing that was green in their way. The inhabitants, to stop their progress, laid trenches all over their fields and gardens, filling them with water. Some placed large quantities of heath, stubble, and such like combustible matter, in rows, and set them on fire on the approach of the locusts. But all this was to no purpose; for the trenches were quickly filled up, and the fires put out by the vast number of swarms that succeeded each other. A day or two after one of these was in motion, others that were just hatched came to glean after them, gnawing off the young branches and the very bark of the trees. Having lived near a month in this manner, they arrived at their full growth, and threw off their worm-like state, by casting their skins. To prepare themselves for this change, they fixed their hinder feet to some bush or twig, or corner of a stone, when immediately, by an undulating motion used on this occasion, their heads would first appear, and soon after the rest of their bodies. The whole transformation was performed in seven or eight minutes' time; after which, they were a little while in a languishing condition; but as soon as the sun and air had hardened their wings, and dried up the moisture that remained after casting off their sloughs, they returned again to their former greediness, with an addition both of strength and agility. But they did not continue long in this state before they were entirely dispersed; after laying their eggs, directing their course northward, they probably perished in the sea. It is said that the holes these animals make, to deposit their eggs, are four feet deep in the ground; the eggs are about fourscore in number, of the size of caraway comforts, and bundled up together in clusters.[1]

It would be endless to recount all the mischiefs which these famished insects have at different times occasioned; but what can have induced them to take such distant flights, when

---

[1] *The Locust.*—Dr Clarke, in his Travels in Tartary, on approaching Cuffa, thus notices the number of locusts: "We now began to perceive the truth of those surprising relations which we had often heard and read concerning the locust in countries infested with that insect. The *steppes* were entirely covered by their bodies; and their numbers falling, resembled flakes of snow, carried obliquely by the wind, and spreading a thick mist over the sun. Myriads fell over the carriage, the horses, and the drivers. The stories of these animals, told us by the Tartars, were more marvellous than any we had before heard. They said that instances had occurred of persons being suffocated by a fall of locusts in the *steppes*. It was now the season, they further added, in which their numbers began to diminish. When they first make their appearance, a thick dark cloud is seen very high in the air, which, as it passes, obscures the sun. I had always supposed the stories of the locust to exaggerate their real appearance; but found their swarms so astonishing in all the *steppes* over which we passed in this part of our journey, that the whole face of nature might have been described as concealed by a living veil. They were of two kinds; the *gryllus Tartaricus*, and the *gryllus migratorius*, or common migratory locust. The first is almost twice the size of the second, and since it precedes the other, bears the name of the herald or messenger. The migratory locust has red legs, and its inferior wings have a lively red colour, which gives a bright fiery appearance to the animal when fluttering in the sun's rays. The strength of limbs possessed by it is amazing: when pressed down by the hand upon a table, it has almost power to raise the fingers; but this force resides wholly in the legs; for if one of these be broken off, which happens by the slightest accident, the power of action ceases. There is yet a third variety of locust, *gryllus viridissimus* of Linnæus, found near the Don and the Kuban, which is entirely of a green colour. This last I have since seen upon the banks of the Cam in my own country, and felt for the moment intimidated, lest such a presage should be the herald of the dreadful scourge which the locust bears wherever it abounds. On whatever spot these animals fall, the whole vegetable produce disappears. Nothing escapes them, from the leaves of the forest to the herbs of the plain. Fields, vineyards, gardens, pastures, everything is laid waste; and sometimes the only appearance left upon the naked soil is a disgusting superficies caused by their putrefying bodies, the stench of which is sufficient to breed a pestilence."

Ravages of Locusts.—When Captains Irby and Mangles were travelling round the southern extremity of the Dead Sea, in the end of May, they had an opportunity of observing these insect depredators. "In the morning," say they, "we quitted Shobek. On our way we passed a swarm of locusts that were resting themselves in a gully; they were in sufficient numbers to alter apparently the colour of the rock on which they had alighted, and to make a sort of crackling noise while eating, which we heard before we reached them. Volney compares it to the foraging of an army. Our conductors told us they were on their way to Gaza, and that they pass almost annually."

Even our own island has been alarmed by the appearance of locusts, a considerable number having visited us in 1748; but they happily perished without propagating. Other parts of Europe have not been so fortunate. They have frequently come also from Africa into Italy and Spain. In the year 591 an infinite army of locusts, of a size unusually large, ravaged a considerable part of Italy, and being at last cast into the sea, (as seems for the most part to be their fate,) a pestilence, it is alleged, arose from their stench, which carried off nearly a million of men and beasts. In the Venetian territory, likewise, in 1478, more than 30,000 persons are said to have perished in a famine chiefly occasioned by the depredations of locusts.—*Insect Transformation.*

Mode of Dispersing Locusts.—We traversed the grand *steppe* or desert of Astrakhan for two days. On the evening of the 1st of August, we arrived at a Russian village, which was surrounded by a considerable tract

they come into Europe, is not easy to be accounted for. It seems most probable, that, by means of a very dry season, in the heart of Africa, they are propagated in such numbers, that the vegetables of the spot where they are produced are not sufficient to sustain them. Thus being obliged to find out other countries, they traverse the sandy deserts, where they can find no sustenance: still meeting with nothing to allure them from their height, they proceed forward across the sea, and thus come into Europe, where they alight upon the first green pastures that occur.

In some parts of the world the inhabitants turn what seems a plague to their own advantage. Locusts are eaten by the natives in many kingdoms of the East; and are caught in small nets provided for that purpose. They parch them over the fire in an earthen pan; and when their wings and legs are fallen off, they turn reddish, of the colour of boiled shrimps. Dampier has eaten them thus prepared, and thinks them a tolerable dish. The natives of Barbary also eat them fried with salt; and they are said to taste like cray-fish.

There is a locust in Tonquin, about the bigness of the top of a man's finger, and as long as the first joint. It breeds in the earth, in low grounds; and in the months of January and February, which is the season for taking them, they issue from the earth in vast swarms. At first they can hardly fly, so that they often fall into the rivers in great numbers: however, the natives in these months watch the rivers, and take them up in multitudes in small nets. They either eat them fresh, broiled on the coals, or pickle them for keeping. They are considered as a great delicacy in that part of the world, as well by the rich as the poor. In the countries where they are eaten, they are regularly brought to market, and sold as larks or quails in Europe. They must have been a common food with the Jews, as Moses, in the book of Leviticus, permits them to eat four different kinds of this animal, which he takes care to specify. This dish, however, has not yet made its way into the kitchens of the luxurious in Europe; and though we may admire the delicacies of the East, we are as yet happily deprived of the power of imitation.

Of all animals, however, of this noxious tribe, the Great West Indian Locust, individually considered, is the most formidable. It is about the thickness of the barrel of a goose-quill, and the body is divided into nine or ten joints; in the whole, about six or seven inches long. It has two small eyes standing out of the head, like those of crabs; and two feelers, like long hair. The whole body is studded with small excrescences, which are not much bigger than the points of pins. The shape is roundish, and the body diminishes in circumference to the tail, which is forked into two horns. Between this, there is a sort of a sheath containing a small dangerous sting. If any person happens to touch this insect, he is sure to be stung; and is immediately taken with a shivering and trembling all over the body; which, however, may soon be put a stop to, by rubbing the place that was affected with a little palm oil.[1]

From the locust we descend to the Cricket, which is a very inoffensive and pretty animal. Though there be a species of this insect that lives entirely in the woods and fields, yet that with which we are best acquainted is the House-cricket, whose voice is so well known behind a country fire in a winter's evening. There is something so unusual in hearing a sound while we do not see the animal producing it, nor discover the place from whence it comes, that, among the country people, the chirping of the cricket is always held ominous; and whether it deserts the fire-side, or pays an unexpected visit, the credulous peasantry always find something to be afraid of. In general, however, the killing of a cricket is considered as a most unlucky omen: and though their company is not much desired, yet no methods must be taken to remove them.[2]

---

of well-cultivated land. While changing horses, I witnessed what was to me a very curious sight—a vast flight of locusts, extending fifteen miles, suddenly made their appearance from the east, and came in a huge phalanx to attack the crops. In an instant every villager was on the road to his own field. Some took dogs, others were on horseback, and others ran shouting and clapping their hands all the way, the inhabitants finding from experience that the locusts very much dislike noise. My fellow-traveller told me, that in the colony of Karass, when the locusts come in sight, not only all the inhabitants, but the military turn out, and endeavour to drive them off, by drums and fifes, and a perpetual discharge of musketry. The enemy, thus repulsed, make a speedy retreat and commit their depredations on the land of those who are less on the alert to resist them.—*Captain Keppel's Travels.*

[1] It is now known that every insect of this tribe is perfectly harmless.

[2] *The Cricket.*—While many other insects must be sought after in fields, and woods, and waters, the *gryllus domesticus*, or house-cricket, resides altogether within our dwellings, intruding itself upon our notice whether we will or not. This species delights in new-built houses, being, like the spider, pleased with the moisture of the walls; and, besides, the softness of the mortar enables them to burrow and mine between the joints of the bricks or stones, and to open communications from one room to another. They are particularly fond of kitchens and bakers' ovens, on account of their perpetual warmth.

Tender insects that live abroad either enjoy only the short period of one summer, or else doze away the cold uncomfortable months in profound slumbers; but these, residing as it were in a torrid zone, are always alert and merry; a good Christmas fire is to them like the heats of the dog-days. Though they are frequently heard by day, yet is their natural time of motion only in the night. As soon as it grows dusk, the chirping increases, and they come running forth, and are from the size of a flea

The cricket very much resembles the grasshopper in its shape, its manner of ruminating, its voice, its leaping, and methods of propagation. It differs in its colour, which is uniformly of a rusty brown; in its food, which is more various; and in its place of residence, which is most usually in the warmest chinks behind a country hearth. They are in some measure obliged to the bad masonry employed in making peasants' houses for their retreats. The smallest chink serves to give them shelter; and where they once make their abode they are sure to propagate. They are of a most chilly nature, seldom leaving the fireside: and, if undisturbed, are seen to hop from their retreats to chirrup at the blaze in the chimney. The wood-cricket is the most timorous animal in nature; but the chimney-cricket, being used to noises, disregards not only those, but the appearance of people near it. Whether the voice of this animal is formed in the same manner with that of the grasshopper, by a fine membrane at the base of the wings, which is moved by a muscle, and which being coiled up, gives a sound like a quail-pipe, is not yet ascertained; nor do we well know the use of this voice, since anatomical inspection has not yet been able to discover the smallest organs of hearing. Still, however, we can make no doubt of their power of distinguishing sounds, though probably not in the same manner with the more perfect ranks of nature. Certain it is, that I have often heard them call, and this call was as regularly answered by another, although none but the males are vocal.

As the cricket lives chiefly in the dark, so its eyes seem formed for the gloominess of its abode; and those who would surprise it, have only to light a candle unexpectedly; by which it is dazzled, and cannot find the way back to its retreat. It is a very voracious little animal, and will eat bread, flour, and meat; but it is particularly fond of sugar. They never drink, but keep for months together at the back of the chimney, where they could possibly have had no moisture. The warmth of their situation only serves to increase their mirth and loquacity. Except in the very coldest weather, they never cease their chirruping, but continue that little piercing note, which is as pleasing to some as it is disagreeable to others. The great Scaliger was particularly delighted with the chirruping of crickets, and kept several of them for his amusement, enclosed in a box, which he placed in a warm situation. Others, on the contrary, think there is something ominous and melancholy in the sound, and use every endeavour to banish this insect from their houses. Ledelius tells us of a woman who was very much incommoded by crickets, and tried, but in vain, every method of banishing them from her house. She at last accidentally succeeded; for having one day invited several guests to her house, where there was a wedding, in order to increase the festivity of the entertainment, she procured drums and trumpets to entertain them. The noise of these was so much greater than what the little animals were used to, that they instantly forsook their situation, and were never heard in that mansion more.

But of all the cricket kind, that which is called the *Mole Cricket* is the most extraordinary. This animal is the largest of all the insects with which we are acquainted in this country, being two inches and a half in length, and three quarters of an inch in breadth. The colour is of a dusky brown; and at the extremity of the tail there are two hairy excrescences, resembling, in some sense, the tail of a mouse. The body consists of eight scaly joints, or separate folds; is brown on the upper part, and more deeply tinged below. The wings are long, narrow, and terminate in a sharp point, each having a blackish line running down it: however, when they are extended, they appear to be much broader than could at

to that of their full stature. As one should suppose, from the burning atmosphere which they inhabit, they are a thirsty race, and show a great propensity for liquids, being found frequently drowned in pans of water, milk, broth, or the like. Whatever is moist they affect; and, therefore, often gnaw holes in wet woollen stockings and aprons that are hung to the fire; they are the housewife's barometer, foretelling her when it will rain; and are prognostics sometimes, she thinks, of ill or good luck; of the death of a near relation, or the approach of an absent lover. By being the constant companions of her solitary hours, they naturally become the objects of her superstition. These crickets are not only very thirsty, but very voracious; for they will eat the scummings of pots, and yeast, salt, crumbs of bread, and any kitchen offal or sweepings. In the summer we have observed them to fly, when it became dusk, out of the windows, and over the neighbouring roofs. This feat of activity accounts for the sudden manner in which they often leave their haunts, as it does for the method by which they come to houses where they were not known before. It is remarkable, that many sorts of insects seem never to use their wings but when they have a mind to shift their quarters and settle new colonies. When in the air, they move *volatu undoso*, in waves, or curves, like woodpeckers, opening and shutting their wings at every stroke, and so are always rising or sinking.

When they increase to a great degree, as they did once in the house where I am now writing, they become noisome pests, flying into the candles, and dashing into people's faces; but may be blasted and destroyed by gunpowder discharged into their crevices and crannies. In families, at such times, they are, like Pharaoh's plague of frogs, "in their bed-chambers, and upon their beds, and in their ovens, and in their kneading-troughs." Their shrilling noise is occasioned by a brisk attrition of their wings. Cats catch hearth-crickets, and, playing with them as they do with mice, devour them. Crickets may be destroyed, like wasps, by phials half filled with beer, or any liquid, set in their haunts; for, being always eager to drink, they will crowd in till the bottles are full.—*Natural History of Selborne.*

first sight be supposed. The shield of the breast is of a firm texture, of a blackish colour, and hairy. The fore-feet, which are this animal's principal instruments of burrowing in the earth, are strong, webbed, and hairy; it generally, however, runs backward; but it is commonly under ground, where it burrows even faster than a mole. It is thought also to be amphibious, and capable of living under water, as well as under ground.

Of all insects this is the most detested by gardeners, as it chiefly resides in that ground which lies light, and where it finds sufficient plenty under the surface. Thus, in a single night's time, it will run along a furrow, which has been newly sown, and rob it of all its contents. Its legs are formed in such a manner that it can penetrate the earth in every direction; before, behind, and above it. At night it ventures from its under-ground habitation, and, like the cricket, has its chirping call. When the female is fecundated, she makes a cell of clammy earth, the inside of which is large enough to hold two hazel-nuts; and in this she lays her eggs. The whole nest is about the size of a common hen's egg, closed up on every side, and well defended from the smallest breath of air. The eggs generally amount to the number of a hundred and fifty, being white, and about the size of a caraway comfort. They are thus carefully covered, as well to defend them from the injuries of the weather, as from the attacks of the black-beetle; that being itself an under-ground inhabitant, would, but for this precaution, devour or destroy them. To prevent this, the female mole-cricket is often posted as a sentinel near the nest; and when the black invader plunges in to seize its prey, the guardian insect seizes him behind, and instantly bites him in two.[1]

Nothing can exceed the care and assiduity which these animals exhibit in the preservation of their young. Wherever the nest is placed, there seems to be a fortification, avenues, and entrenchments drawn round it: there are numberless winding-ways that lead to it, and a ditch drawn about it, which few of its insect enemies are able to pass. But their care is not confined to this only; for at the approach of winter they carry their nest entirely away, and sink it deeper in the ground, so that the frost can have no influence in retarding the young brood from coming to maturity. As the weather grows milder, they raise their magazine in proportion; till, at last, they bring it as near the surface as they can, to receive the genial influence of the sun, without wholly exposing it to view; yet should the frost unexpectedly return, they sink it again as before.

[1] Among this tribe may be numbered the *great Lantern Fly of Peru*, an insect the most splendid and luminous of all that are yet known. In the head is contained a phosphorescent light, sufficiently vivid to serve the purposes of a candle in a dark room; or, when two or three are put together at the end of a stick, to light travellers on the road like a lantern. It is about the size of a larger kind of locust, and the wings and whole body are beautifully variegated.

CHAP. V.

OF THE EARWIG, THE FROTH INSECT, AND SOME OTHERS BELONGING TO THE SECOND ORDER OF INSECTS.

We should still keep in memory, that all insects, of the second order, though not produced quite perfect from the egg, yet want very little of their perfection, and require but a very small change to arrive at that state which fits them for flight and generation. The natural functions in these are never suspended: from the instant they leave the egg, they continue to eat, to move, to leap, and pursue their prey: a slight change ensues; a skin, that inclosed a part of their body and limbs, bursts behind, like a woman's stays, and gives freedom to a set of wings, with which the animal expatiates, and flies in pursuit of its mate.

Of all this class of insects, the earwig[2] undergoes the smallest change. This animal is so common, that it scarce needs a description: its swiftness in the reptile state is not less remarkable than its indefatigable velocity when upon the wing. That it must be very prolific, appears from its numbers; and that it is very harmless, every one's experience can readily testify. It is provided with six feet, and two feelers; the tail is forked; and with this it often attempts to defend itself against every

[2] *The Earwig.*—The name of this insect, in almost all European languages, has given it a character which causes a feeling of alarm even at the sight of it. Whether or not they ever did enter the human ear is doubtful, —that they might endeavour to do so, under the influence of fear, is more than probable; and this, perhaps, has been the origin of their name, and the universal prejudice against them. As it is said that anatomists deny the possibility of their deep or dangerous entrance into the ear, it is a pity that this is not generally known, as it might defend the constitutionally timid from unnecessary alarm, and give a more favourable idea of a part of animal creation, which forms a most necessary link in the chain of being.—*Brande's Journal.*

The great dread of the Ear-wig entering the ear is a popular error, whence, indeed, the animal derives its trivial name. Like many other insects, it enters any cavity in search of food or shelter; and it may, like them, enter the human ear as well as any other hole or hollow, but that it has a special predilection for that situation is a mistaken notion respecting the habits of the Forficula. —"*Miscellaneous Memoranda*" *in Notes on Nets, by the Hon. and Rev. C. Bathurst.*

assailant. But its attempts are only the threats of impotence; they draw down the resentment of powerful animals, but no way serve to defend it. The deformity of its figure, and its slender make, have also subjected it to an imputation, which though entirely founded in prejudice, has more than once procured its destruction. It is supposed, as the name imports, that it often enters into the ears of people sleeping; thus causing madness from the intolerable pain, and soon after death itself. Indeed, the French name which signifies the Ear-piercer, urges the calumny against the harmless insect in very plain terms; yet nothing can be more unjust: the ear is already filled with a substance which prevents any insect from entering; and besides, it is well lined and defended with membranes, which would keep out any little animal, even though the ear-wax were away. These reproaches, therefore, are entirely groundless: but it were well if the accusations which gardeners bring against the earwig were as slightly founded. There is nothing more certain than that it lives among flowers, and destroys them. When fruit also has been wounded by flies, the earwig generally comes in for a second feast, and sucks those juices which they first began to broach. Still, however, this insect is not so noxious as it would seem; and seldom is found but where the mischief has been originally begun by others. Like all of this class, the earwig is hatched from an egg. As there are various kinds of this animal, so they choose different places to breed in: in general, however, they lay their eggs under the bark of plants, or in the clefts of trees, when beginning to decay. They proceed from the egg in that reptile state in which they are most commonly seen; and as they grow larger, the wings bound under the skin begin to bourgeon. It is amazing how very little room four large wings take up before they are protruded; for no person could ever conceive such an expansion of natural drapery could be rolled up in so small a packet. The sheath in which they are enveloped, folds and covers them so neatly, that the animal seems quite destitute of wings;[1] and even when they are burst from their confinement, the animal, by the power of the muscles and joints which it has in the middle of its wings, can closely fold them into a very narrow compass. When the earwig has become a winged insect, it flies in pursuit of the female, ceasing to feed, and is wholly employed in the business of propagation. It lives in its winged state but a few days; and having taken care for the continuance of posterity, dries up, and dies to all appearance consumptive.[2]

To this order of insects we may also refer the Cuckoo Spit, or Froth Worm, that is often found hid in that frothy matter which we find on the surface of plants. It has an oblong obtuse body; and a large head with small eyes. The external wings, for it has four, are of a dusky brown, marked with two white spots: the head is black. The spume in which it is found wallowing is all of its own formation, and very much resembles frothy spittle. It proceeds from the vent of the animal, and other parts of the body; and if it be wiped away, a new quantity will be quickly seen ejected from the little animal's body. Within this spume it is seen in time to acquire four tubercles on its back, wherein the wings are enclosed: these bursting, from a reptile it becomes a winged animal; and thus rendered perfect, it flies to meet its mate, and propagate its kind.

The Water Tipula also belongs to this class. It has an oblong slender body, with four feet fixed upon the breast, and four feelers near the mouth. It has four weak wings, which do not at all seem proper for flying, but leaping only. But what this insect chiefly demands our attention for, is the wonderful lightness wherewith it runs on the surface of the water, so as scarce to put it in motion. It is sometimes seen in rivers, and on their banks, especially under shady trees; and generally in swarms of several together.

The Common Water-fly also breeds in the same manner with those above mentioned. This animal is by some called Notonecta, because it does not swim, in the usual manner, upon its belly, but on its back: nor can we help admiring that fitness in this insect for its situation, as it feeds on the under-side of plants which grow on the surface of the water; and therefore it is thus formed with its mouth upwards, to take its food with greater convenience and ease.

We may also add the Water-Scorpion, which is a large insect, being near an inch in length, and about half an inch in breadth. Its body is nearly oval, but very flat and thin; and its tail long and pointed. The head is small; and the feelers appear like legs, resembling the claws of a scorpion, but without sharp points. This insect is generally found in ponds; and is, of all others, the most tyrannical and rapacious. It destroys, like a wolf among sheep, twenty times as many as its hunger requires. One of these, when put into a basin of water, in which were thirty or forty worms of the libellula kind, each as large as itself, destroyed them all in a few minutes; getting on their backs, and piercing with its trunk through their body. These animals,

[1] Swammerdam, p. 114.

[2] The indefatigable M. de Geer has discovered that the female earwig sits over her eggs, and fosters her young, in the same manner as a hen does her chickens.

however, though so formidable to others, are nevertheless themselves greatly overrun with a little kind of louse, about the size of a nit, which very probably repays the injury which the water-scorpion inflicts upon others.

The water-scorpions live in the water by day: out of which they rise, in the dusk of the evening, into the air, and so flying from place to place often betake themselves, in quest of food, to other waters. The insect, before its wings are grown, remains in the place where it was produced; but when come to its state of perfection, sallies forth in search of a companion of the other sex, in order to continue its noxious posterity.

CHAP. VI.

OF THE EPHEMERA.[1]

The last insect we shall add to the second order is the Ephemera; which, though not strictly belonging to it, yet seems more properly referred to this rank than any other. Indeed, we must not attend to the rigour of method in a history where Nature seems to take delight to sport in variety.

That there should be a tribe of flies whose duration extends but to a day, seems, at first, surprising; but the wonder will increase, when we are told, that some of this kind seem to be born and to die in a space of a single hour. The reptile, however, from which they are bred, is by no means so short-lived; but is sometimes seen to live two years, and many times three years together.

All ephemeras, of which there are various

[1] *Ephemera.*—There are many species of these insects, some larger and some smaller, some longer-lived and some shorter, but as few of them live to behold the rising and the setting sun, they are all called *ephemera*, or "things of a day," their name is used to express all things that are very fleeting.

In autumn any one who walks by the water-side when the air is still, especially towards morning or evening, may catch them by thousands. They have four-wings, of a beautiful transparent membrane or film, spread out upon a fine net-work, of a substance very similar to horn. These fibres in the wings are called *nerves*, and the insects which have such wings are by naturalists called *neuroptera*, which is the Greek for "nerve-winged;" but these are not nerves. Nerves are understood to be organs of feeling or sensation; whereas, the fibres in the wings of those insects, merely support the membrane, just as the arm-frames of a windmill, or the masts and yards of a ship, support the canvas.

The eggs of the day-flies are all laid in the water, and hatched there; so that they so far partake of the nature of the eggs, or race of fishes, that they "come into active life," in less heat than land eggs, and do not need any *incubation*, or sitting, of the mother. Each female lays from 700 to 800, and she does it in less time than it takes to speak the words. The eggs are expelled in two portions, one of each at a time; but so fast, that the eggs seem two little knotted rods; but they separate and sink to the bottom undiscovered by the keen eyes of the fish. The female instantly dies, exhausted by the effort, which appears to be the only labour of her winged state of existence; if, indeed, she is not captured in the midst of her maternal duty by some darting fish, or skimming swallow; both of which prey upon countless thousands of the day-flies. When the fly lights to deposit her eggs, she raises her wings over her back, till they are nearly touching; and, at the same time, she elevates the hinder part of her body, and erects the three *setæ*, or bristles, in which it terminates. The wings and these bristles support her so that she barely touches the water, and so rises and falls with the ripple.

The moment that the females are in a condition to lay their eggs, they hasten to the waters, so that they are not so often seen as the males, whose only occupation is to sport in the air, in the neighbourhood of the cradle of their future offspring. Of these the little day-fly, which is born after dawn, produces her eight hundred, and is dead and gone, before the first gleam of the sun breaks over the eastern hill!

How long the eggs remain in the water before they are hatched, is not known; but possibly it varies with the season and the weather. The *larvæ* or young, in their first state, not only burrow, or make holes in the mud, but live on it; they are consequently not so numerous in sand and gravel as in places that are fat and oozy.

In summer the ponds, brooks, and ditches, are full of these larvæ, and so are water tanks, cisterns, and butts, if they are not kept clean. They (with the larvæ of other species) are among the chief summer impurities in the water at London and other places. If the water is not settled, they *may* come from the river; but the mud and sediment will enable them to breed in vessels, and the parent flies are every where. In themselves they are not unwholesome,—and, as they are alive, *they* cannot render the water putrid. The mud that breeds them, *is* putrid, however, as it contains dead animal and vegetable matter; and thus, though the young flies are not in themselves unwholesome, they are accompanied by substances that are so.

The larvæ remain in the mud two or three years; but in that they probably vary. The banks of rivers, in some parts of the continent, are so full of them, that to the depth of some inches, they actually contain more living matter than dead. They are all, however, lower than the surface of the water, and they breathe water, like fishes, by means of little gills on their sides. At length they attain their full size, and change into *nymphæ*, which are not unlike the larvæ, only they have wings folded up under their coats, of which they still have two, and must get out of both before they appear as flies.

The time that they remain nymphs is uncertain, and must vary, as the weather is one element in bringing about their last change. When that is to take place, they come out of the water, in vast numbers, and leave their old coats so abundant as to cover the water like a scum. After a little while they cast their inner coat; their wings stretch and become firm, and they mount into the air, to spend the hour, or the day, which is to them the whole period of air-breathing life.

That period is short; but that is necessary: for, in some places, if they were to live long, there would absolutely not be room for them. They eat nothing, and so destroy nothing; but there are places in France and Germany where, if they lived but for a month on the wing, they would build up the air solid to the tops of the trees. As it is, they sometimes fall on the ground near the rivers in showers like snow, and the people collect them in heaps as manure to the fields.

kinds are produced from the egg in the form of worms; from whence they change into a more perfect form; namely, that of aurelias, which is a kind of middle state between a worm and a fly; and from thence they take their last mutation, which is into a beautiful fly, of longer or shorter duration, according to its kind.

The ephemera, in its fly state, is a very beautiful-winged insect, and has a strong similitude to the butterfly, both from its shape and its wings. It is about the size of a middling butterfly; but its wings differ in not being covered with the painted dust with which those of butterflies are adorned, and rendered opaque, for they are very transparent, and very thin. These insects have four wings, the uppermost of which are much the largest; when the insect is at rest, it generally lays its wings one over the other, on the back. The body is long, being formed of six rings, that are larger at the origin than near the extremity; and from this a tail proceeds, that is longer than all the rest of the fly, and consists sometimes of three threads of an equal length, or sometimes of two long and one short. To acquire this beautiful form, the insect has been obliged to undergo several transmutations: but its glory is very short-lived, for the hour of its perfection is the hour of its death; and it seems scarcely introduced to pleasure, when it is obliged to part with life.

The reptile that is to become a fly, and that is granted so long a term, when compared to its latter duration, is an inhabitant of the water, and bears a very strong resemblance to fishes, in many particulars; having gills by which it breathes at the bottom, and also the tapering form of aquatic animals. These insects have six scaly legs, fixed on their corselet. Their head is triangular: the eyes are placed forward, and may be distinguished by their largeness and colour. The mouth is furnished with teeth; and the body consists of six rings; that next the corselet being largest, but growing less and less to the end: the last ring is the shortest, from which the three threads proceed, which are as long as the whole body. Thus we see that the reptile bears a very strong resemblance to the fly; and only requires wings to be very near its perfection.

As there are several kinds of this animal, their aurelias are consequently of different colours; some yellow, some brown, and some cream-coloured. Some of these also bore themselves cells at the bottom of the water, from which they never stir out, but feed upon the mud composing the walls of their habitation, in contented captivity; others, on the contrary, range about, go from the bottom to the surface, swim between two waters, quit that element entirely to feed upon plants by the river side, and then return to their favourite element for safety and protection.

The reptile, however, though it lives two or three years, offers but little, in its long duration, to excite curiosity: it is hid at the bottom of the water, and feeds almost wholly within its narrow habitation. The most striking facts command our attention during the short interval of its fly state; into which it crowds the most various transactions of its little life. It then may be said to be in a hurry to live, as it has but so small a time to exist. The peculiar sign whereby to know that these reptiles will change into flies in a short time, consists in a protuberance of the wings on the back. About that time the smooth and depressed form of the upper part of the body is changed into a more swollen and rounder shape; so that the wings are, in some degree, visible through the external sheath that covers them. As they are not natives of England, he who would see them in their greatest abundance must walk, about sun-set, along the banks of the Rhine, or the Seine near Paris; where, for about three days, in the midst of summer, he will be astonished at their numbers and assiduity. The thickest descent of the flakes of snow in winter seems not to equal their number: the whole air seems alive with the new-born race; and the earth itself is all over covered with their remains. The aurelias, or reptile insects, that are, as yet, beneath the surface of the water, wait only for the approach of evening to begin their transformation. The most industrious shake off their old garments about eight o'clock; and those who are the most tardy, are transformed before nine.

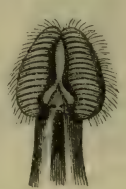
We have already seen that the operation of change in other insects is laborious and painful; but with these nothing seems shorter, or performed with greater ease. The aurelias are scarcely lifted above the surface of the water, than their old sheathing-skin bursts; and through the cavity which is thus formed, a fly issues, whose wings, at the same instant, are unfolded, and, at the same time, lift it into the air. Millions and millions of aurelias rise in this manner to the surface; and at once become flies, and fill every quarter with their flutterings. But all these sports are shortly to have an end; for, as the little strangers live but an hour or two, the whole swarm soon falls to the ground, and covers the earth, like a deep snow, for several hundred yards, on every side of the river. Their numbers are then incredible, and every object they touch becomes fatal to them; for they instantly die if they hit even against each other.

At this time the males and females are very differently employed. The males, quite in-

active, and apparently without desires, seem only born to die: no way like the males of other insects, they neither follow the opposite sex, nor bear any enmity to each other: after fluttering for an hour or two, they drop upon land, without seeming to receive wings for scarce any other purpose but to satisfy an idle curiosity. It is otherwise with the females; they are scarce risen from the surface of the water, and have dried their wings, but they hasten to drop their eggs back again. If they happen also to flutter upon land, they deposit their burden in the place where they drop. But then it may be demanded, where, and in what manner, are these eggs fecundated, as no copulation whatever appears between the sexes in their transitory visits in air? Swammerdam is of opinion, that they are impregnated in the manner of fish-spawn, by the male, after being ejected by the female; but beside that this doctrine is exploded even from the history of fishes, it is certain that the males have not time for this operation, as the eggs drop to the bottom the instant they are laid on the water. Reaumur is of opinion that they copulate; but that the act bears a proportion in shortness to the small duration of their lives; and, consequently, must be so soon performed as to be scarcely visible. This, however, is at best forcing a theory; and it is probable, that as there are many insects known to breed without any impregnation from the male, as we have already seen in muscles and oysters, and shall hereafter see in the gnat, and a species of the beetle, so the ephemera may be of this number. Be this as it may, the females are in such haste to deposit their eggs, that multitudes of them fall to the ground; but the greatest part are laid in the water. As they flutter upon the surface, two clusters are seen issuing from the extremity of their body, each containing about three hundred and fifty eggs, which make seven hundred in all. Thus, of all insects, this appears to be the most prolific; and it would seem that there was a necessity for such a supply, as, in its reptile state, it is the favourite food of every kind of fresh-water fish. It is in vain that these little animals form galleries at the bottom of the river, from whence they seldom remove; many kinds of fish break in upon their retreats, and thin their numbers. For this reason fishermen are careful to provide themselves with these insects, as the most grateful bait; and thus turn the fish's rapacity to its own destruction.

But though the usual date of those flies is two or three hours at farthest, there are some kinds that live several days; and one kind in particular, after quitting the water, has another case or skin to get rid of. These are often seen in the fields and woods distant from the water; but they are more frequently found in its vicinity. They are often found sticking upon walls and trees; and frequently with the head downwards, without changing place, or having any sensible motion. They are then waiting for the moment when they shall be divested of their last incommodious garment, which sometimes does not happen for two or three days together.[1]

---

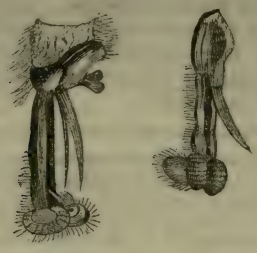


[1] *House-fly.*—Of all insects, perhaps the most widely distributed and abundant in number of individuals, is the house fly, *Musca Domestica*, a species which from its constant occurrence in every situation, will render any precise description of it unnecessary; and yet, many of our readers are, perhaps, unaware that, of the flies which crawl up our windows, there are not only several distinct species, but also that the insect at whose tormenting attacks upon our legs in the showery days of summer, we are so often enraged, does not even belong, notwithstanding its apparent identity, to the same genus. If one of these annoying tormentors (which is the *Stomoxys calcitrans*) be caught and examined, it will be found that the mouth is formed into a horny sharp-pointed weapon, capable of piercing the flesh, whilst the soft blunt apparatus of the mouth of the musca is quite incompetent to such an operation, being fitted only for the sipping of fluids, or the extraction of honied sweets; forming in fact, a long tubular sucker, jointed in the middle so as

B A

Head of the fly, with the mouth extended; A. seen sideways, B. seen from above.

to fold back close to the head (Fig. A. and B.), and armed at the base with a pair of exarticulate feelers and at the extremity with two fleshy lobes, which are employed as instruments of suction. This organ possesses very great muscular power, and we have seen the insect by its assistance alone carry off pieces of sugar much larger than its head. The under surface of the terminal lobes is also transversely ridged, which must necessarily give greater facility to the actions of the organs, by enabling it to adapt itself more readily to rough surfaces (Fig. C.). It is essential, however, that the mouth should be provided



C

Extremity of the sucker of the fly, showing its annulated appearance.

with some instrument for piercing even the soft substances of which the food is composed, and we accordingly find a fine point (the tongue) arising near the elbowed part of the proboscis, which is for safety lodged in a stronger point (the labrum), both when at rest fitting into the canal of the proboscis, as represented in our figure B.

In figure D, we have exhibited the mouth in another position, showing the sharpened upper lip raised from

E D

the fleshy proboscis, and in figure E the mouth of the blue-bottle fly is represented, having the tongue disengaged from the superior stronger labrum.

Another interesting peculiarity observable in the domestic fly, arises from the structure of its feet, enabling it to walk with the greatest facility, not only upon upright surfaces, but also upon the ceilings of rooms, back downwards, without its position being disturbed in consequence of being contrary to gravity. Much diversity of opinion has taken place amongst naturalists upon this curious subject, and even in the latest works we find the matter still forming a "questio vexata." Dr Derham, in his "Physico-Theology," speaking of the means

Leg of the fly highly magnified, with the terminal joint still more increased, seen in different positions, to show the suckers.

whereby insects maintain their position upon smooth substances, states, that "divers flies and other insects, besides their sharp-hooked nails, have also skinny palms to their feet, to enable them to stick on glass and other smooth bodies by means of the pressure of the atmosphere, after the manner as I have seen boys carry heavy stones with only a wet piece of leather clapped on the top of the stone." Gilbert White, of Selborne, adopted Derham's opinion, adding, that although the flies are easily enabled, from their lightness and alertness, to overcome the weight of air in warm weather, yet that in the decline of the year this resistance becomes too mighty for their diminished strength, and we see flies labouring along and lugging their feet in windows as if they stuck fast to the glass, and it is with the utmost difficulty that they can draw one foot from another, and disengage their hollow caps from the slippery surface.

This opinion, which has been entertained by the majority of Entomologists of the present day, has acquired additional weight by the elaborate investigations of Sir Everard Home, undertaken at the suggestion of Sir Joseph Banks, with the assistance of that unrivalled microscopic artist, M. Bauer, and published in the Philosophical Transactions for 1816. The suckers, of which several kinds of flies possess three to each foot, are attached, as will be seen from our figures, beneath the base of the claws, and are of an oval shape and membranous texture, being convex above, having the sides minutely serrated, and the under concave surface covered with down or hairs. In order to cause the alleged vacuum, these suckers are extended, but, when the fly wishes to raise its legs, they are brought together and folded up as it were between the hooks. Messrs. Kirby and Spence have likewise adopted this opinion, considering it as "proved most satisfactorily." Other authors of no mean repute have, however, entertained a different opinion, and have entirely rejected the idea of a vacuum being produced; thus Dr Hooke describes the suckers as palms or soles, beset underneath with small bristles or tenters like the cone teeth of a card for working wool, which he conceived gives them a strong hold upon objects having irregular or yielding surfaces; and he imagined that there is upon glass a kind of smcky substance, penetrable by the points of their bristles. The same opinion is also given by Shaw in his "Nature Displayed," and, more recently, Mr Blackwall has considered that the motions of the fly are to be accounted for upon mechanical principles alone; thus upon inspecting the structure of the parts of the suckers (regarding which great want of accordance exists in the descriptions of authors), "it was immediately perceived that the function ascribed to them by Dr Derham and Sir E. Home is quite incompatible with their organisation. Minute hairs very closely set and directed downwards so completely cover the inferior surface of the expanded membranes, improperly denominated suckers, with which the terminal joint of the foot of flies is provided, that it cannot possibly be brought into contact with the object on which those insects move, by any muscular force they are capable of exerting; the production of a vacuum between each membrane and the plane of position is therefore clearly impracticable, unless the numerous hairs on the underside of these organs individually perform the office of suckers; and there does not appear to be any thing in their mechanism, which in the slightest degree countenances such a hypothesis. When highly magnified, their extremities, it is true, are seen to be somewhat enlarged, but when they are viewed in action or in repose, they never assume a figure at all adapted to the formation of a vacuum."—Moreover, on enclosing a house-fly in the receiver of an air-pump, "it was demonstrated to the entire satisfaction of several intelligent gentlemen present, that the house-fly, while it retains its vital powers unimpaired, cannot only traverse the upright sides, but even the interior of the dome of an *exhausted* receiver, and that the cause of its relaxing its hold, and ultimately falling from the station it occupied, was a diminution of muscular force, attributable to impeded respiration." Hence Mr Blackwall is induced to believe, in the memoir above referred to, that insects are enabled to take hold of any roughness, or irregularity of surface, by means of the fine hairs composing the brushes, the most carefully polished

glass not being found free from flaws and imperfections, when viewed in a favourable light with a powerful lens.

A still different opinion has been maintained by other authors upon this subject; who, setting aside all idea of a vacuum, have conjectured that the suckers, as they have been termed, contain a glutinous secretion, capable of adhering to well-cleaned glass; thus the Abbé de la Pluche states, that when the fly marches over any polished body, on which neither her claws nor her points can fasten, she sometimes compresses her sponge and causes it to evacuate a fluid, which fixes her in such a manner as prevents her falling, without diminishing the facility of her progress; "but it is much more probable," he adds, "that the sponges correspond with the fleshy balls which accompany the claws of dogs and cats, and that they enable the fly to proceed with a softer pace, and contribute to the preservation of its claws, whose pointed extremities would soon be impaired without this prevention." Notwithstanding the ridicule which has been thrown upon this opinion in a recent entomological work, it appears, from still more recent investigations, to be the best founded of any hitherto advanced. Thus, an anonymous writer has published an account of various experiments and examinations upon this subject, which appear satisfactorily to prove, that it is not by the application of extremely small points to invisible irregularities on the surface of glass, that the pulvilli or suckers are attached, but by simple adhesion of the enlarged ends of the hairs assisted by a fluid that is probably secreted there, and the author is therefore reduced to refer the effect to molecular attraction only. It is also stated, that when the foot of the fly is detached, a distinct fluid trace will often be left by each individual hair, the spotty pattern thus left on the glass appearing to be of an oily character, for if breathed on, it remains after the moisture is evaporated. The contrary opinion, although contained in a review of Mr Blackwall's Memoir above noticed, was evidently written in ignorance of the subsequent observations of that author contained in the appendix of the volume in which it appeared, and in which several facts are stated, which appear "quite inexplicable, except on the supposition that an adhesive secretion is emitted by the instruments employed in climbing;" and it is subsequently affirmed, that careful and repeated examinations made with lenses of moderately high magnifying powers, in a strong light and at a favourable angle, speedily convinced Mr Blackwall that his conjecture was well founded, as he never failed to discover "unequivocal evidence of its truth."

We have had a two-fold object in thus setting before the reader, at considerable length, the various opinions promulgated upon the subject,—the first being occasioned by the interest attached to so peculiar a phenomenon; and the second resulting from a desire to show that, even in the commonest insects, there are most ample materials of no ordinary or uninteresting kind for the full exercise of the mind of the ingenious observer of nature. It will seem extraordinary, but it is nevertheless true, that there is scarcely any domestic insect of whose economy we are more ignorant than that of the *Musca domestica*.—*History of Insects*, London 1835.

HISTORY OF INSECTS, &c.

BOOK III.

INSECTS OF THE THIRD ORDER.

CHAP. I.

OF CATERPILLARS IN GENERAL.

If we take a cursory view of insects in general, caterpillars alone, and the butterflies and moths they give birth to, will make a third part of the number. Wherever we move, wherever we turn, these insects, in one shape or another, present themselves to our view. Some, in every state, offer the most entertaining spectacle; others are beautiful only in their winged form. Many persons, of which number I am one, have an invincible aversion to caterpillars and worms of every species: there is something disagreeable in their slow crawling motion, for which the variety of their colouring can never compensate. But others feel no repugnance at observing, and even handling, them with the most attentive application.

There is nothing in the butterfly-state so beautiful or splendid as these insects. They serve, not less than the birds themselves, to banish solitude from our walks, and to fill up our idle intervals with the most pleasing speculations. The butterfly makes one of the principal ornaments of oriental poetry; but in those countries, the insect is larger and more beautiful than with us.

The beauties of the fly may, therefore, very well excite our curiosity to examine the reptile. But we are still more strongly attached to this tribe from the usefulness of one of the number. The silk-worm is, perhaps, the most serviceable of all other animals; since, from its labours, and the manufacture attending it, near a third part of the world are clothed, adorned, and supported.

Caterpillars may be easily distinguished from worms or maggots, by the number of their feet; and by their producing butterflies or moths.[1] When the sun calls up vegetation, and vivifies the various eggs of insects, the caterpillars are the first that are seen upon almost every vegetable and tree, eating its leaves, and preparing for a state of greater perfection. They have feet both before and behind; which not only enable them to move forward by a sort of steps made by their fore and hinder parts, but also to climb up vegetables, and to stretch themselves out from the boughs and

---

[1] There is one tribe of caterpillar called *Surveyors*, or *Geometers*, which walk by first fixing the fore-feet, and then doubling the body into a vertical arch; this action brings up the hind part of the caterpillar, which is furnished with prolegs, close to the head. The hind extremity, being then fixed by means of the prolegs situated at that part, the body is again extended into a straight line; and this process being repeated, the caterpillar advances by a succession of paces, as if it were measuring the distance, by converting its body into a pair of compasses. At the same time that they employ this process, they further provide for their security, by spinning a thread, which they fasten to different points of the ground, as they go along.

Many other species of caterpillar practise the same art of spinning fine silken threads, which especially assist them in their progression over smooth surfaces, and also in descending from a height through the air. The caterpillar of the cabbage-butterfly, is thus enabled to climb up and down a pane of glass, for which purpose it fixes the threads that it spins in a zigzag line, forming so many steps of a rope-ladder. The material of which these threads are made, is a glutinous secretion, which, on being deposited on glass, adheres firmly to it, and very soon acquires consistence and hardness by the action of the air.

Other caterpillars, which feed on trees, and have often occasion to descend from one branch to another, send out a rope made with the same material, which they can prolong indefinitely; and thus either suspend themselves at pleasure in the air, or let themselves down to the ground. They continue, while walking, to spin a thread as they advance, so that they can always easily retrace their steps by gathering up the clue they have left, and re-ascend to the height from which they had allowed themselves to drop.—*Dr Roget's Bridgewater Treatise.*

stalks to reach their food at a distance. All of this class have from eight feet, at the least, to sixteen; and this may serve to distinguish them from the worm-tribe, that never have so many. The animal into which they are converted is always a butterfly or moth; and these are always distinguished from other flies, by having their wings covered over with a painted dust, which gives them such various beauty. The wings of flies are transparent, as we see in the common flesh-fly; while those of beetles are hard, like horn: from such, the wing of a butterfly may be easily distinguished; and words would obscure their differences.

From hence it appears, that caterpillars, whether in the reptile state, or advanced to their last state of perfection into butterflies, may easily be distinguished from all other insects; being animals peculiarly formed, and also of a peculiar nature. The transmutations they undergo are also more numerous than those of any insect hitherto mentioned; and, in consequence, they have been placed in the third order of changes by Swammerdam, who has thrown such lights upon this part of natural history. In the second order of changes, mentioned before, we saw the grasshopper and the earwig, when excluded from the egg, assume a form very like that which they were after to preserve; and seemed arrived at a state of perfection, in all respects, except in not having wings; which did not bud forth until they were come to maturity. But the insects of this third order, that we are now about to describe, go through a much greater variety of transformations; for when they are excluded from the egg, they assume the form of a small caterpillar, which feeds and grows larger every day, often changing its skin, but still preserving its form. When the animal has come to a certain magnitude in this state it discontinues eating, makes itself a covering or husk, in which it remains wrapped up, seemingly without life or motion; and after having, for some time, continued in this state, it once more bursts its confinement, and comes forth a beautiful butterfly. Thus we see this animal put on no less than three different appearances from the time it is first excluded from the egg. It appears a crawling caterpillar; then an insensible aurelia, as it is called, without life or motion; and, lastly, a butterfly, variously painted, according to its different kind. Having thus distinguished this class of insects from all others, we will first survey their history in general; and then enter particularly into the manners and nature of a few of them, which most deserve our curiosity and attention.

CHAP. II.

OF THE TRANSFORMATION OF THE CATERPILLAR INTO ITS CORRESPONDING BUTTERFLY OR MOTH.

When winter has disrobed the trees of their leaves, nature then seems to have lost her insects. There are thousands of different kinds, with and without wings, which, though swarming at other seasons, then entirely disappear. Our fields are re-peopled, when the leaves begin to bud, by the genial influence of spring; and caterpillars, of various sorts, are seen feeding upon the promise of the year, even before the leaves are completely unfolded. Those caterpillars, which we then see, may serve to give us a view of the general means, which nature employs to preserve such a number of insects during that season, when they can no longer find subsistence. It is known, by united experience, that all these animals are hatched from the eggs of butterflies; and those who observe them more closely, will find the fly very careful in depositing its eggs, in those places, where they are likely to be hatched, with the greatest safety and success. During winter, therefore, the greatest number of caterpillars are in an egg-state; and in this lifeless situation brave all the rigours and the humidity of the climate; and though often exposed to all its changes, still preserve the latent principles of life, which is more fully exerted at the approach of spring. That same power that pushes forth the budding leaf and the opening flower, impels the insect into animation; and nature at once seems to furnish the guest and the banquet. When the insect has found force to break its shell, it always finds its favourite aliment provided in abundance before it.

But all caterpillars are not sent off from the egg in the beginning of spring; for many of them have subsisted during the winter in their aurelia state; in which as, we have briefly observed above, the animal is seemingly deprived of life and motion. In this state of insensibility, many of these insects continue during the rigours of winter; some inclosed in a kind of shell, which they have spun for themselves at the end of autumn; some concealed under the bark of trees; others in the chinks of old walls; and many buried under ground. From all these, a variety of butterflies are seen to issue in the beginning of spring; and adorn the earliest part of the year with their painted flutterings.

Some caterpillars do not make any change whatsoever at the approach of winter; but continue to live in their reptile state through all the severity of the season. They choose

themselves some retreat, where they may remain undisturbed for months together; and there they continue motionless, and as insensible as if they were actually dead. Their constitution is such, that food at that time would be useless; and the cold prevents their making those dissipations which require restoration. In general, caterpillars of this kind are found in great numbers together, inclosed in one common web, that covers the mall, and serves to protect them from the injuries of the air.

Lastly, there are some of the caterpillar kind, whose butterflies live all the winter; and who, having fluttered about for some part of the latter end of autumn, seek for some retreat during the winter, in order to answer the ends of propagation at the approach of spring. These are often found lifeless and motionless in the hollows of trees or the clefts of timber; but by being approached to the fire, they recover life and activity, and seem to anticipate the desires of the spring.

In general, however, whether the animal has subsisted in an egg state, during the winter; or whether as a butterfly, bred from an aurelia, in the beginning of spring; or a butterfly that has subsisted during the winter, and lays eggs as soon as the leaves of plants are shot forward; the whole swarm of caterpillars are in motion to share the banquet that nature has provided. There is scarcely a plant that has not its own peculiar insects; and some are known to support several of different kinds. Of these, many are hatched from the egg, at the foot of the tree, and climb up to its leaves for subsistence; the eggs of others have been glued by the parent butterfly to the leaves; and they are no sooner excluded from the shell, but they find themselves in the midst of plenty.

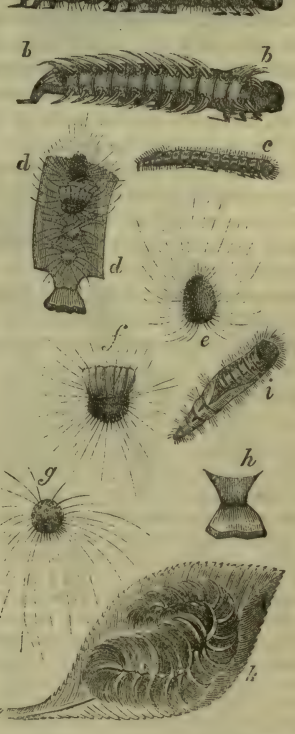
When the caterpillar first bursts from the egg, it is small and feeble; its appetites are in proportion to its size, and it seems to make no great consumption; but as it increases in magnitude, it improves in its appetites; so that, in its adult caterpillar state, it is the most ravenous of all animals whatsoever. A single caterpillar will eat double its own weight of leaves in a day, and yet seems no way disordered by the meal. What would mankind do, if their oxen or their horses were so voracious?

These voracious habits, with its slow crawling motion, but still more a stinging like that of nettles, which follows upon handling the greatest number of them, make these insects not the most agreeable objects of human curiosity. However, there are many philosophers who have spent years in their contemplation; and who have not only attended to their habits and labours, but minutely examined their structure and internal conformation.

The body of the caterpillar, when anatomically considered, is found composed of rings, whose circumference is pretty near circular or oval. They are generally twelve in number, and are all membranaceous; by which caterpillars may be distinguished from many other insects, that nearly resemble them in form. The head of the caterpillar is connected to the first ring by the neck; that is generally so short and contracted, that it is scarce visible. All the covering of the head in caterpillars seems to consist of a shell; and they have neither upper nor under jaw, for they are both placed rather vertically, and each jaw armed with a large thick tooth, which is singly equal to numbers. With these the animals devour their food in such amazing quantities; and with these, some of the kind defend themselves against their enemies. Though the mouth be kept shut, the teeth are always uncovered; and while the insect is in health they are seldom without employment. Whatever the caterpillar devours, these teeth serve to chop it into small pieces, and render the parts of the leaf fit for swallowing. Many kinds, while they are yet young, eat only the succulent part of the leaf, and leave all the fibres untouched; others, however, attack the whole leaf, and eat it clean away. One may be amused, for a little time, in observing the avidity with which they are seen to feed; some are seen eating the whole day; others have their hours of repast; some choose the night, and others the day. When the caterpillar attacks a leaf, it places its body in such a manner that the edge of the leaf shall fall between its feet, which keeps it steady while the teeth are employed in cutting it: these fall upon the leaf somewhat in the manner of a pair of gardener's shears; and every morsel is swallowed as soon as cut. Some caterpillars feed upon leaves so very narrow, that they are not broader than their mouths; in this case the animal is seen to devour it from the point, as we would eat a radish.

As there are various kinds of caterpillars, the number of their feet are various; some having eight, and some sixteen. Of these feet the six foremost are covered with a sort of shining gristle; and are therefore called the shelly legs. The hindmost feet, whatever be their number, are soft and flexible, and are called membranaceous. Caterpillars also, with regard to their external figure, are either smooth or hairy. The skin of the first kind is soft to the touch, or hard like shagreen; the skin of the latter is hairy, and as it were thorny; and generally, if handled, stings like nettles. Some of them even cause this stinging pain if but approached too nearly.

Caterpillars, in general, have six small black spots placed on the circumference of the



fore ring, and a little to the side of the head. Three of these are larger than the rest, and are convex and transparent: these Reaumur takes to be the eyes of the caterpillar; however most of these reptiles have very little occasion for sight, and seem only to be directed by their feeling.

But the parts of the caterpillar's body which most justly demand our attention, are the stigmata, as they are called; or those holes on the sides of its body, through which the animal is supposed to breathe. All along this insect's body, on each side, these holes are easily discoverable. They are eighteen in number, nine on a side, rather nearer the belly than the back; a hole for every ring, of which the animal's body is composed, except the second, the third, and the last. These oval openings may be considered as so many mouths, through which the insect breathes; but with this difference, that as we have but one pair of lungs, the caterpillar has no less than eighteen. It requires no great anatomical dexterity to discover these lungs in the larger kind of caterpillars: they appear, at first view, to be hollow cartilaginous tubes, and of the colour of mother-of-pearl. These tubes are often seen to unite with each other; some are perceived to open into the intestines; and some go to different parts of the surface of the body. That these vessels serve to convey the air, appears evidently, from the famous experiment of Malpighi; who, by stopping up the mouths of the stigmata with oil, quickly suffocated the animal, which was seen to die convulsed the instant after. In order to ascertain his theory, he rubbed oil upon other parts of the insect's body, leaving the stigmata free; and this seemed to have no effect upon the animal's health, but it continued to move and eat as usual: he rubbed oil on the stigmata of one side, and the animal underwent a partial convulsion, but recovered soon after. However, it ought to be observed, that air is not so necessary to these as to the nobler ranks of animals, since caterpillars will live in an exhausted receiver for several days together; and though they seem dead at the bottom, yet when taken out, recover, and resume their former vivacity.

If the caterpillar be cut upon longitudinally along the back, its intestines will be perceived running directly in a straight line from the mouth to the anus. They resemble a number of small bags opening into each other; and strengthened on both sides by a fleshy cord by which they are united. These insects are, upon many occasions, seen to cast forth the internal coat of their intestines with their food, in the changes which they so frequently undergo. —But the intestines take up but a small part of the animal's body, if compared to the fatty substance in which they are involved. This substance changes its colour when the insect's metamorphosis begins to approach; and from white it is usually seen to become yellow. If to these parts we add the caterpillar's implements for spinning, (for all caterpillars spin at one time or another,) we shall have a rude sketch of this animal's conformation: however, we shall reserve the description of those parts till we come to the history of the silk-worm, where the manner in which these insects spin their webs, will most properly find a place.

The life of a caterpillar seems one continued succession of changes, and it is seen to throw off one skin only to assume another; which also is divested in its turn: and thus for eight or ten times successively.[1] We must not, however, confound this changing of the skin with the great metamorphosis which

[1] One of the most singular circumstances respecting the moult of caterpillars, is the manner in which the hairs are deposited in the new skin before moulting. These are not, like the feet and other organs, sheathed

Moulting of caterpillars. *a a*, caterpillar magnified, *b b*, the same when it has just cast its skin, the hairs still moist; *c*, the same, natural size; *d e f g*, tufts of its hairs magnified; *h*, leg and foot magnified; *i*, the caterpillar wedging through the old skin; *k*, hairy caterpillar of the sycamore.

in the hairs of the old skin, but smoothly folded down in separate tufts; and if the old skin be removed a short

it is afterwards to undergo. The throwing one skin, and assuming another, seems, in comparison, but a slight operation among these animals: this is but the work of a day; the other is the great adventure of their lives. Indeed, this faculty of changing the skin, is not peculiar to caterpillars only, but is common to all the insect kind; and even to some animals that claim a higher rank in nature. We have already seen the lobster and the crab outgrowing their first shells, and then bursting from their confinement, in order to assume a covering more roomy and convenient. It is probable that the louse, the flea, and the spider, change their covering from the same necessity; and growing too large for the crust in which they have been for some time enclosed, burst it for another. This period is probably that of their growth; for as soon as their new skin is hardened round them, the animal's growth is necessarily circumscribed, while it remains within it. With respect to caterpillars, many of them change their skins five or six times in a season; and this covering, when cast off, often seems so complete, that many might mistake the empty skin for the real insect. Among the hairy caterpillars, for instance, the cast skin is covered with hair; the feet, as well gristly as membranous, remain fixed to it; even the parts which nothing but a microscope can discover, are visible in it; in short, all the parts of the head; not only the skull, but the teeth.

In proportion as the time approaches in which the caterpillar is to cast its old skin, its colours become more feeble, the skin seems to wither and grow dry, and in some measure resembles a leaf, when it is no longer supplied with moisture from the stock. At that time, the insect begins to find itself under a necessity of changing; and it is not effected without violent labour, and perhaps pain. A day or two before the critical hour approaches, the insect ceases to eat, loses its usual activity, and seems to rest immovable. It seeks some place to remain in security; and no longer timorous, seems regardless even of the touch. It is now and then seen to bend itself and elevate its back; again it stretches to its utmost extent; it sometimes lifts up the head, and then lets it fall again; it sometimes waves it three or four times from side to side, and then remains in quiet. At length, some of the rings of its body, particularly the first and second, are seen to swell considerably, the old skin distends and bursts, till by repeated swellings and contractions in every ring, the animal disengages itself, and creeps from its inconvenient covering.

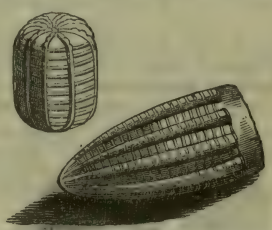
How laborious soever this operation may be, it is performed in the space of a minute; and the animal, having thrown off its old skin, seems to enjoy new vigour, as well as acquired colouring and beauty. Sometimes it happens that it takes a new appearance, and colours very different from the old. Those that are hairy still preserve their covering; although their ancient skin seems not to have lost a single hair: every hair appears to have been drawn like a sword from the scabbard. However, the fact is, that a new crop of hair grows between the old skin and the new, and probably helps to throw off the external covering.

The caterpillar having in this manner continued for several days feeding, and at intervals casting its skin, begins at last to prepare for its change into an aurelia. It is most probable that, from the beginning, all the parts of the butterfly lay hid in this insect, in its reptile state; but it required time to bring them to perfection; and a large quantity of food, to enable the animal to undergo all the changes requisite for throwing off these skins, which seemed to clog the butterfly form. However, when the caterpillar has fed sufficiently, and the parts of the future butterfly have formed themselves beneath its skin, it is then time for it to make its first great and principal change into an aurelia, or a chrysalis, as some have chosen to call it; during which, as was observed, it seems to remain for several days, or even months, without life or motion.

Preparatory to this important change, the caterpillar most usually quits the plant, or the tree on which it fed: or at least attaches itself to the stalk or the stem, more gladly than the leaves. It forsakes its food, and prepares, by fasting, to undergo its transmutation. In this period, all the food it has taken is thoroughly digested; and it often voids even the internal membrane which lined its intestines.

Some of this tribe, at this period also, are seen entirely to change colour; and the vivacity of the tints, in all, seems faded.

---



time before it would be naturally cast, these tufts may be seen in a moist state, very similar to small wetted camel's hair pencils lying close to the inner skin,—those on the fore part of the body laid towards the head, and from the fourth ring backwards in a contrary direction. Swammerdam, Reaumur, and other naturalists, repeatedly tried the experiment of cutting off the hair from caterpillars about to moult, without in the least affecting the hairs on the new skin; but when a foot or any other member is accidently mutilated, it is also wanting in the moulted caterpillar. It is a still more singular circumstance, ascertained by Swammerdam, De Geer, Lyonnet, and Bonnet, that caterpillars and grubs not only cast their external skins, but also that which lines their breathing-tubes and intestines. "Some days," says Bonnet, "before the change, the caterpillar voids, along with its excrements, the membrane which invests the interior of its stomach and intestines. I have also remarked, that during the moult, packets of the tracheal vessels may be seen attached to the cast skin, and thrown off along with it."—*Insect Transformations.*

Those of them which are capable of spinning themselves a web, set about this operation; those which have already spun, await the change in the best manner they are able. The web or cone, with which some cover themselves, hides the aurelia contained within from the view; but in others, where it is more transparent, the caterpillar, when it has done spinning, strikes into it the claws of the two feet under the tail, and afterwards forces in the tail itself, by contracting those claws, and violently striking the feet one against the other. If, however, they be taken from their web at this time, they appear in a state of great languor; and, incapable of walking, remain on that spot where they are placed. In this condition they remain one or two days, preparing to change into an aurelia; somewhat in the manner they made preparations for changing their skin. They then appear with their bodies bent into a bow, which they now and then are seen to straighten: they make no use of their legs; but if they attempt to change place, do it by the contortions of their body. In proportion as their change into an aurelia approaches, their body becomes more and more bent; while their extensions and convulsive contractions become more frequent. The hinder end of the body is the part which the animal first disengages from its caterpillar skin; that part of the skin remains empty, while the body is drawn up contractedly towards the head. In the same manner they disengage themselves from the two succeeding rings; so that the animal is then lodged entirely in the fore part of its caterpillar covering: that half which is abandoned, remains flaccid and empty; while the fore part on the contrary, is swollen and distended. The animal, having thus quitted the hinder part of its skin, to drive itself up into the forepart, still continues to heave and work as before; so that the skull is soon seen to burst into three pieces, and a longitudinal opening is made in the three first rings of the body, through which the insect thrusts forth its naked body with strong efforts. Thus at last it entirely gets free from its caterpillar skin, and for ever forsakes its most odious reptile form.

The caterpillar, thus stripped of its skin for the last time, is now become an aurelia: in which the parts of the future butterfly are all visible; but in so soft a state, that the smallest touch can discompose them. The animal is now become helpless and motionless; but only waits for the assistance of the air to dry up the moisture on its surface, and supply it with a crust capable of resisting external injuries. Immediately after being stripped of its caterpillar skin, it is of a green colour, especially in those parts which are distended by an extraordinary afflux of animal moisture; but in ten or twelve hours after being thus exposed, its parts harden, the air forms its external covering in a firm crust, and in about four and twenty hours the aurelia may be handled, without endangering the little animal that is thus left in so defenceless a situation. Such is the history of the little pod or cone that is found so common by every path way, sticking to nettles, and sometimes shining like polished gold. From the beautiful and resplendent colour with which it is thus sometimes adorned, some authors have called it a Chrysalis, implying a creature made of gold.[1]

---

[1] *Transformations of the Butterfly.* The metamorphoses which a butterfly undergoes will be found depicted in the following Cuts. The *eggs of a butterfly and moth* are first given, as they appear under magnifying glasses.

The eggs of insects vary much more in form than those of birds, and the reason of this appears to be that the in

sects themselves differ from each other in their general form more than birds. In the annexed cut, fig. 1. represents the larva just issued from the egg. Fig 2. the

Such are the efforts by which these little animals prepare for a state of perfection; but their care is still greater to provide themselves a secure retreat, during this season of their imbecility. It would seem like erecting themselves a monument, where they were to rest secure, until Nature had called them into a new and more improved existence. For this purpose, some spin themselves a cone or web, in which they lie secure till they have arrived at maturity: others, that cannot spin so copious a covering, suspend themselves by the tail, in some retreat where they are not likely to meet disturbances. Some mix sand with their gummy and moist webs, and thus make themselves a secure incrustation; while others, before their change, bury themselves in the ground, and thus avoid the numerous dangers that might attend them. One would imagine that they were conscious of the precise time of their continuance in their aurelia state; since their little sepulchres, with respect to the solidity of the building, are proportioned to such duration. Those that are to lie in that state of existence but a few days, make choice of some tender leaf, which they render still more pliant by diffusing a kind of glue upon it: the leaf thus gradually curls up, and withering as it unfolds, the insect wraps itself within, as in a mantle, till the genial warmth of the sun enables it to struggle for new life, and burst from its confinement.[1] Others,

same in progress to maturity. 3. The same at its full growth. 4. Its appearance when about to change into the pupa state. 5. In the act of changing on the following day. 6. The pupa come forth, the change having been performed in about four minutes. The exuvia of the larva being raised up to the point of suspension, was thrown off, and is represented afterwards at fig. 7. After remaining in the pupa state about twelve days, the perfect insect begins to appear as at fig. 8. 9 represents the butterfly in the act of escape, and 11 *a* the pupa case. The following (11 *b*) is the insect totally extricated, with

the wings folded, collapsed, and humid. 15 is the head of the larva magnified. We have now (12) the insect gradually expanding the wings, during which oper-

ation it voids a sanguineous-looking excrement. And last (fig. 13) the perfect insect (a *papileo Urticæ*) is seen

with the wings expanded for flight. The whole of the process from fig. 8. is performed in about seven minutes.

[1] *Leaf-Rolling Caterpillars.*—The caterpillars which are familiarly termed leaf-rollers, are perfect hermits. Each lives in a cell, which it begins to construct almost immediately after it is hatched; and the little structure is at once a house which protects the caterpillar from its enemies, and a store of food for its subsistence, while it remains shut up in its prison. But the insect only devours the inner folds. The art which these caterpillars exercise, although called into action but once, perhaps, in their lives, is perfect. They accomplish their purpose with a mechanical skill, which is remarkable for its simplicity and unerring success. The art of rolling leaves into a secure and immovable cell may not appear very difficult; nor would it be so if the caterpillars had fingers, or any parts which were equivalent to those delicate and admirable natural instruments with which man accomplishes his most elaborate works. And yet the human fingers could not roll a rocket-case of paper more regularly than the caterpillar rolls his house of leaves. A leaf is not a very easy substance to roll. In some trees it is very brittle. It has also a natural elasticity,—a disposition to spring back if it be bent,—which is caused by the continuity of its threads, or nervures. This elasticity is speedily overcome by the ingenuity with which the caterpillar works; and the leaf is thus retained in its artificial position for many weeks, under every variety of temperature. We will examine, in detail, how these little leaf-rollers accomplish their task.

One of the most common as well as the most simple fabrics constructed by caterpillars, may be discovered during summer on almost every kind of bush and tree. We shall take as examples those which are found on the lilac, and on the oak.

A small but very pretty chocolate-coloured moth, abundant in every garden, but not readily seen from its frequently alighting on the ground which is so nearly of its own colour, deposits its eggs on the leaves of the lilac, and of some other trees, appropriating a leaf to each egg. As soon as the caterpillar is hatched, it begins to secure itself from birds and predatory insects by rolling up the lilac leaf into the form of a gallery, where it may feed in safety. We have repeatedly seen one of them when just escaped from the egg, and only a few lines long, fix several silk threads from one edge of a leaf, to the other, or from the edge to the mid-rib. Then going to the middle of the space, he shortened the threads by bending them with his feet, and consequently pulled the edges of the leaves into a circular form; and he retained them in that position by glueing down each thread as he shortened it. In their younger state, these caterpillars seldom roll more than a small portion of the leaf; but when farther advanced, they unite the two edges toge-

whose time of transformation is also near at hand, fasten their tails to a tree, or to the first worm-hole they meet in a beam, and wait in that defenceless situation. Such caterpillars, on the other hand, as are seen to lie several months in their aurelia state, act with much greater circumspection. Most of them mix their web with sand, and thus make themselves a strong covering: others build in wood, which serves them in the nature of a coffin. Such as have made the leaves of willows their favourite food, break the tender twigs of them first into small pieces, then pound them as it were to powder; and, by means of their glutinous silk, make a kind of paste, in which they wrap themselves up. Many are the forms which these animals assume in this helpless state; and it often happens, that the most deformed butterflies issue from the most beautiful aurelias.

In general, however, the aurelia takes the rude outline of the parts of the animal which is contained within it; but as to the various colours which it is seen to assume, they are rather the effect of accident; for the same species of insect does not at all times assume the same hue, when it becomes an aurelia. In some the beautiful gold colour is at one time found; in others, it is wanting. This brilliant hue, which does not fall short of the best gilding, is formed in the same manner in which we see leather obtain a gold colour, though none of that metal ever enters into the tincture. It is only formed by a beautiful brown varnish, laid upon a white ground; and the white thus gleaming through the transparency of the brown, gives a charming golden yellow. These two colours are found, one over the other, in the aurelia of the little animal we are describing; and the whole appears gilded without any real gilding.

The aurelia thus formed, and left to time to expand into a butterfly, in some measure resembles an animal in an egg, that is to wait for external warmth to hatch it into life and vigour. As the quantity of moisture, that is

---

ther in their whole extent, with the exception of a small opening at one end, by which an exit may be made in case of need.

Nest of a Lilac-leaf Roller.

Another species of caterpillar closely allied to this, rolls up the lilac-leaves in a different form, beginning at the end of a leaf, and fixing and pulling its threads till it gets it nearly into the shape of a scroll of parchment. To retain this form more securely, it is not contented, like the former insect, with threads fixed on the inside of the leaf; but has also recourse to a few cables which it weaves on the outside.

Another species of moth allied to the two preceding, is of a pretty green colour, and lays its eggs upon the leaves of the oak. This caterpillar folds them up in a similar manner, but with this difference, that it works on the under surface of the leaf, pulling the edge downwards and backwards, instead of forwards and upwards. This species is very abundant, and may readily be found as soon as the leaves expand. In June, when the perfect insect has appeared, by beating a branch of an oak, a whole shower of these pretty green moths may be shook into the air.

Among the leaf-rolling caterpillars, there is a small dark-brown one, with a black head and six feet, very common in gardens on the currant-bush or the leaves of the rose-tree. (*Lozotænia Rosana*, Stephens.) It is exceedingly destructive to the flower-buds. The eggs are deposited in the summer, and probably also in the autumn or in spring, in little oval or circular patches of a green colour. The grub makes its appearance with the first opening of the leaves, of whose structure in the half-expanded state it takes advantage to construct its summer tent. It is not, like some of the other leaf-rollers, contented with a single leaf, but weaves together as many as there are in the bud where it may chance to have been hatched, binding their discs so firmly with silk, that all the force of the ascending sap, and the increasing growth of the leaves, cannot break through; a farther expansion is of course prevented. The little inhabitant in the mean while banquets securely on the partitions of its tent, eating door-ways from one apartment into another, through which it can escape in case of danger or disturbance.

The leaflets of the rose, it may be remarked, expand in nearly the same manner as a fan, and the operations of this ingenious little insect retain them in the form of a fan nearly shut. Sometimes, however, it is not contented with one bundle of leaflets, but by means of its silken cords unites all which spring from the same bud into a rain proof canopy, under the protection of which it can feast on the flower-bud, and prevent it from ever blowing.

In the instance of the currant leaves, the proceedings of the grub are the same, but it cannot unite the plaits so smoothly as in the case of the rose leaflets, and it requires more labour also, as the nervures being stiff, demand a greater effort to bend them. When all the exertions of the insect prove unavailing in its endeavours to draw the edges of a leaf together, it bends them inwards as far as it can, and weaves a close web of silk over the open space between. This is well exemplified in one of the commonest of our leaf-rolling caterpillars, which may be found as early as February on the leaves of the nettle and the white archangel (*Lamium album*,) It is of a light dirty-green colour, spotted with black, and covered with a few hairs. In its young state it confines itself to the bosom of a small leaf, near the insertion of the leaf-stalk, partly bending the edges inwards, and covering in the interval with a silken curtain. As this sort of covering is not sufficient for concealment when the animal advances in growth, it abandons the base of the leaf for the middle, where it doubles up one side in a very secure and ingenious manner.—*Rennie's Insect Architecture.*

inclosed within the covering of the aurelia, continues to keep its body in the most tender state, so it is requisite that this humidity should be dried away, before the little butterfly can burst its prison. Many have been the experiments to prove that nature may in this respect be assisted by art; and that the life of the insect may be retarded or quickened, without doing it the smallest injury. For this purpose, it is only requisite to continue the insect in its aurelia state, by preventing the evaporation of its humidity; which will consequently add some days, nay weeks, to its life: on the other hand, by evaporating its moisture in a warm situation, the animal assumes its winged state before its usual time, and goes through the offices assigned its existence. To prove this, Mr Reaumur enclosed the aurelia in a glass tube; and found the evaporated water, which exhaled from the body of the insect, collected in drops at the bottom of the tube: he covered the aurelia with varnish; and this making the evaporation more difficult and slow, the butterfly was two months longer than its natural term in coming out of its case: he found, on the other hand, that by laying the animal in a warm room, he hastened the disclosure of the butterfly; and by keeping it in an ice-house, in the same manner he delayed it. Warmth acted, in this case, in a double capacity: invigorating the animal, and evaporating the moisture.

The aurelia, though it bears a different external appearance, nevertheless contains within it all the parts of the butterfly in perfect formation; and lying each in a very orderly manner, though in the smallest compass. These, however, are so fast and tender, that it is impossible to visit without discomposing them. When either by warmth, or increasing vigour, the parts have acquired the necessary force and solidity, the butterfly then seeks to disembarrass itself of those bands which kept it so long in confinement. Some insects continue under the form of an aurelia not above ten days; some twenty; some several months; and even for a year together.

The butterfly, however, does not continue so long under the form of an aurelia, as one would be apt to imagine. In general those caterpillars that provide themselves with cones, continue within them but a few days after the cone is completely finished. Some, however, remain buried in this artificial covering for eight or nine months, without taking the smallest sustenance during the whole time: and though in the caterpillar state no animals were so voracious, when thus transformed they appear a miracle of abstinence. In all, sooner or later, the butterfly bursts from its prison; not only that natural prison which is formed by the skin of the aurelia, but also from that artificial one of silk, or any other substance in which it has enclosed itself.

The efforts which the butterfly makes to get free from its aurelia state, are by no means so violent as those which the insect had in changing from the caterpillar into the aurelia. The quantity of moisture surrounding the butterfly is by no means so great as that attending its former change; and the shell of the aurelia is so dry, that it may be cracked between the fingers.

If the animal be shut up within a cone, the butterfly always gets rid of the natural internal skin of the aurelia, before it eats its way through the external covering which its own industry has formed round it. In order to observe the manner in which it thus gets rid of the aurelia covering, we must cut open the cone, and then we shall have an opportunity of discovering the insect's efforts to emancipate itself from its natural shell. When this operation begins, there seems to be a violent agitation in the humours contained within the little animal's body. Its fluids seem driven by a hasty fermentation, through all the vessels; while it labours violently with its legs, and makes several other violent struggles to get free. As all these motions concur with the growth of the insect's wings and body, it is impossible that the brittle skin which covers it should longer resist: it at length gives way by bursting into four distinct and regular pieces. The skin of the head and legs first separates; then the skin at the back flies open, and dividing into two regular portions, disen gages the back and wings: then there likewise happens another rupture, in that portion which covered the rings of the back of the aurelia. After this, the butterfly, as if fatigued with its struggles, remains very quiet for some time, with its wings pointed downwards, and its legs fixed in the skin which it had just thrown off. At first sight the animal, just set free, and permitted the future use of its wings, seems to want them entirely; they take up such little room, that one would wonder where they were hidden. But soon after they expand so rapidly, that the eye can scarce attend their unfolding. From reaching scarce half the length of the body, they acquire, in a most wonderful manner, their full extent and bigness, so as to be each five times larger than they were before. Nor is it the wings alone that are thus increased; all their spots and paintings before so minute as to be scarce discernible, are proportionably extended; so that what a few minutes before seemed only a number of confused unmeaning points, now become distinct and most beautiful ornaments. Nor are the wings, when they are thus expanded, unfolded in the manner in which earwigs and grasshoppers display theirs, who unfurl them

like a lady's fan: on the contrary, those of butterflies actually grow to their natural size in this very short space. The wing, at the instant it is freed from its late confinement, is considerably thicker than afterwards; so that it spreads in all its dimensions, growing thinner as it becomes broader. If one of the wings be plucked from the animal just set free, it may be spread by the fingers, and it will soon become as broad as the other which has been left behind. As the wings extend themselves so suddenly, they have not yet had time to dry; and accordingly appear like pieces of wet paper, soft and full of wrinkles. In about half an hour they are perfectly dry, their wrinkles entirely disappear, and the little animal assumes all its splendour. The transmutation being thus perfectly finished, the butterfly discharges three or four drops of a blood-coloured liquid, which are the last remains of its superfluous moisture.[1] Those aurelias which are enclosed within a cone, find that exit more difficult, as they have still another prison to break through: this, however, they perform in a short time; for the butterfly, freed from its aurelia skin, butts with its head violently against the walls of its artificial prison; and probably with its eyes, that are rough and like a file, it rubs the internal surface away; till it is at last seen bursting its way into open light; and, in less than a quarter of an hour, the animal acquires its full perfection.

Thus, to use the words of Swammerdam, we see a little insignificant creature distinguished, in its last birth, with qualifications and ornaments, which man, during his stay upon earth, can never even hope to acquire. The butterfly, to enjoy life, needs no other food but the dews of heaven, and the honeyed juices which are distilled from every flower. The pageantry of princes cannot equal the ornaments with which it is invested; nor the rich colouring that embellishes its wings. The skies are the butterfly's proper habitation, and the air is its element: whilst man comes into the world naked, and often roves about without habitation or shelter; exposed on one hand to the heat of the sun, and on the other to the damps and exhalations of the earth; both alike enemies of his happiness and existence. A strong proof that, while this little animal is raised to its greatest height, we are as yet in this world only candidates for perfection!

[1] These red drops, which several of the butterfly tribe discharge immediately upon their transformation, have been recorded by ancient writers as showers of blood, portending some convulsion of nature, or national calamity. In the year 1608, the inhabitants of the town of Aix were in the utmost consternation, in consequence of a discharge of this kind, which fell in the suburbs, and for some miles round. But the philosopher Pieresc soon quieted their alarms, by showing them that the whole of this wonder originated in a flight of harmless butterflies, that had just taken wing from their chrysalis state.—*Note by Goldsmith.*

CHAP. III.

OF BUTTERFLIES AND MOTHS.[2]

It has been already shown, that all butterflies are bred from caterpillars; and we have

[2] *Butterflies*, *Hawk-moths*, and *Moths* belong to the order *Lepidoptera*, so called from the scales on their wings. Their generic names are *Papilio*, *Sphinx*, and *Phalæna*: recent writers have divided them according to the seasons of their flight, into Diurnal, Crepuscular, and Nocturnal. "The term *Butterfly*," says Mr Duncan, in the Naturalist's Library, "is a literal translation of the Saxon word *Buttor-fleoze*, and is supposed to be applied because the insects first become prevalent in the beginning of the season for butter. They are distinguished from the other scaly-winged kinds, by possessing antennæ with a knob or club at the summit, * and holding their wings, when in a state of repose, erect or very slightly inclined. They are the most generally and familiarly known of our insect tribes, and, by their conspicuous appearance, seldom fail to attract the notice even of those whose perceptions are least alive to the beauty of natural objects. The graceful curves of their outline—their gay and fitful flight—the splendour of their colouring and decorations, which present every variety of tint found in the different kingdoms of nature, distributed in markings and delineations of the most beautiful and diversified character, seem to confer on them a kind of superiority over other insects. Some naturalists have accordingly considered them as entitled to stand at the head of the insect class: and if, as Mr Kirby remarks, beauty, and grace, and gaiety, and splendour of colours were the great requisite, and the law enjoined *Detur pulchriori*—they are doubtless deserving of this preference. Their wings are augmented to a size that seems quite disproportioned to that of the body, as if nature had wished to enlarge the surface on which she was to employ her pencil, that it might admit of more varied and profuse decoration. Even the under face of the wings, contrary to what is observed in other flying animals, is usually as much adorned as the surface, and often in an entirely different manner. Each wing, therefore, presents what may be called two different pictures. No kind of ornament found among other insects is omitted in this favoured tribe: and so many new modes of embellishment are employed, that nature seems to have made them the objects of her peculiar care, and designed them, as has been remarked by the learned and pious Ray, for the adornment of the universe, and to form delightful objects for the contemplation of man, bearing conspicuous marks of the hand of a divine Artist.

"The habits of these insects are well fitted to confirm the preference we assign to their beauty. Unlike many others of this class, which delight to riot among substances most offensive to our senses, or which destroy the property and lives of their less powerful companions, butterflies derive their sustenance from the nectareous juices and secretions of fruits and flowers. Instead of grovelling on the 'dungy earth,' they are generally seen either sporting in the air, or resting on the disk of some ex-

* Certain foreign genera, however, such as Morpho and Urania, form an exception to this rule, as they have antennæ either of equal thickness throughout, or tapering slightly to the summit.

exhibited the various circumstances of that surprising change. It has been remarked, that butterflies may be easily distinguished from flies of every other kind, by their wings: for, in others, they are either transparent, like gauze, as we see in the common flesh-fly; or they are hard and crusted, as we see in the wings of the beetle. But in the butterfly, the

panded flower, and all their habits are such as beseem 'pure creatures of the element.' They are seldom noticed but in fine weather, and never in profusion but when the season is in its highest bloom, and their appearance thus becomes associated in our minds with the charms of external nature, and is connected with those images of life and beauty which give rise to many of the genial influences of summer. Several species also contrive to outlive the winter, although their frail forms seem but ill adapted to resist the rigours of that inclement season, and issuing from their retreats in the first warm days of spring, are among the earliest and not least interesting heralds of the 'purple year *.' These circumstances, together with the very striking manner in which they exhibit the phenomena of transformation, have long rendered them general favourites, and caused their history to be investigated with greater attention than has been bestowed on insects of a less conspicuous and attractive kind.

"The diurnal Lepidoptera (or butterflies) are very numerous in species, although but a limited number inhabit this country. Between 2000 and 3000 have been described, and it is probable that no inconsiderable number yet remain undiscovered. About seventy-five different species are recorded as indigenous to Britain. A great proportion of the largest and most highly ornamented kinds are natives of the new world, especially of Brazil; but they abound in all tropical countries, and some of these exotics present the most sumptuous examples of insect beauty. 'I should undertake an endless task,' say Messrs Kirby and Spence, or one or other of these authors 'did I attempt to specify all the modes of marking, clouding, and spotting, that variegate a wing, and all the shades of colour that paint it, among the lepidopterous tribes; I shall therefore confine myself to a few of the principal, especially those that distinguish particular tribes and families. Of whole coloured wings, I know none that dazzle the eye of the beholder so much as the upper surface of those of *Morpho Menelaus* and *Telemachus*. Linné justly observes, that there is scarcely any thing in nature that, for brightness and splendour, can be paralleled with this colour: it is a kind of rich ultramarine, that vies with the deepest and purest azure of the sky; and, what must cause a striking contrast in flight, the prone surface of the wings is as dull and dark as the supine is brilliant, so that one can conceive this animal to appear like a planet in full radiance, and under eclipse, as its wings open and shut in the blaze of a tropical sun. Another butterfly *(Papilio Ulysses)* by its radiating cerulean disk, surrounded on every side by a margin intensely black, gives the idea of light first emerging from primeval obscurity: it was probably this idea of light shining in darkness, that induced Linné to give it the name of the wisest of the Greeks in a dark and barbarous age. I know no insect upon which the sight rests with such untired pleasure as upon the lovely butterfly that bears the name of the unhappy Trojan king *(P. Priamus)*; the contrast of the rich green and black of the velvet of its wings with each other, and with the orange of its abdomen, is beyond expression regal and magnificent.'

"Although our British butterflies can in no way compete with the magnificent examples just referred to, we yet possess many of great beauty, whether as regards the brilliancy of their colour, or the harmonious manner in which these colours are distributed. The bluish-purple reflection that plays on the wings of the Emperor of the woods, has a richness and brilliancy of tint, which is not often surpassed. The prevailing hue among the *Lycænæ*, is fulgid copper colour, of a high degree of resplendency; and the *Polyommati*, which are so abundant in our pastures, are remarkable for exhibiting, in great variety of shade, the most delicate and beautiful tints of blue. What can exceed the fine pencilling and harmonious tinting on the under surface of the wings of *Cynthia Cardui*, *Limenitis Camilla*, and *Vanessa Atalanta*; or the richness of the eye-like spots that decorate the wings of the peacock butterfly, and numerous other species? The warm and beautiful shades of yellow in *Colias* and *Gonepteryx*, render them objects on which the eye rests with continual pleasure; and the silvery spots and streaks on the under side of the *Fritillaries*, form a fine relief, by their brilliant metallic lustre, to the uniform and comparatively duller tints of black and brown which predominate among that tribe.

"The mode of painting employed to produce these rich tints, may not improperly be called a kind of natural mosaic, for the colours invariably reside in the scales, which form a dense covering over the whole surface. These scales are usually of an oval or elongated form, and truncated at the tip, where they are occasionally divided into teeth; but sometimes they are conical, linear, or triangular. They are fixed in the wing by means of a narrow pedicle, and are most commonly disposed in transverse rows, placed close together, and overlapping each other like the tiles of a roof. In some instances, they are placed without any regular order, and in certain cases there appear to be two layers of scales on both sides of the wings. When they are rubbed off, the wing is found to consist of an elastic membrane, thin and transparent, and marked with slightly indented lines, forming a kind of groove for the insertion of the scales. The latter are so minute that they appear to the naked eye like powder or dust, and as they are very closely placed, their numbers on a single insect are astonishingly great. Leeuwenhoek counted upwards of 400,000 on the wings of the silk moth, an insect not above one-fourth of the size of some of our native butterflies. But how much inferior must this number be to that necessary to form a covering to some foreign butterflies, the wings of which expand upwards of half a foot: or certain species of moths, some of which (such as the atlas moth of the east, or the great owl moth of Brazil,) sometimes measure nearly a foot across the wings! A modern mosaic picture may contain 870 tesserulæ, or separate pieces, in one square inch of surface: but the same extent of a butterfly's wing sometimes consists of no fewer than 100,736!

"In common with several other extensive races of insects, butterflies derive their nourishment entirely from liquid substances, and the structure of the mouth is consequently very different from that of the masticating kinds. They are hence classed among the haustellated or suctorial tribes of insects. The most conspicuous and elaborately constructed organ, is the long flexible tube projecting from the mouth, which forms a canal through which the alimentry juices are absorbed. This instrument, which is sometimes of great length, is spirally convoluted when unemployed, but it can be unrolled with great rapidity, and is admirably fitted to explore the tubular corollas and deep-seated nectaries of flowers, for the purpose of extracting their sweet secretions. It is of

* In the sunny clime of Italy, where it may be said that nature never dies, and probably also in other southern countries of Europe, most of the species which with us retire on the approach of winter into the crevices of walls, and other sheltered situations, are seen upon the wing throughout even the colder months—at least we know that it is so with *Van. cardui, Atalanta*, and a few others.

wings are soft, opaque, and painted over with a beautiful dust, that comes off with handling.

The number of these beautiful animals is very great; and though Linnæus has reckoned up above seven hundred and sixty different kinds, the catalogue is still very incomplete. Every collector of butterflies can show undescribed species: and such as are fond of minute discovery can here produce animals that have been examined only by himself. In general, however, those of the warm climates are larger and more beautiful than such as are bred at home; and we can easily admit the beauty of the butterfly, since we are thus freed from the damage of the caterpillar. It has been the amusement of some to collect these animals from different parts of the world; or to breed them from caterpillars at home. These they arrange in systematic order, or dispose so as to make striking and agreeable pictures; and all must grant, that this specious idleness is far preferable to that unhappy state which is produced by a total want of employment.

The wings of butterflies, as was observed, fully distinguish them from flies of every other kind. They are four in number; and though two of them be cut off, the animal can fly with the two others remaining. They are, in their own substance, transparent; but owe their opacity to the beautiful dust with which they are covered; and which has been likened, by some naturalists, to the feathers of birds; by others, to the scales of fishes: as their imaginations were disposed to catch the resemblance. In fact, if we regard the wing of a butterfly with a good microscope, we shall perceive it studded over with a variety of little grains of different dimensions and forms, generally supported upon a footstalk, regularly laid upon the whole surface. Nothing can exceed the beautiful and regular arrangement of these little substances: which thus serve to paint the butterfly's wing like the tiles of a house. Those of one rank are a little covered by those that follow: they are of many figures; on the part of the wing may be seen a succession of oval studs; on another part, a cluster of studs, each in the form of a heart: in one place they resemble a hand open; and in another they are long or triangular; while all are interspersed with taller studs, that grow between the rest, like mushrooms upon a stalk. The wing itself is composed of several thick nerves, which render the construction very strong, though light; and though it be covered over with thousands of these scales or studs, yet its weight is very little increased by the number. The animal is with ease enabled to support itself a long while in air, although its flight be not very graceful. When it designs to fly to a considerable distance, it ascends and descends alternately; going sometimes to the right and sometimes to the left, without any apparent reason. Upon closer examination, however, it will be found that it flies thus irregularly in pursuit of its mate; and as dogs bait and quarter the ground in pursuit of their game, so these insects traverse the air in quest of their mates, whom they discover at more than a mile's distance.

If we prosecute our description of the butterfly, the animal may be divided into three parts; the head, the corselet, and the body.

The body is the hinder part of the butterfly, and is composed of rings, which are generally concealed under long hair, with which that part of the animal is clothed. The corselet is more solid than the rest of the body, because the forewings and the legs are fixed therein. The legs are six in number, although four only are made use of by the animal; the two forelegs being often so much concealed in the long hair of the body, that it is sometimes difficult to discover them. If we examine these parts internally, we shall find the same set of vessels in the butterfly that we observed in the caterpillar; but with this great difference, that as the blood or humours in the caterpillar circulated from the tail to the head, they are found in the butterfly to take a direct contrary course, and to circulate from the head to the tail; so that the caterpillar may be considered as the embryo animal, in which, as we have formerly seen, the circulation is carried on

---

a cartilaginous substance, and owes its great flexibility to its being composed of numerous rings or transverse fibres, bearing some resemblance to the annulose structure of earth-worms and some other animals. It is formed of two distinct pieces, which admit of being separated throughout their whole length. Each of these pieces is traversed longitudinally by a cylindrical tube, and being grooved on their inner side, they form when united another canal in the centre, of a somewhat square form, and wider than either of the two lateral ones. The junction of the two parts is so close that the enclosed tube is perfectly air-tight: and this union is effected by means of an infinite number of filets, resembling the laminæ of a feather, which interlace and adhere to each other. Of these three tubes, the central one alone serves for the influx of the alimentary fluids, the two lateral ones being probably employed in transmitting air in aid of respiration, which, however, is mainly carried on by means of stigmata or literal pores. The outer extremity of the proboscis is frequently beset with many membraneous papillæ, resembling leaflets, which have been regarded by some authors as absorbents. From having observed them chiefly in long and slender trunks, Reaumur was led to conceive, that their only use is to render that organ more steady, by affording numerous points of support, and adhering in some degree to the substances into which it is inserted;—an explanation rendered highly probable by the fact, that the long and slender ovipositors of ichneumons, and many other insects, are generally provided with some pointed projections near the tip, evidently intended for this purpose."—*Naturalist's Library. British Butterflies. By James Duncan, Edin.* 1835.

differently from what it is in animals when excluded.

But leaving the other parts of the butterfly, let us turn our attention particularly to the head. The eyes of butterflies have not all the same form; for in some they are large, in others small; in some they are the larger portion of a sphere, in others they are but a small part of it, and just appearing from the head. In all of them, however, the outward coat has a lustre, in which may be discovered the various colours of the rainbow. When examined a little closely, it will be found to have the appearance of a multiplying-glass; having a great number of sides or facets, in the manner of a brilliant cut diamond. In this particular the eye of the butterfly, and of most other insects, entirely correspond; and Leuwenhoek pretends there are about six thousand facets on the cornea of the flea. These animals, therefore, see not only with great clearness, but view every object multiplied in a surprising manner. Puget adapted the cornea of a fly in such a position as to see objects through it by the means of a microscope; and nothing could exceed the strangeness of its representation. A soldier, who was seen through it, appeared like an army of pigmies; for while it multiplied, it also diminished the object; the arch of a bridge exhibited a spectacle more magnificent than human skill could perform; the flame of a candle seemed a beautiful illumination. It still, however, remains a doubt, whether the insect sees objects singly, as with one eye; or whether every facet is itself a complete eye, exhibiting its own object distinct from all the rest.

Butterflies, as well as most other flying insects, have two instruments, like horns, on their heads, which are commonly called feelers. They differ from the horns of greater animals, in being movable at their base; and in having a great number of joints, by which means the insect is enabled to turn them in every direction. Those of butterflies are placed at the top of the head, pretty near the external edge of each eye. What the use of these instruments may be, which are thus formed with so much art, and by a Workman who does nothing without reason, is as yet unknown to man. They may serve to guard the eye; they may be of use to clean it; or they may be the organ of some sense which we are ignorant of: but this is only explaining one difficulty by another. We are not so ignorant of the uses of the trunk, which few insects of the butterfly kind are without. This instrument is placed exactly between the eyes; and when the animal is not employed in seeking its nourishment, it is rolled up like a curl. A butterfly, when it is feeding, flies round some flower and settles upon it. The trunk is then uncurled, and thrust out either wholly or in part; and is employed in searching the flower to its very bottom, let it be ever so deep. This search being repeated seven or eight times, the butterfly then passes to another; and continues to hover over those agreeable to its taste, like a bird over its prey. This trunk consists of two equal hollow tubes, nicely joined to each other, like the pipes of an organ.

Such is the figure and conformation of these beautiful insects, that cheer our walks, and give us the earliest intimations of summer. But it is not by day alone that they are seen fluttering wantonly from flower to flower, as the greatest number of them fly by night, and expand the most beautiful colouring at those hours when there is no spectator. This tribe of insects has, therefore, been divided into Diurnal and Nocturnal Flies; or, more properly speaking, into Butterflies and Moths: the one flying only by day, the other most usually on the wing in the night. They may be easily distinguished from each other by their horns or feelers: those of the butterfly being clubbed or knobbed at the end; those of the moth tapering finer and finer to a point. To express it technically—the feelers of butterflies are elevated: those of moths are filiform.[1]

---

[1] Moths are distinguished from butterflies, among other characters, by having at the base of the under wings, near the anterior edge, a stiff bristle or hair which passes through a hook on the under side of the anterior wings and maintains them when at rest in a horizontal or somewhat inclined position. The most characteristic and distinctive mark of the *hawk-moths* is to be found in the form of the antennæ, which encrease in diameter from a slender base nearly to the apex, forming a prismatic, fusiform club, and usually terminating in a subulated point which is occasionally somewhat curved. This thickening of the antennæ upwards indicates affinity to the diurnal lepidoptera, but in most of their other properties they are more closely allied to the moths or nocturnal kinds. The wings are narrow and elongated, of a firm consistence, and never borne perpendicularly in repose, but either parallel to the plain of position or slightly deflexed. The suctorial trunk (*maxillæ*) is usually of great length, often equal to that of the whole body; and appears, at least in some instances, to be of a more simple structure than among butterflies, consisting only of a simple semi-cylindric canal. When, for example, that of the death's-head-moth, which is short and rigid, and so sharply pointed as to be able to pierce the skin of the hand, is cut across, only a single perforation of an oval shape is visible. The palpi embrace the base of the trunk, consist of three articulations, and are so densely invested with hairs and scales, that their jointed structure is not discernible till these are rubbed off. The eyes are large, globose, and prominent, composed of a great number of facets. The tarsi are all divided into five joints; the intermediate tibiæ are furnished with two spines, and the hinder ones with four; and in the anterior pair, which are destitute of spines, there is a slender lobe lying along a part of the under side of the tibia, and attached to it by the upper extremity.

These insects constituted the genus *Sphinx* of Linnæus, and they compose the family named Crepuscularia by

The butterflies, as well as the moths, employ the short life assigned them in a variety of enjoyments. Their whole time is spent either in quest of food, which every flower offers; or in pursuit of the female, whose approach they can often perceive at two miles' distance. Their sagacity in this particular is not less astonishing than true; but by what

Latreille. The latter term has been applied to them, because many of the most conspicuous species are observed on the wing chiefly during the morning and evening twilight; others, however, do not shun the "garish eye of day," but may be seen darting about in the sunshine in company with butterflies and other exclusively diurnal kinds. Their flight is exceedingly rapid, and continued nearly in a direct line, somewhat like that of a bird, differing greatly in this respect from the devious zig-zag motion of most other lepidoptera, many of which seem to *float* rather than to be impelled by muscular exertion. The wings, notwithstanding, are rather of small size compared with the body; but the thickness and massiveness of the latter admits of great development in the muscles by which these organs are moved, and a momentum is thus communicated to them more than sufficient to compensate for their somewhat limited extent of surface. By their rapid vibration, the taper body of the insect is poised in the air like that of a hawk, while it hovers over the petals of a flower, and extracts the mellifluous juices by means of its long tubular proboscis. The resemblance just alluded to has caused them to be named hawk-moths; and as many of them, when thus hovering in the air, produce a humming sound, and in this respect, as well as in feeding on the wing and in the darting rapidity of their movements, bear some likeness to humming-birds, a few are named after these "winged gems," and are well known under the somewhat composite title of humming-bird hawk-moths.

The number of these insects found in Britain is not inconsiderable, and includes all the kinds indigenous to Europe, except a few species. Several conspicuous kinds have been admitted into our native lists, in consequence of the occurrence of one or two examples; but from what we know of their history and geographical distribution, it seems more proper to ascribe their appearance in this country to fortuitous causes,—such as accidental importation along with foreign productions, than to their being aboriginal natives of the soil.

Although *moths* (proper) may be characteristically said to be nocturnal insects, it must not be understood that their appearance is exclusively confined to the night, or even the twilight. The gamma-moth, the majority of the male bombycidæ, and others too numerous to mention, may often be seen "floating amid the liquid noon," associated with the multitude of other tribes which the sunshine awakes to active life and enjoyment. But with far the larger proportion, night is the chosen and appropriate season of activity. During the day they conceal themselves in clefts of trees, among tangled vegetation and under leaves, and seldom issue from their retreats till the light is beginning to fail. Some are on the wing only in the earlier part of the night, others are later in appearing, and continue their flight till the morning is far advanced. During these excursions many fall a prey to bats and night-birds of various kinds, which delight to capture their insect food when on the wing, seldom searching for it when at rest, according to the general practice of their day-feeding companions.

The great beauty of many of these insects, the almost infinite variety of their colours and markings, as well as their curious habits and economy, have long rendered this a favourite branch of study with the generality of entomologists. A large proportion of the works relating to insects, especially works of the illustrated class, are devoted to the elucidation of this tribe; and in almost every collection of indigenous specimens, they occupy a prominent place. The zeal with which the rarer and more beautiful kinds have been sought after, and the estimation in which they have been held when obtained, is sufficiently evinced by the high-sounding names, by means of which collectors have attempted to express their admiration. Such designations as the Emperor, Nonpareil, Kentish Glory, Richmond Beauty, &c. have been applied to them almost as liberally as similar names are used by the fanciers of gigantic gooseberries and peerless tulips, in reference to the objects of their predilection. In proportion to the eagerness shown in the pursuit, has been the variety of plans adopted to obtain specimens with the greatest ease and in the best possible condition. One of the most satisfactory methods is to rear the larvæ, when these can be obtained, till they change to pupæ, and the moths are thus secured as soon as they emerge, with the beauty of their plumage unimpaired. Mr Kirby mentions, that the seasons in which the London amateurs repair to the woods in search of larvæ, are the beginning of April, June, the beginning of July, and September; and they dig for the pupæ late in July, and in January and February. The perfect insects are to be found all the summer and autumn, and certain kinds even in winter. The attractions of a youthful female of their own species affords a means of procuring several of the larger Bombycidæ, even in places where they might not previously be supposed to exist. Advantage is often taken of the propensity which these insects show, in common with many other nocturnal animals, to repair to a light, when they may be readily seized as they continue to flutter around it in a kind of bewildered state. As the most effectual means of employing a light, it is recommended that it should be placed in a lanthorn, and the latter fixed on the breast by means of a belt around the waist, both hands being thus left at liberty. If indisposed, however, to make much personal exertion, the Aurelian may often reap a rich harvest merely by opening the windows of a lighted apartment, especially if his dwelling be in the vicinity of woods, and securing such visitors as make their appearance within. The following extract shows with what success this plan has been attended. "My success in obtaining lepidoptera, to which I am particularly attached," says the Rev. C. S. Bird, "I owe to the use of a lamp to attract moths. During the moonless nights of summer, I sit with a Sinumbra-lamp, and perhaps one or two smaller lamps, placed on a table close to the window. The moths speedily enter the room, if the weather be warm. I have had a levee of more than a hundred between the hours of ten and twelve. In the spring, too, and autumn, I have been frequently fortunate, though generally having my patience sufficiently tried. In March, for instance, I have taken many specimens of *Biston prodromarius* in one evening; *Glæa rubricosa* and *Lytæa leucographa* have accompanied them. In April and May, *Cucullia fissina* and *Peridæa serrata* have visited me. When November has arrived, *Petasia cassinea* and *Pœcilocampa populi* have crowded into my room. Of course, at such cool times of the year the window must be kept shut till the moths knock for admittance. If at any time of the year a warm mist pervade the air, there is almost a certainty of success. But should any one be induced by this account to try the lamp, he must make up his mind to experience more of unfavourable evenings than favourable. There is, however, this advantage in my sedentary plan of mothing, that it can be combined with reading or writing; and the intervals between the arrivals need not be lost. Moths are extremely sensible of any keenness in the air; a north or east wind is very likely to keep them from venturing abroad. Different species have different hours of flight. Thus, on a mild and dark

sense they are thus capable of distinguishing each other at such distances is not easy to conceive. It cannot be by the sight, since such small objects as they are, must be utterly imperceptible at half the distance at which they perceive each other: it can scarcely be by the sense of smelling, since the animal has no organs for that purpose. Whatever be their powers of perception, certain it is that the male, after having fluttered, as if carelessly about for some time, is seen to take wing, and go forward, sometimes for two miles together, in a direct line, to where the female is perched on a flower.

The general rule among insects is, that the female is larger than the male; and this obtains particularly in the tribe I am describing. The body of the male is smaller and slenderer; that of the female more thick and oval. Previous to the junction of these animals, they are seen sporting in the air, pursuing and flying from each other, and preparing, by a mock combat, for the more important business of their lives. If they be disturbed while

November evening, *Pœcilocampa populi* will occupy from seven to ten o'clock, after which it will make way for *Petasia cassinea*, which will fly till one or two in the morning. I have for experiment's sake, sat up in the summer till three o'clock, when the whole heaven was bright with the rising sun, and moths of various kinds have never ceased arriving in succession till that time. Some of them must come from a considerable distance. *Scotophila porphyrea*, being a heath moth, must come nearly a mile. Moths like butterflies, have their peculiar modes of flight, by which I can generally distinguish them on their entrance, before I can see their colours. Some announce themselves by a loud knock on the floor; this is the case with *Leiocampa dicæa*. Some ascend instantly to the ceiling, as *Agrotis corticea*. Many, I might say the majority, pass the lamp rapidly: and this shows the comparative inutility of using the lamp out of doors, where only those that loiter about it can be taken. Some have a soft and gentle flight; as, for instance, *Cosmia pyralina*, one of my most welcome visitors, whose entrance I am usually made aware of by seeing something drop down on the table, as quick as hail, but as light as a fleece of snow; whilst, on the contrary, the conceited vagaries and absurd violence of *Clisiocampa neustria* are absolutely amusing; and *cratægi* and *populi* are nearly as bad. It is not the *Nocturna* alone that come to me in the night—many of what Mr Stephens calls the *Semidiurna*, the *Geometridæ*, accompany them at all hours. It may likewise be worth while to say a word on my method of securing my prey. Suppose that, either with or without a *bag-net*, I have imprisoned a moth under an inverted wine-glass, I then light a small piece of German tinder, half the size of a sixpence, or less, and introduce it under the edge, and by means of the smoke the insect is stupified almost immediately. It is then wholly in my power, though it would quickly revive:—I pierce it; and, by means of a pin dipped in oxalic acid, and thurst into the body beneath the thorax, I prevent its revival, and fix it on the settling board. The German tinder does not injure the colour, as brimstone would, whilst it puts the moth so completely in my power for a few moments, that the specimens I thus take and kill are often as perfect and beautiful as if I had bred them. Of course, I use it for insects taken in the day, or bred, as well as for those captured by the lamp." The locality to which the above account refers is the vicinity of Reading in Berkshire. The list given by Mr Bird of the species taken in the manner described, includes many of the rarer and most beautiful kinds found in this country.

Another method of capturing moths has recently been practised in the north of England by P. J. Selby, Esq. of Twizel, and has been attended with so much success, that we have much pleasure in being enabled to subjoin the following account of it as communicated by that distinguished naturalist. "In the course of my entomological pursuits—for that fascinating department of Zoology has for the last year engrossed a great part of my leisure,—my attention was first directed to the mode I have since adopted for the capture of nocturnal lepidoptera, by the extraordinary success that I understood had attended the exposure of a sugar-cask, recently emptied, in a favourable situation; and by means of which attraction a great variety of moths, some of them of very rare occurrence, had been secured. As sugar casks are not easily procured in this country, I bethought myself of some succedaneum, and it presently struck me that a beehive, or as it is generally called here, a *skep*, recently emptied of its honey, or well anointed with the same, might answer the purpose, as it was evident the insects were attracted by the saccharine matter and smell. I accordingly had one prepared, and the very first evening was convinced that it would prove a very efficient trap, as several moths of different species were seen and taken upon it. Unfortunately, the best part of the season was nearly over before I commenced operations, as it was not exposed till after the middle of August; but from the success I have had up to the present time, I am convinced it is one of the most effectual modes of obtaining the noctuidæ, and that many which would otherwise escape observation are thus to be obtained. Indeed, some of those I have already procured, I had never before met with in this district; and I dare say, but for this attractive trap, they would have remained long undiscovered, as some of them are in their force or full flight at a much later period than we are generally accustomed to look after moths. I anticipate a rich harvest during the ensuing spring and summer, not only of the noctuidæ, but also of the other large moths; the Geometridæ and smaller species I know come to it, as some of them have already been taken upon it. By this mode also, many interesting particulars relating to their natural history are likely to become known to us, such as the period of duration of different species, the proportion of males and females, &c. I find that in the early part of the season their duration is much shorter than at a later; in many of those occurring in August and September, it seldom exceeded two or three weeks; whereas such as did not appear till towards the end of October have continued till the present period, that is, nearly three months; as I have taken every mild evening specimens of *Clæa Satellitia* up to the 26th of January, and *Calocampa exoleta* as late as the 7th of the same month. The skep should be well anointed on the exterior with honey (the refuse will answer perfectly well), and should be supported on a forked stake about four feet from the ground, or so that the insect can be easily got at and enclosed in the flappers as they alight and settle upon it. In this way they may be taken in as fine and perfect condition as if they had been bred from the larvæ within doors. I generally select a sheltered situation and near to wood; of late I have had it near a service tree, whose berries I had previously observed attracted the moths. The following are a few of the species taken:—Agrotis suffusa, Pyrophila Tragopogonis, Pyrophila tetra, Glæa Vaccinii, Glæa spadicea, Apamea nictitans, Polia occulta, Polia Chi, Xanthia fulvago, Xanthia gilvago, Phlogophora meticulosa, several species of Hadena, Caradrina glareosa," &c. &c.—*Naturalist's Library. British Moths. By James Duncan, Edin.* 1836.

united, the female flies off with the male on her back, who seems entirely passive upon the occasion.

But the females of many moths and butterflies seem to have assumed their airy form for no other reason but to fecundate their eggs, and lay them. They are not seen fluttering about in quest of food or a mate: all that passes during their short lives, is a junction with the male of about half an hour; after which they deposit their eggs and die, without taking any nourishment, or seeking any. It may be observed, however, that in all the females of this tribe, they are impregnated by the male by one aperture, and lay their eggs by another.

The eggs of female butterflies are disposed in the body like a bed of chaplets; which, when excluded, are usually oval, and of a whitish colour: some, however, are quite round; and others flatted like a turnip. The covering, or shell of the egg, though solid, is thin and transparent: and in proportion as the caterpillar grows within the egg, the colours change, and are distributed differently. The butterfly seems very well instructed by nature in its choice of the plant, or the leaf, where it shall deposit its burthen. Each egg contains but one caterpillar: and it is requisite that this little animal, when excluded, should be near its peculiar provision. The butterfly, therefore, is careful to place her brood only upon those plants that afford good nourishment to its posterity. Though the little winged animal has been fed itself upon dew, or the honey of flowers, yet it makes choice for its young of a very different provision, and lays its eggs on the most unsavoury plants; the rag-weed, the cabbage, or the nettle. Thus every butterfly chooses not the plant most grateful to it in its winged state; but such as it has fed upon in its reptile form.

All the eggs of butterflies are attached to the leaves of the favourite plant, by a sort of size or glue; where they continue unobserved, unless carefully sought after. The eggs are sometimes placed round the tender shoots of plants, in the form of bracelets, consisting of above two hundred in each, and generally surrounding the shoot like a ring upon a finger. Some butterflies secure their eggs from the injuries of air, by covering them with hair plucked from their own bodies, as birds sometimes are seen to make their nests: so that their eggs are thus kept warm, and also entirely concealed.

All the tribe of female moths lay their eggs a short time after they leave the aurelia; but there are many butterflies that flutter about the whole summer, and do not think of laying till the winter begins to warn them of their approaching end: some even continue the whole winter in the hollows of trees, and do not provide for posterity until the beginning of April, when they leave their retreats, deposit their eggs, and die. Their eggs soon begin to feel the genial influence of the season: the little animals burst from them in their caterpillar state, to become aurelias and butterflies in their turn, and thus to continue the round of nature.

CHAP. IV.

OF THE ENEMIES OF THE CATERPILLAR.

Nature, though it has rendered some animals surprisingly fruitful, yet ever takes care to prevent their too great increase. One set of creatures is generally opposed to another: and those are chiefly the most prolific that are, from their imbecility, incapable of making any effectual defence. The caterpillar has, perhaps, of all other animals, the greatest number of enemies; and seems only to exist by its surprising fecundity. Some animals devour them by hundreds; others more minute, yet more dangerous, mangle them in various ways; so that, how great soever their numbers may be, their destroyers are in equal proportion. Indeed, if we consider the mischiefs these reptiles are capable of occasioning, and the various damages we sustain from their insatiable rapacity, it is happy for the other ranks of nature, that there are thousands of fishes, birds, and even insects, that live chiefly upon caterpillars, and make them their most favourite repast.

When we described the little birds that live in our gardens, and near our houses, as destructive neighbours, sufficient attention was not paid to the services which they are frequently found to render us. It has been proved, that a single sparrow and its mate, that have young ones, destroy above three thousand caterpillars in a week; not to mention several butterflies in which numberless caterpillars are destroyed in embryo. It is in pursuit of these reptiles that we are favoured with the visits of many of our most beautiful songsters, that amuse us during their continuance, and leave us when the caterpillars disappear.

The maxim which has often been urged against man, that he, of all other animals, is the only creature that is an enemy to his own kind, and that the human species only are found to destroy each other, has been adopted by persons who never considered the history of insects. Some of the caterpillar kind, in particular, that seem fitted only to live upon leaves and plants, will, however, eat each other;

and the strongest will devour the weak in preference to their vegetable food. That which lives upon the oak is found to seize any of its companions, which it conveniently can, by the first rings, and inflict a deadly wound: it then feasts in tranquillity on its prey, and leaves nothing to the animal but the husk.

But it is not from each other they have the most to fear, as in general they are inoffensive; and many of this tribe are found to live in a kind of society. Many kinds of flies lay their eggs either upon or within their bodies; and, as these turn into worms, the caterpillar is seen to nourish a set of intestine enemies within its body, that must shortly be its destruction: Nature having taught flies, as well as all other animals, the surest methods of perpetuating their kind.—"Towards the end of August," says Reaumur, "I perceived a little fly, of a beautiful gold colour, busily employed in the body of a large caterpillar, of that kind which feeds upon cabbage. I gently separated that part of the leaf on which these insects were placed, from the rest of the plant, and placed it where I might observe them more at ease. The fly, wholly taken up by the business in which it was employed, walked along the caterpillar's body, now and then remaining fixed to a particular spot. Upon this occasion, I perceived it every now and then dart a sting, which it carried at the end of its tail, into the caterpillar's body, and then draw it out again, to repeat the same operation in another place. It was not difficult for me to conjecture the business which engaged this animal so earnestly; its whole aim was to deposit its eggs in the caterpillar's body; which was to serve as a proper retreat to bring them to perfection. The reptile thus rudely treated, seemed to bear all very patiently, only moving a little when stung too deeply; which, however, the fly seemed entirely to disregard. I took particular care to feed this caterpillar; which seemed to me to continue as voracious and vigorous as any of the rest of its kind. In about ten or twelve days, it changed into an aurelia, which seemed gradually to decline, and died: upon examining its internal parts, the animal was entirely devoured by worms; which, however, did not come to perfection, as it is probable they had not enough to sustain them within."

What the French philosopher perceived upon this occasion is every day to be seen in several of the larger kinds of caterpillars, whose bodies serve as a nest to various flies, that very carefully deposit their eggs within them. The large cabbage caterpillar is so subject to its injuries, that, at certain seasons, it is much easier to find them with than without them. The ichneumon fly, as it is called, particularly infests these reptiles, and prevents their fecundity. This fly is of all others the most formidable to insects of various kinds. The spider, that destroys the ant, the moth, and the butterfly, yet often falls a prey to the ichneumon; who pursues the robber to his retreat, and despising his net, tears him in pieces, in the very labyrinth he has made. This insect, as redoubtable as the little quadruped that destroys the crocodile, has received the same name; and from its destruction of the caterpillar tribe, is probably more serviceable to mankind. This insect, I say, makes the body of the caterpillar the place for depositing its eggs, to the number of ten, fifteen or twenty. As they are laid in those parts which are not mortal, the reptile still continues to live and to feed, showing no signs of being incommoded by its new guests. The caterpillar changes its skin, and sometimes undergoes the great change into an aurelia: but still the fatal intruders work within, and secretly devour its internal substance: soon after they are seen bursting through its skin, and moving away, in order to spin themselves a covering, previous to their own little transformation. It is indeed astonishing sometimes to see the number of worms, and those pretty large, that thus issue from the body of a single caterpillar and eat their way through its skin: but it is more extraordinary still that they should remain within the body, devouring its entrails, without destroying its life. The truth is, they seem instructed by nature not to devour its vital parts; for they are found to feed only upon that fatty substance which composes the largest part of the caterpillar's body. When this surprising appearance was first observed, it was supposed that the animal thus gave birth to a number of flies different from itself; and that the same caterpillar sometimes bred an ichneumon, and sometimes a butterfly: but it was not till after more careful inspection it was discovered, that the ichneumon tribe were not the caterpillar's offspring, but its murderers.

CHAP. V.

OF THE SILKWORM.

Having mentioned, in the last chapter, the damages inflicted by the caterpillar tribe, we now come to an animal of this kind, that alone compensates for all the mischief occasioned by the rest. This little creature, which only works for itself, has been made of the utmost service to man; and furnishes him with a covering more beautiful than any other animal can supply. We may declaim indeed against the luxuries of the times, when silk is so generally worn; but were such garments

to fail, what other arts could supply the deficiency?

Though silk was anciently brought in small quantities to Rome [1] yet it was so scarce as to be sold for its weight in gold; and was considered as such a luxurious refinement in dress, that it was infamous for a man to appear in habits of which silk formed but half the com-

[1] Silk was very little known at Rome till the reign of Augustus, and during a long succeeding period it remained extremely costly, only a small quantity reaching the imperial city by a circuitous and expensive land and water carriage. The increasing luxury of the Roman people caused the demand for silk manufacture to increase much faster than the supply, and the price became exorbitantly high.

Two monks, engaged as missionaries in China, succeeded in obtaining a quantity of silkworms' eggs, which they concealed in a hollow cane; and at length in the year 552, they conveyed them in safety to Constantinople. The eggs were hatched in the proper season by the warmth of manure; and the worms were fed with the leaves of the wild mulberry-tree. These worms in due time spun their silk, and propagated under the careful tendence of the monks, who also instructed the Romans in the whole process of manufacturing their production. The insects thus produced were the progenitors of the generations of silkworms which have since been reared in Europe and the western parts of Asia. Thus, a caneful of the eggs of an oriental insect became the means of establishing a manufacture which fashion and luxury have rendered so important.

The mulberry-tree was then eagerly planted in Europe, for the nourishment of these valuable insect labourers; and on this, their natural food, they were successfully reared in different parts of Greece.

The Venetians soon after this time opened commercial relations with the Greek empire, and continued for many centuries the channel for supplying the western parts of Europe with silks. The estimation in which this manufacture was held, continued sufficiently high for it to be considered worthy of being made a regal gift: it appears that in the year 790, the Emperor Charlemagne gave two silken vests to Offa, king of Mercia.

Although at this period the Roman empire was fast declining, they alone possessed the valuable breed of silkworms, which 600 years before had been transferred from the remotest extremity of the East; and none others had manufactured its costly spoils. Roger I., king of Sicily, led into captivity a considerable number of silk-weavers, whom he compulsorily settled in Palermo, obliging them to impart to his subjects the knowledge of their art. In twenty years from this forcible establishment of the manufacture, the silks of Italy are described as having obtained a decided excellence, being of diversified patterns and colours: some fancifully interwoven with gold. By degrees the manufacture spread over the greater part of Italy, and was carried into Spain; and in the reign of Francis I., took root in France.

A still longer interval occurred before its adoption into England, and its introduction was very slow, till the beginning of the sixteenth century. Bologna was the only city of Italy which possessed proper throwing mills, or the machinery necessary for twisting and preparing silken fibres for weaving.

The business of a silk-factory was considered a noble employment in Venice, and might be followed without degradation by the higher classes.

The silk trade made very little progress in France till the reign of Francis I., who procured artisans from Milan, and introduced them into Lyons. The French then made rapid progress in this pursuit; and, in addition to those of Lyons, many manufactories were speedily started in the southern provinces; supplying sufficient for their own consumption, and soon afterwards a superabundance for competition in foreign markets; furnishing many parts of Europe with the fruits of their newly-cultivated art; deriving great wealth from prosecuting this branch of trade with England. Queen Elizabeth, in the third year of her reign, 1560, was gratified by being presented with a pair of knitted black silk stockings by Mrs Montague, her silk woman; at which she was so delighted that she never afterwards condescended to wear those of cloth. Sir Thomas Gresham presented Edward VI. with a pair of long Spanish silk stockings, and, from their rarity, this offering was deemed worthy of much notice.

When Antwerp was captured by the Duke of Parma, in 1585, it was consigned during three days to indiscriminate plunder and destruction; and about a third part of their artisans and merchants who wrought and dealt in silk, took refuge in England, where they finally settled, and taught those arts by which they had long prospered in their native land, by which means the manufacture was materially improved in this country.

Every attempt at rearing silk-worms and producing silk having, after endless trials, failed, attention was directed to the establishments for producing both raw and wrought silks in the settlements at British India; where proximity to the country of its original production, the fitness of the climate, and, above all, the cheapness of labour, have contributed to insure complete success. The island of Cossimbuzar and its neighbourhood, in the province of Bengal, are particularly favourable to the labours of the silkworm. There are at this time eight principal silk-filatures, the produce of eight factories, belonging to the East India Company, in Bengal. In every filature there are employed, according to its size, from 3000 to 10,000 people; and if to these were added the mulberry-planters, worm feeders, &c., the number dependent on each establishment, would be from 10,000 to 40,000 men, women, and children. Silk requires so much care and attention for its production, and so great a number of persons must be employed in an establishment for rearing silkworms, that it is only in countries where the number of the poorer classes is in great proportion to capital, and therefore labour very cheap, that silk can be reared at an expense which offers successfully to compete with other countries. The silk, consumed in England alone, exceeds four millions of pounds in a year. Fourteen thousand millions of animated creatures annually live and die to supply this little corner of the world with an article of luxury. The importation of raw silk from China in 1829 amounted to 600,000 lbs.

A Lyons newspaper in 1812 states that there were 10,720 looms, employing 15,506 workmen. In 1824 there were 24,000 looms employing 36,000 hands.

In the year 1685, the revocation of the edicts of Nantes compelled many merchants, manufacturers, and artificers, to fly from France. About 70,000 made their way to England and Ireland; many of them resorted to Spitalfields, contributing much by their knowledge and skill to the improvement of the silk manufacture. To them we are indebted for the art of manufacturing brocades, satins, black and coloured mantuas, black paduasoys, ducates, watered satins, and velvets, all of which fabrics had been imported up to the year 1718. Our machinery being very defective, we were in a great degree dependent on the throwsters of Italy for a supply of organzine; but at that time, Mr Lombe, of Derby, having, in the disguise of a common workman, succeeded in taking accurate drawings of the throwing machinery in Piedmont, erected a stupendous mill for that purpose on the river Derwent, at Derby, and obtained a patent for the sole and exclusive property in the same for fourteen years. This grand machine was constructed with 26,586

position. It was most probably brought among them from the remotest parts of the East; since it was, at the time of which I am speaking, scarcely known even in Persia.

Nothing can be more remote from the truth, than the manner in which their historians describe the animal by which silk is produced. Pausanias informs us, that silk came from the country of the Seres, a people of Asiatic Scythia; in which place an insect as large as the beetle, but in every other respect resembling a spider, was bred up for that purpose. They take great care, as he assures us, to feed and defend it from the weather; as well during the summer's heat as the rigours of winter. This insect, he observes, makes its web with its feet, of which it has eight in number. It is fed for the space of four years upon a kind of paste, prepared for it; and at the beginning of the fifth, it is supplied with the leaves of the green willow, of which it is particularly fond. It then feeds till it bursts with fat; after which they take out its bowels, which are spun into the beautiful manufacture so scarce and costly.

The real history of this animal was unknown among the Romans till the time of Justinian; and it is supposed, that silk-worms were not brought into Europe till the beginning of the twelfth century; when Roger, of Sicily, brought workmen in this manufacture from Asia Minor, after his return from his expedition to the Holy Land, and settled them in Sicily and Calabria. From these the other kingdoms of Europe learned this manufacture; and it is now one of the most lucrative carried on among the southern provinces of Europe.

The silkworm is now very well known to be a large caterpillar, of a whitish colour, with twelve feet, and producing a butterfly of the moth kind.[1] The cone on which it spins, is formed for covering it while it continues in the aurelia state; and several of these, properly wound off, and united together, form those strong and beautiful threads which are woven

---

wheels, and 97,746 movements, which worked 73,726 yards of organzine thread with every revolution of the water-wheel, whereby the machinery was actuated. So rapid was the growth of the silk trade from this time, that in 1783 the estimated value of silk goods manufactured in England was £3,350,000.

A great improvement had been effected (ten years before, viz. 1772) in Bengal raw silk. Better machinery being brought into use on the Italian system, and competent persons employed as heads of each factory. The shipments about this period, being from 515,000 to 560,000 lbs., have steadily increased to 1,500,000 lbs. annually. In Italy there is but one regular crop in the year; while in Bengal there are three at intervals of four months, March, July, and November.

[1] The *silkworm*, like all other insects of the same class, undergoes a variety of changes during the short period of its life; assuming, in each of its three successive transformations, a form wholly dissimilar to that with which it was previously invested.

We will proceed to trace the changes which it undergoes, commencing with the egg, which is about the size of a grain, and of a yellow colour, when fresh; but after a few days, become rather dark, of a bluish cast. The period which the egg requires is dependent on the temperature of the climate; so much so, that some eggs may be preserved during the winter and spring; or they may be quickened by artificial means, when the natural food appears in sufficient quantity for their support.

When hatched, it appears as a black worm, about a quarter of an inch in length, gradually becomes larger and whiter, and in about eight days its head enlarges and it is attacked by illness, which lasts for three days; refusing food, and remaining in a state of lethargy. This illness is supposed to be on account of the smallness of the skin. The worm appears at the end of the third day much wasted, and throwing off a kind of humour, which has exuded between its body and the skin about to be cast off, at the same time emits from its body silken cords, so as to fasten the abandoned skin to a spot whilst the insect forsakes it, which it performs in the following manner. It first rubs its head among the leafy fibres, so as to disencumber itself of the scaly covering, and then breaks through that part of the skin nearest the head. This action causes the larva very great exertion. Soon afterwards, it disengages its fore feet, and then the body is quickly drawn from the skin, which remains stationary. This operation occupies two or three minutes. The insect then begins to feed with renewed vigour and health. The skin sometimes refuses to separate from the body; in which case, the pressure occasions swelling and inflammation, and generally terminates in death.

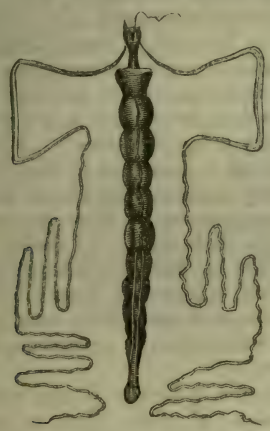
Those worms which have recently shed their skin, are easily known from the others, by the pale colour and wrinkled appearance of their new skin. The larva changes its skin five separate times; and, on each occasion, increases in size and weight, as may be seen in following table.

	Inches.	Take to an ounce.
When born	¼	54,526
One moult	⅜	3,840
Two	⅝	610
Three	1¼	144
Four	2	35
Five	2½ to 3	6

Thus, in the space of a few short weeks, the worm increases in weight more than nine thousand times.

The annexed figures represent the worm in its last stage, the chrysalis, and the cocoon.

The caterpillar, having arrived at its last moult, devours its food most voraciously, and for ten days continues increasing in size; so that its structure can be better explained than in its former stages. It is now about three inches in length, and is composed of twelve membranous rings; the head is scaly, hard, and tapering; the mouth is horizontal; it has sixteen feet, six of which are placed in front, armed with claws, on the three rings nearest to the head; the other ten feet are placed behind, eight of which are on the sixth to the ninth, and two on the last



into silk. The feeding these worms, the gathering, the winding, the twisting, and the weaving their silk, is one of the principal manufactures of Europe; and, as our luxuries increase, seems every day to become more and more necessary to human happiness.

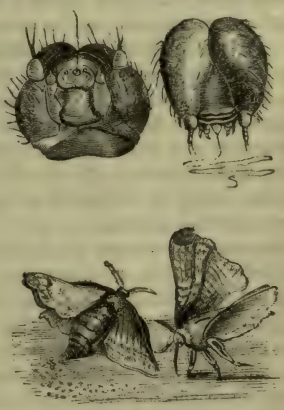
There are two methods of breeding silkworms; for they may be left to grow, and to remain at liberty upon the trees where they are hatched; or they may be kept in a place built for that purpose, and fed every day with fresh leaves. The first method is used in

---

ring. These feet may be termed holders. There is also a kind of tail on the upper part of the last ring but one.

At the end of the period above stated, the worm's desire for food begins to lessen, though it continues to nibble the leaves, which it scatters about; its colour is now of a light green; it is very restless and uneasy, erects its head, and moves from side to side in a circular manner, seeking a corner where it can commence its labour of forming its cocoon, before which, however, the

body becomes firmer, more glossy, and somewhat transparent towards its head; it also lessens in size.



It may not be out of place to mention here from whence the silk proceeds;—The silk is secreted in the form of a fine yellow gum, in two long slender vessels, one on each side of the body. This silky material, when drawn from the orifices beneath the mouth, appears to be one thread, but is, in fact, composed of two fibres, which are extracted from the orifices, and brought together by means of two hooks placed in the mouth.

The worm, having fixed upon some corner that will suit its purpose, commences the labour by spinning thin and irregular threads, so as to support its future dwelling; it then forms upon these a loose structure of an oval shape, which is called floss silk; in the three following days it forms a firm and consistent yellow ball, the anterior of which is smeared with a peculiar gum, so as to shield it against the rain and various changes of temperatures. The filament is not spun in regular concentric circles, but in stops, going backwards and forwards with a sort of waving motion, which the worm effects by means of its fore feet while it remains in the interior.

Isnard, an old author, affirms, that the length of the silk of one cocoon, when drawn out, will measure six miles, that is, 10,565 yards; but Count Dandolo says, the probable length is 625 yards; other authors state it to be about 400 yards, while Pullein says the average length is 300 yards. The latter author thus writes:—"There is scarcely anything among the various wonders which the animal creation affords, more admirable than the variety of changes which the silkworm undergoes; but the curious texture of that silken covering with which it surrounds itself, when it arrives at the perfection of its animal life, vastly surpasses what is made by other animals of this class. All the caterpillar kind do, indeed, undergo changes like those of the silkworm, and the beauty of them in their butterfly state greatly exceeds it; but the covering which they put on before this change into a fly is poor and mean, when compared to that golden tissue in which the silkworm wraps itself. They, indeed, come forth in a variety of colours, their wings bedropped with gold and scarlet, yet are they but the beings of a summer's day; both their life and beauty quickly vanish, and they leave no remembrance after them, but the silkworm leaves behind it such beautiful, such beneficial monuments, as at once record both the wisdom of their Creator and his bounty to man."

The worm, having finished its cocoon, rests awhile from its labour, and at the same time decreases in size and bulk; it then throws off its last skin, and undergoes its metamorphosis into a chrysalis, which is of a chestnut colour, and smooth. The time during which the insect remains in this state of lethargy is generally from fifteen to thirty days, as it is influenced by the temperature of the climate in which this metamorphosis is about to take place, viz. in England it requires thirty days, in France twenty-one, in Spain and Italy eighteen to twenty, and in India only eleven days.

After the above stated periods the insect breaks through the upper end of the cocoon, by emitting a liquid from its mouth, which moistens the gum with which it has lined the interior of its chamber. After this operation, it appears as the perfect insect, with four wings of a grayish white colour, with two transverse undulated bands on

the fore and wings. The stationary and sluggish habits of these moths are not entirely owing, as is generally supposed, to the insect being confined within certain limits during the period of several generations; as these habits are also common to others of the same family, which are only found in certain local districts; and thus proves that this valuable insect partakes of the same mode of life in the domestic as in the wild or natural state. Their life continues for the short period of two or three days, in which time they are wholly occupied in securing the continuance of their kind. Various accounts are given as to the number of eggs which the female lays, some stating 250, while others mention 400 to 500 as the usual number.—*Natural History of Insects, London*, 1835. *Vol. II.*

China, Tonquin, and other hot countries; the other is used in those places where the animal has been artificially propagated, and still continues a stranger. In the warm climates, the silkworm proceeds from an egg, which has been glued by the parent moth upon proper parts of the mulberry-tree, and which remains in that situation during the winter. The manner in which they are situated and fixed to the tree, keeps them unaffected by the influence of the weather; so that those frosts which are severe enough to kill the tree, have no power to injure the silkworm.

The insect never proceeds from the egg till Nature has provided it a sufficient supply; and till the budding leaves are furnished, in sufficient abundance, for its support. When the leaves are put forth, the worms seem to feel the genial summons, and bursting from their little eggs, crawl upon the leaves, where they feed with a most voracious appetite. Thus they become larger by degrees; and after some months' feeding, they lay, upon every leaf, small bundles or cones of silk, which appear like so many golden apples, painted on a fine green ground. Such is the method of breeding them in the East; and without doubt it is the best for the worms, and least troublesome for the feeder of them. But it is otherwise in our colder European climates; the frequent changes of the weather, and the heavy dews of our evenings, render the keeping them all night exposed, subject to so many inconveniences, as to admit of no remedy. It is true, that, by the assistance of nets, they may be preserved from the insults of birds; but the severe cold weather, which often succeeds the first heats of summer, as well as the rain and high winds, will destroy them all: and, therefore, to breed them in Europe, they must be sheltered and protected from every external injury.

For this purpose, a room is chosen, with a south aspect; and the windows are so well glazed as not to admit the least air: the walls are well built, and the planks of the floor exceedingly close, so as to admit neither birds nor mice, nor even so much as an insect. In the middle there should be four pillars erected, or four wooden posts, so placed as to form a pretty large square. Between these are different stories made with osier hurdles; and under each hurdle there should be a floor with an upright border all round. These hurdles and floors must hang upon pullies, so as to be placed or taken down at pleasure.

When the worms are hatched, some tender mulberry leaves are provided, and placed in the cloth or paper-box in which the eggs were laid, and which are large enough to hold a great number. When they have acquired some strength, they must be distributed on beds of mulberry leaves, in the different stories of the square in the middle of the room, round which a person may freely pass on every side. They will fix themselves to the leaves, and afterwards to the sticks of the hurdles, when the leaves are devoured. They have then a thread, by which they can suspend themselves on occasion, to prevent any shock by a fall; but this is by no means to be considered as the silk which they spin afterwards in such abundance. Care must be taken that fresh leaves be brought every morning, which must be strewed very gently and equally over them; upon which, the silkworms will forsake the remainder of the old leaves, which must be carefully taken away, and every thing kept very clean; for nothing hurts these insects so much as moisture and uncleanliness. For this reason their leaves must be gathered when the weather is dry, and kept in a dry place, if it be necessary to lay in a store. As these animals have but a short time to live, they make use of every moment, and almost continually are spinning, except at those intervals when they change their skins. If mulberry leaves be difficult to be obtained, the leaves of lettuce, or hollyhock, will sustain them; but they do not thrive so well upon their new diet; and their silk will neither be so copious, nor of so good a quality.

Though the judicious choice and careful management of their diet is absolutely necessary, yet there is another precaution of equal importance; which is, to give them air, and open their chamber windows, at such times as the sun shines warmest. The place also must be kept as clean as posible; not only the several floors that are laid to receive their ordure, but the whole apartments in general. These things well observed, contribute greatly to their health and increase.

The worm, at the time it bursts the shell, is extremely small, and of a black colour; but the head is of a more shining black than the rest of the body: some days after, they begin to turn whitish, or of an ash-coloured gray. After the skin begins to grow too rigid, or the animal is stinted within it, the insect throws it off, and appears clothed anew: it then becomes larger, and much whiter, though it has a greenish cast; after some days, which are more or less, according to the different heat of the climate, or to the quality of the food, it leaves off eating, and seems to sleep for two days together: then it begins to stir, and put itself into violent motions, till the skin falls off the second time, and is thrown aside by the animal's feet. All these changes are made in three weeks or a month's time; after which it begins to feed once more, still in its caterpillar form, but a good deal differing from itself before its change. In a few days'

time it seems to sleep again; and, when it awakes, it again changes its clothing, and continues feeding as before. When it has thus taken a sufficiency of food, and its parts are disposed for assuming the aurelia form, the animal forsakes, for the last time, all food and society, and prepares itself a retreat to defend it from external injuries, while it is seemingly deprived of life and motion.

This retreat is no other than its cone, or ball of silk, which Nature has taught it to compose with great art; and within which it buries itself, till it assumes its winged form. This cone or ball is spun from little longish kinds of bags that lie above the intestines, and are filled with a gummy fluid, of a marigold colour. This is the substance of which the threads are formed; and the little animal is furnished with a surprising apparatus for spinning it to the degree of fineness which its occasions may require. This instrument in some measure resembles a wire-drawer's machine, in which gold or silver threads are drawn to any degree of minuteness; and through this the animal draws its thread with great assiduity. As every thread proceeds from two gum-bags, it is probable that each supplies its own; which however, are united, as they proceed from the animal's body. If we examine the thread with a microscope, it will be found that it is flatted on one side, and grooved along its length: from hence we may infer, that it is doubled just upon leaving the body: and that the two threads stick to each other by that gummy quality of which they are possessed. Previous to spinning its web, the silkworm seeks out some convenient place to erect its cell, without any obstruction. When it has found a leaf, or a chink fitted to its purpose, it begins to wreathe its head in every direction, and fastens its thread on every side to the sides of its retreat. Though all its first essays seem perfectly confused, yet they are not altogether without design: there appears, indeed, no order or contrivance in the disposal of its first threads; they are by no means laid artfully over each other, but are thrown out at random, to serve as an external shelter against rain; for nature having appointed the animal to work upon trees in the open air, its habits remain, though it is brought up in a warm apartment.

Malpighi pretends to have observed six different layers in a single cone of silk: but what may easily be observed is, that it is composed externally of a kind of rough cotton-like substance, which is called floss; within, the thread is more distinct and even; and next the body of the aurelia, the apartment seems lined with a substance of the hardness of paper, but of a much stronger consistence. It must not be supposed, that the thread which goes to compose the cone, is rolled round, as we roll a bottom; on the contrary, it lies upon it in a very irregular manner, and winds off now from one side of the cone, and then from the other. This whole thread, if measured, will be found about three hundred yards long; and so very fine, that eight or ten of them are generally rolled off into one by the manufacturers. The cone, when completed, is in form like a pigeon's egg, and more pointed at one end than the other: at the smaller end, the head of the aurelia is generally found: and this is the place that the insect, when converted into a moth, is generally seen to burst through.

It is generally a fortnight or three weeks before the aurelia is changed into a moth; but no sooner is the winged insect completely formed, than having divested itself of its aurelia skin, it prepares to burst through its cone, or outward prison: for this purpose it extends its head towards the point of the cone, butts with its eyes, which are rough, against the lining of its cell, wears it away, and at last pushes forward, through a passage which is small at first, but which enlarges as the animal increases its efforts for emancipation; while the tattered remnants of its aurelia skin lie in confusion within the cone, like a bundle of dirty linen.

The animal, when thus set free from its double confinement, appears exhausted with fatigue, and seems produced for no other purpose but to transmit a future brood. It neither flies nor eats; the male only seeking the female, whose eggs he impregnates; and their union continues for four days, without interruption. The male dies immediately after separation from his mate; and she survives him only till she has laid her eggs, which are not hatched into worms till the ensuing spring.

However, there are few of these animals suffered to come to a state of maturity; for as their bursting through the cone destroys the silk the manufacturers take care to kill the aurelia, by exposing it to the sun, before the moth comes to perfection. This done, they take off the floss, and throw the cones into warm water, stirring them till the first thread offers them a clue for winding all off. They generally take eight of the silken threads together; the cones being still kept under water, till a proper quantity of the silk is wound off: however, they do not take all; for the latter parts grow weak, and are of a bad colour. As to the paper-like substance which remains, some stain it with a variety of colours, to make artificial flowers; others let it lie in the water, till the glutinous matter which cements it is all dissolved: it is then carded like wool, spun with a wheel, and converted into silk stuffs of an inferior kind.

HISTORY OF INSECTS, &c.

BOOK IV.

INSECTS OF THE FOURTH ORDER.

CHAP. I.

OF THE FOURTH ORDER OF INSECTS IN GENERAL.

In the foregoing part we treated of caterpillars changing into butterflies; in the present will be given the history of grubs changing into their corresponding winged animals. These, like the former, undergo their transformation, and appear as grubs or maggots, as aurelias, and at last as winged insects. Like the former, they are bred from eggs; they feed in their reptile state; they continue motionless and lifeless, as aurelias; and fly and propagate, when furnished with wings. But they differ in many respects: the grub or maggot wants the number of feet which the caterpillar is seen to have; the aurelia is not so totally wrapped up, but that its feet and its wings appear. The perfect animal, when emancipated, also has its wings either cased, or transparent like gauze; not coloured with that beautifully painted dust which adorns the wings of the butterfly.

In this class of insects, therefore, we may place a various tribe, that are first laid as eggs, then are excluded as maggots or grubs, then change into aurelias, with their legs and wings not wrapped up but appearing; and, lastly, assuming wings, in which state they propagate their kind. Some of these have four transparent wings, as bees; some have two membranous cases to their wings, as beetles; and some have but two wings, which are transparent as ants. Here, therefore, we will place the bee, the wasp, the humble-bee, the ichneumon fly, the gnat, the tipula or long legs, the beetle, the may-bug, the glow-worm, and the ant. The transformations which all these undergo, are pretty nearly similar; and though very different animals in form, yet are produced nearly in the same manner.

CHAP. II.

OF THE BEE.

To give a complete history of this insect in a few pages, which some have exhausted volumes in describing, and whose nature and properties still continue in dispute, is impossible.[1] It will be sufficient to give a general idea of the animal's operations; which, though they have been studied for more than two thousand years, are still but incompletely known. The account given us by Reaumur is sufficiently minute; and, if true, sufficiently wonderful: but I find many of the facts which he relates, doubted by those who are most conversant with bees: and some of them actually declared not to have a real existence in nature.

It is unhappy, therefore, for those whose method demands a history of bees, that they are unfurnished with those materials which have induced so many observers to contradict so great a naturalist. His life was spent in

[1] Many works have been written on the nature and habits of bees. Among those who have contributed largely to our knowledge of the subject may be mentioned, Swammerdam, Reaumur, Schirach, Thorley, Wildman, Huish, Howison, Huber, and Bonner. The two latter made many valuable discoveries regarding the bee under very peculiar and, one would almost imagine, insurmountable disadvantages. Huber was stone blind, and Bonner's researches were conducted in the midst of a populous city, and during the pressure of daily toil,—he being a poor weaver, and his hives being kept for many years in a *garret* in the Gallowgate of Glasgow! Bonner's work on Bees was published at Edinburgh in 1795, (one volume, 8vo) and an English translation of Huber's was published in 1806, (12mo.)

the contemplation; and it requires an equal share of attention, to prove the error of his discoveries. Without entering, therefore, into the dispute, I will take him for my guide; and just mention, as I go along, those particulars in which succeeding observers have begun to think him erroneous. Which of the two are right, time only can discover; for my part, I have only heard one side, for as yet none have been so bold as openly to oppose Reaumur's delightful researches.

There are three different kinds of bees in every hive.[1] First, the labouring bees, which make up the far greatest number, and are thought to be neither male nor female, but merely born for the purposes of labour, and continuing the breed, by supplying the young with provision, while yet in their helpless state. The second sort are the drones; they are of a darker colour, longer, and more thick by one-third than the former; they are supposed to be the males; and there is not above a hundred of them in a hive of seven or eight thousand bees. The third sort is much larger than either of the former, and still fewer in number; some assert that there is not above

[1] *Functions of the inmates of a hive.*—A hive consists of the Queen, or mother-bee, the Workers varying in numbers, from 10,000, to 20,000 or 30,000, and the Males or Drones, from 700 to double that number.

Functions of the Queen.—The Queen is the parent

of the hive, and her sole province and occupation consist in laying the eggs, from which originate those prodigious multitudes that people a hive, and emigrate from it in the course of one summer. In the height of the season, her fertility is truly astonishing, as she lays not fewer than 200 eggs per day, and even more when the season is particularly warm and genial, and flowers are abundant; and this laying continues, though at a gradually diminishing rate, till the approach of cold weather in October. So early as February, she resumes her labours in the same department, and supplies the great blank made in the population by the numerous casualties that take place between the end of summer and commencement of spring. Her *great laying* of the eggs of workers begins generally about the fifth day of her age; and she continues to deposit eggs of the same kind for the succeeding eleven months; after which she commences laying those of males. It is during the depositing of these last, that the Bees are led by their instinct to lay the foundation of royal cells, in which, if the population be abundant, the Queen deposits eggs at intervals of one or two days between each. In the operation of laying, which we have a thousand times witnessed, the Queen puts her head into a cell, and remains in that position about a second or two, as if to ascertain whether it is in a fit state to receive the deposit. She then withdraws her head, curves her body downwards, inserts her abdomen into the cell, and turns half round on herself; having kept this position for a few seconds, she withdraws her body, having in the meantime laid an egg. The egg itself, which is attached to the bottom of the cell by a glutinous matter with which it is imbued, is of a slender oval shape, slightly curved, rather more pointed in the lower end than in the other. She passes on from cell to cell, furnishing each with the germ of a future inhabitant; and during these proceedings, she receives the most marked and affectionate attention from the workers. She is seen continually surrounded by a circle of them, who caress her fondly with their antennæ, and occasionally supply her with food from their probosces. This appearance has given rise to the notion commonly entertained, and asserted even by some Naturalists, that the Queen is followed in her progress through the hive by a number of her subjects formed in a circle round her, and these of course have been regarded as the Queen's *body guards*. The truth is, however, that her Bee-majesty has no attendants, strictly speaking; none who follow in her train; but wherever she moves, the workers whom she encounters in her progress instantly and hurriedly clear the way before her, and all turning their heads towards their approaching sovereign, lavish their caresses upon her with much apparent affection, and touch her softly with their antennæ; and these circumstances, which may be observed every hour in the day, in a properly constructed glass hive, have given rise to the idea of guards. The moment she has left the circle, the bees who had surrounded her instantly resume their labours, and she passes on, receiving from every group in her way the homage due to a Mother and a Queen

Functions of the Worker-Bee.—The workers, to the

number of 10,000, 20,000, and even 30,000, constitute the great mass of the population of a hive, and on them devolve the whole labours of the establishment. Theirs is the office of searching for and collecting the precious fluid which not only furnishes their daily food, as well as that of their young, and the surplus of which is laid up for winter stores, but also the materials from which they rear their beautiful combs. In the little basket-shaped cavity in their hind-legs, they bring home the pollen or farinaceous dust of flowers, kneaded by the help of the morning dew into tiny balls, which form an important ingredient in the nourishment of the brood; and also the propolis or adhesive gum extracted from willows, &c., with which they attach their combs to the upper part and sides of the hive, and stop every crevice that might admit the winter's cold. Exploring a glass hive in a soft spring morning, and following with his eye a bee loaded with farina, the observer will perceive the little active forager, on her arrival in the interior, hurrying over the surface of the comb in search of a proper cell in which to deposit her burden; and having found one, fastening herself by the two fore-feet on its superior border, then bending her body a little forward, that her hinder feet may catch hold of the opposite edge of the cell. In this position she is next seen thrusting back her second pair of feet, one on each side, and sweeping with them from top to bottom along the two hinder legs, where the farina balls are fixed, and by this means detaching them from the hairy linings of the cavities, and depositing them in the cell. To the workers, also, are committed the various offices of guarding the entrance

one in every swarm : but this later observers affirm not to be true, there being sometimes five or six in the same hive. These are called queen bees, and are said to lay all the eggs from which the whole swarm is hatched in a season.

In examining the structure of the common working bee, the first remarkable part that

of the hive by night and day, during the honey season ; of repulsing marauders ; of keeping their abode free from all offensive matters ; of renewing the air within by an ingenious mode of ventilation ; of replacing a lost Queen, and of destroying the drones at the decline of the honey season. Receiving from nature these weighty charges, they labour assiduously to fulfil them ; and, while each member of the community acts by the impulse of its individual instinct, it works less for private than for the general good. These labours appear unceasing ; yet do the weary labourers sometimes snatch an interval of repose. During the busy season, we have seen hundreds of the workers retiring into the cells, and exhibiting all the marks of profound sleep. This fact is very easily observable, especially in those cells which are constructed, as sometimes happens, against the glass, and where that substance forms one side of the cell. There they are, the fatigued labourers, stretched at full length, with their heads at the bottom, and every limb apparently in a relaxed state, while the little body is seen heaving gently from the process of respiration. Huber thinks he has ascertained that there are two kinds of workers in a hive, one of which he calls *Wax-workers*, and the other *Nurses*. The office of the first class, according to Huber, is not only to collect honey, which both kinds do, but also to elaborate the wax, and construct the combs. The particular function of the other, is to take care of the young. They may be distinguished in entering the hive, by carefully examining their shape ; the wax-workers having their bellies somewhat cylindrical, while those of the nurses retain their ovoidal figure. The anatomical structure of the two is said to be different, and the capacity of stomach not the same ; so that the one species is incapable of fulfilling all the functions of the other. Huber has also directed our attention to a class of workers, which he calls *Black Bees*, and which he first observed in 1809, and on several other occasions from that time to the year 1813. In every thing they bear a perfect resemblance to their fellow-workers, except in colour, which in them is a deep black. He describes them as persecuted by the other workers, and finally expelled the hives, or destroyed. We have noticed them, though rarely ; perhaps not more than one or two in a season. The other bees did not molest them, as far as we observed, nor indeed seem in any way sensible of their presence. It is not improbable, as Kirby and Spence conjecture, that they are merely *aged bees*, and that their deeper colour arises from the hair or down, with which the young are so thickly clothed, being worn off their bodies.

In describing the functions of the Working Bee, it would be improper to pass over unnoticed the fact, that it sometimes exercises the functions of a mother. To account for this apparent anomaly, we must remember that it has been ascertained by minutely accurate dissection, that all the workers are *females*, though of imperfect organization ; a fact confirmed by the very circumstance we are now discussing. We must also keep in mind, that the larva of a Queen is nourished with food of a different kind from that of common bees ; and this difference, in conjunction with a more roomy cell, has, in the opinion of naturalists, the effect of expanding the ovarium, and qualifying her to become a mother. It is evident, therefore, that, if the larva of a common bee were fed with the royal jelly, the imperfection in her bodily organs would, as far at least as depended on the nature of the food, be removed, and she would become capable of laying eggs. Now this does occasionally take place ; some of the royal food is dropped, probably by accident, into some of the cells adjoining that of the Queen, and the bees therein reared acquire the power of laying eggs. This fact was discovered by the naturalist Riem, and has been confirmed by Huber. There is, however, a very material and hitherto unaccounted for difference between these fertile workers and perfect Queens ; the former lay the eggs of *males* only. We would certainly have expected, *a priori*, that a difference between them *should* exist ; because the workers have fed on the royal jelly only for a short time, and because their birth-place is so much smaller. But we cannot easily conceive how these circumstances should be the cause of their laying only *male eggs*. In truth, it appears to be one of those mysteries in bee-economy, which, with all our researches on the subject, we cannot yet unravel. These fertile workers are never found in any hives but such as have lost their natural Queen.

The natural term of the worker's existence does not extend, we think, beyond six or eight months. It is the opinion of Dr Bevan that all the bees brought into existence at the Queen's great laying in spring die before winter. But many never reach that period. Showers of rain, violent blasts of wind, sudden changes of atmosphere, destroy them in hundreds. In the clear cold mornings and evenings of autumn, their eagerness for foraging entices them abroad early and late ; when, alighting on the ground, many are chilled, and quickly perish. And should they escape the blighting atmosphere at the close of autumn, a bright sunshine in a winter day, when the ground perhaps is covered with snow, brings them abroad in multitudes, and the half of them never return. From these causes, independent of the numbers which fall a prey to enemies, a swarm which in July amounted to fifteen or twenty thousand, will, by the following February or March, have dwindled to a mere handful. It is otherwise with the Queen ; going seldom abroad, she is little exposed to accidents. Her natural life is prolonged to several years, though the precise extent has not been accurately ascertained. In 1834 we had one in our possession, which we had every reason to believe was not less than four years old.

Functions of the Male or Drone.—The sole office of

the Male, or at least the primary one, is to pair with the Queen. He is the father of the hive. Indolent and luxurious, he takes no part in the internal operations of the domicile, and never leaves it with a view of sharing in the labours of the field. When he does venture abroad, it is only in the finest weather, and during the warmest part of the day, at which time the young Queens are instinctively led to go out in search of the male. He is easily distinguished from the workers by his larger size, by his heavy motion in flight, and by his loud humming sound. We have said that the primary function of the drones is to perpetuate the race of bees by pairing with the Queen, but some naturalists have assigned them a secondary office, namely, that of contributing by their numbers to the heat of the hive, and thus aiding in bringing the brood to maturity. In some parts of the

offers is the trunk, which serves to extract the honey from flowers. It is not formed, like that of other flies, in the manner of a tube, by which the fluid is to be sucked up; but like a besom to sweep, or a tongue to lick it away. The animal is furnished also with teeth, which serve it in making wax. This substance is gathered from flowers, like honey; it consists of that dust or farina which contributes to the fecundation of plants, and is moulded into wax

---

continent, accordingly, Feburier tells us, they have received the name of *Hatchers*. There are occasionally found drones of a small size in hives where the impregnation of the Queen has been retarded. In such circumstances, her instinct is so impaired, that she lays her eggs indiscriminately in all kinds of cells; those of males sometimes in the cells of workers. The consequence is, that these males, when hatched, are diminutive in size, having been cramped in their growth by the smallness of their birth-place.

The life of this *vir gregis* is extremely short; the favoured lover perishes soon after his union with the female, and thus anticipates, though only by a short period, the destruction which awaits his race. So early as the beginning of August, the bees, as if wishing to apply "the preventive check" to a superabundant idle population, begin to manifest deadly intentions towards them; and the unfortunate victims, as if to derive consolation from one another's society, or perhaps driven together by their irascible superiors, may be seen about that period clustering closely together in some corner of the combs, where they remain without motion, and without once venturing to approach the provision-cells. Thus weakened by hunger and captivity, and disqualified for resistance by the want of a sting, they fall an easy prey to their merciless assailants; and a scene of carnage takes place which it is difficult to describe. The unhappy wretches are seen driven to the bottom of the hive pursued with such fury, that, in spite of their strength, which is greatly superior to that of their persecutors, and which enables them to drag two or three of their assailants along the board, and even to fly off with them, they are unable to avoid the mortal thrust of their formidable stings, and expire instantaneously from the effects of the poison. But death overtakes them in various forms; for their enemies sometimes seize them by the wings, and with their strong mandibles gnaw them at the roots, and disable them from flying. They may then be seen in numbers crawling on the ground, where they perish from the cold, or are trampled under foot, and devoured by birds or frogs. Such as escape for a while, may be seen flying from destruction, lighting on the shrubs and flowers to enjoy a moment's respite from their terrors; or buzzing about our windows, or wandering about from hive to hive, into one of which they no sooner enter than certain death awaits them. Nay, so bitter is the fury of their tormentors, that, not satisfied with destroying these unhappy beings themselves, they tear from the cells such of the doomed race as are yet in the state of larvæ, and sucking from their bodies, with instinctive economy, the fluids they contain, cast the lifeless remains out of the hive. There are cases, however, in which this destruction of males does not take place. "In hives that have lost their Queen," says Huber, "the males are spared; and, while a savage massacre rages in other hives, they here find an asylum. They are tolerated and fed, and many are seen even in the middle of January." The cause of this may perhaps be looked for in the additional heat which they would generate in winter; or perhaps they may be preserved for the purpose of pairing with a new Queen.

The impregnation of the Queen-bee is a branch of Natural History which has given rise to more discussion than almost any other fact, connected with the nature of the insect. And indeed the difficulty, we might almost say *impossibility* of obtaining any thing like ocular evidence on the subject, will readily account for the diversity of opinion that has hitherto prevailed. And we should hope that this difficulty alone, and not any preconceived theory or unreasonable prejudice, is the cause of that determined pertinacity with which the discoveries and conclusions of Huber, on this subject, are still in some instances rejected. That justly celebrated naturalist, instituted a set of experiments on the subject of the Queen's impregnation, the result of which leads to the conclusion that it takes place in the air.

There is a fact connected with this part of the natural history of the mother-bee which involves great difficulties. The fact itself was discovered by Huber, but its cause he was unable to develope, and no succeeding naturalist has been able to free it from the obscurity in which he has left it, we mean the effects of retarded impregnation. These effects are such as we could hardly credit, were not the fact confirmed by numerous experiments. If impregnation be delayed longer than twenty days from the Queen's birth, the consequence is, that none but male eggs are laid, even during the whole of the Queen's life. This phenomenon has baffled every attempt to explain its cause. "There are mysteries," observes Feburier, "in the operations of nature, both in reference to the rational and irrational creation, which will, probably, for ever remain inscrutable to man." In the natural state of things, that is, when fecundation has not been postponed, the Queen lays the eggs of workers in forty-six hours after her union with the male, and continues for the subsequent eleven months to produce these alone, and it is only after this period that a considerable laying of the eggs of drones commences. These male eggs require eleven months to attain to maturity, but, under the effects of retardation, they are matured in forty-six hours. The eggs of workers, which, in the usual state of things, would have been laid first, never come to light; their vitality has been destroyed by some vitiation which has taken place, and the cause of which has not yet been discovered. Huber, in reasoning on the subject, and contemplating the difficulty attending it, declares it to be "an abyss in which he is lost." There is another circumstance which he has not adverted to, and which seems to increase these difficulties. He asserts that before a Queen commences her *great* laying of male-eggs, she must be eleven months old. But he acknowledges that "a Queen hatched in spring, will perhaps lay fifty or sixty eggs of drones in whole, during the course of the ensuing summer." We know this to be true from our own experience; and also as the usual consequence of this appearance of male-eggs, that the bees commence building royal cells; the Queen lays in them, and swarming takes place. Now this partial laying of drone-eggs takes place only in the case of very early swarms; and if the weather be unfavourable, it does not happen even in them. But if in the natural state, the space of eleven months be necessary for the male-eggs to acquire that degree of increment they must have attained when laid, how are we to explain the fact of two or three score of these male-eggs making their appearance before the mother-bee is six weeks old? Leaving this matter in the obscurity which we cannot dispel, we have only further to observe, that in every case of retarded impregnation the instinct of the Queen appears to be greatly impaired. She lays her eggs indiscriminately in drone and worker cells; now and then even in royal cells; and does not evince that jealousy and irritable temperament towards her rivals, which, in the natural state, characterize the Queen.—*Naturalist's Library. Entomology. Vol.* vi. *Bees. Edinburgh*, 1840.

by the little animal at leisure. Every bee, when it leaves the hive to collect this precious store, enters into the cup of the flower, particularly such as seem charged with the greatest quantities of this yellow farina. As the animal's body is covered over with hair, it rolls itself within the flower, and soon becomes quite covered with the dust, which it soon after brushes off with its two hind-legs, and kneads into two little balls. In the thighs of the hind-legs there are two cavities, edged with hair, and into these, as into a basket, the animal sticks its pellets. Thus employed, the bee flies from flower to flower, increasing its store, and adding to its stock of wax; until the ball upon each thigh becomes as big as a grain of pepper: by this time, having got a sufficient load, it returns, making the best of its way to the hive.[1]

The belly of the bee is divided into six rings, which sometimes shorten the body, by slipping one over the other. It contains within it, beside the intestines, the honey-bag, the

[1] The celebrated John Hunter shrewdly remarked that the pellets of pollen seen on the thighs of bees are of different colours on different bees, while the shade of the new-made comb is always uniform; and therefore he concluded that pollen was not the origin of wax. Pollen also, he observed, is collected with greater avidity for old hives, where the comb is complete, than for those where it is only begun, which would hardly be the case were it the material of wax. He found that when the weather was cold and wet in June, so that a young swarm was prevented from going abroad, as much comb was constructed as had been made in an equal time when the weather was favourable and fine. The pellets of pollen on the thighs being thence proved not to be wax, he came to the conclusion that it was an external secretion originating between the plates of the belly. When he first observed this, he felt not a little embarrassed to explain the phenomenon, and doubted whether new plates were forming, or whether bees cast the old ones as lobsters do their shells. By melting the scales, he ascertained at least that they were wax; and his opinion was confirmed by the fact, that the scales are only to be found during the season when the combs are constructed. But he did not succeed in completing the discovery by observing the bees actually detach the scales, though he conjectured they might be taken up by others, if they were once shaken out from between the rings.

That wax is secreted, is proved both by the wax pouches within the rings of the abdomen, and by actual experiment. Huber and others fed bees entirely upon honey or sugar, and, notwithstanding, wax was produced and combs formed as if they had been at liberty to select their food. "When bees were confined," says M. Huber, "for the purpose of discovering whether honey was sufficient for the production of wax, they supported their captivity patiently, and showed uncommon perseverance in rebuilding their combs as we removed them. Our experiments required the presence of grubs; honey and water had to be provided; the bees were to be supplied with combs containing brood, and at the same time it was necessary to confine them, that they might not seek pollen abroad. Having a swarm by chance, which had become useless from the sterility of the queen, we devoted it for our investigation in one of my leaf hives, which was glazed on both sides. We removed the queen, and substituted combs containing eggs and young grubs, but no cell with farina; even the smallest particle of the substance which John Hunter conjectured to be the basis of the nutriment of the young was taken away. Nothing remarkable occurred during the first and second day: the bees brooded over the young, and seemed to take an interest in them; but at sunset, on the third, a loud noise was heard in the hive. Impatient to discover the reason, we opened a shutter, and saw all in confusion; the brood was abandoned; the workers ran in disorder over the combs; thousands rushed towards the lower part of the hive; and those about the entrance gnawed at its grating. Their design was not equivocal; they wished to quit their prison. Some imperious necessity evidently obliged them to seek elsewhere what they could not find in the hive; and apprehensive that they might perish if I restrained them longer from yielding to their instinct, I set them at liberty. The whole swarm escaped; but the hour being unfavourable for their collections, they flew around the hive, and did not depart from it. Increasing darkness and the coolness of the air compelled them very soon to return. Probably these circumstances calmed their agitation; for we observed them peaceably remounting their combs; order seemed re-established, and we took advantage of this moment to close the hive. Next day, the 19th of July, we saw the rudiments of two royal cells, which the bees had formed on one of the brood combs. This evening, at the same hour as on the preceding, we again heard a loud buzzing in the closed hive; agitation and disorder rose to the highest degree, and we were again obliged to let the swarm escape. The bees did not remain long absent from their habitation; they quieted and returned as before. We remarked on the 20th, that the royal cells had not been continued, as would have been the case in the ordinary state of things. A great tumult took place in the evening; the bees appeared to be in a delirium; we set them at liberty, and order was restored on their return. Their captivity having endured five days, we thought it needless to protract it farther; besides, we were desirous of knowing, whether the brood was in a suitable condition, and if it had made the usual progress; and we wished also to try to discover what might be the cause of the periodical agitation of the bees. M. Burnens (the assistant of Huber) having exposed the two brood combs, the royal cells were immediately recognized; but it was obvious that they had not been enlarged. Why should they? Neither eggs, grubs, nor that kind of paste peculiar to the individuals of their species, were there! The other cells were vacant likewise; no brood, not an atom of paste was in them. Thus the worms had died of hunger. Had we precluded the bees from all means of sustenance by removing the farina? To decide this point, it was necessary to confide other broods to the care of the same insects, now giving them abundance of pollen. They had not been enabled to make any collections while we examined their combs. On this occasion they escaped in an apartment where the windows were shut; and after substituting young worms for those they had allowed to perish, we returned them to their prison. Next day we remarked that they had resumed courage; they had consolidated the combs, and remained on the brood. They were then provided with fragments of combs, where other workers had stored up farina; and to be able to observe what they did with it, we took this substance from some of their cells, and spread it on the board of the hive. The bees soon discovered both the farina in the combs and what we had exposed to them. They crowded to the cells, and also descending to the bottom of the hives, took the pollen grain by grain in their teeth, and conveyed it to their mouths. Those that had eaten it most greedily, mounted the combs before the rest, and stopping on the cells of the young worms, inserted their heads, and remained there for a certain time. M. Burnens opened one of the divisions of the

venom-bag, and the sting. The honey-bag is as transparent as crystal, containing the honey that the bee has brushed from the flowers; of which the greater part is carried to the hive, and poured into the cells of the honey-comb, while the remainder serves for the bee's own nourishment; for, during summer, it never touches what has been laid up for winter. The sting which serves to defend this little animal from its enemies, is composed of three parts; the sheath and two darts, which are extremely small and penetrating. Both the darts have several small points or barbs, like those of a fish-hook, which render the sting more painful, and make the darts rankle in the wound. Still, however, this instrument would be very slight, did not the bee poison the wound. The sheath, which has a sharp point, makes the first impression; which is followed by that of the darts, and then the venomous liquor is poured in. The sheath sometimes sticks so fast in the wound, that the animal is obliged to leave it behind; by which the bee soon after dies, and the wound is considerably inflamed. It might at first appear well for mankind, if the bee were without its sting; but upon recollection, it will be found, that the little animal would then have too many rivals in sharing its labours. A hundred other lazy animals, fond of honey, and hating labour, would intrude upon the sweets of the hive; and the treasure would be carried off for want of armed guardians to protect it.

From examining the bee singly, we now come to consider it in society, as an animal not only subject to laws, but active, vigilant, laborious, and disinterested. All its provisions are laid up for the community; and all its arts in building a cell, designed for the benefit of posterity. The substance with which bees build their cells, is wax; which is fashioned into convenient apartments for themselves and their young. When they begin to work in their hives, they divide themselves into four companies: one of which roves in the fields in search of materials; another employs itself in laying out the bottom and partitions of their cells; a third is employed in making the inside smooth from the corners and angles; and the fourth company bring food for the rest, or relieve those who return with their respective burdens. But they are not kept constant to one employment; they often change the tasks assigned them: those that have been at work, being permitted to go abroad; and those that have been in the fields already, take their places. They seem even to have signs, by which they understand each other; for when any of them wants food, it bends down its trunk to the bee from whom it is expected, which then opens its honey-bag, and lets some drops fall into the other's mouth, which is at that time open to receive it. Their diligence and labour is so great, that in a day's time they are able to make cells, that lie upon each other, numerous enough to contain three thousand bees.

If we examine their cells, they will be found formed in the exactest proportion. It was said by Pappus, an ancient geometrician, that of all other figures, hexagons were the most convenient; for when placed touching each other, the most convenient room would be given, and the smallest lost. The cells of the bees are perfect hexagons: these, in every honey-comb, are double, opening on either side, and closed at the bottom. The bottoms

Part of Honey-comb with Queen's cell.

are composed of little triangular panes, which, when united together, terminate in a point, and lie exactly upon the extremities of other panes of the same shape, in opposite cells. These lodgings have spaces, like streets, between them, large enough to give the bees a free passage in and out; and yet narrow enough to preserve the necessary heat. The mouth of every cell is defended by a border, which makes the door a little less than the inside of a cell, which serves to strengthen the

hive gently, and powdered the workers, for the purpose of recognizing them when they should ascend the combs. He observed them during several hours, and by this means ascertained that they took so great a quantity of pollen only to impart it to their young. Then withdrawing the portions of comb which had been placed by us on the board of the hive, we saw that the pollen had been sensibly diminished in quantity. They were returned to the bees, to augment their provision still farther, for the purpose of extending the experiment. The royal, as well as several common cells were soon closed; and, on opening the hive, all the worms were found to have prospered. Some still had their food before them; the cells of others that had spun were shut with a waxen covering. We witnessed these facts repeatedly, and always with equal interest. They so decisively prove the regard of the bees towards the grubs which they are entrusted with rearing, that we shall not seek for any other explanation of their conduct. Another fact, no less extraordinary, and much more difficult to be accounted for, was exhibited by bees constrained to work in wax, several times successively, from the syrup of sugar. Towards the close of the experiment they ceased to feed the young, though in the beginning these had received the usual attention. They even frequently dragged them from their cells, and carried them out of the hive."

whole. These cells serve for different purposes; for laying up their young; for their wax, which in winter becomes a part of their food; and for their honey, which makes their principal subsistence.

It is well known that the habitation of bees ought to be very close; and what their hives want, from the negligence or unskilfulness of man, these animals supply by their own industry: so that it is their principal care, when first hived, to stop up all the crannies. For this purpose they make use of a resinous gum, which is more tenacious than wax, and differs greatly from it. This the ancients called *propolis*: it will grow considerably hard in June; though it will in some measure soften by heat; and is often found different in consistence, colour, and smell. It has generally an agreeable aromatic odour when it is warmed; and by some it is considered as a most grateful perfume. When the bees begin to work with it, it is soft, but it acquires a firmer consistence every day; till at length it assumes a brown colour, and becomes much harder than wax. The bees carry it on their hinder legs; and some think it is met with on the birch, the willow, and poplar. However it is procured, it is certain that they plaster the inside of their hives with this composition.

If examined through a glass hive, from the hurry the whole swarm is in, the whole appears at first like anarchy and confusion; but the spectator soon finds every animal diligently employed, and following one pursuit, with a settled purpose. Their teeth are the instruments by which they model and fashion their various buildings, and give them such symmetry and perfection. They begin at the top of the hive; and several of them work at a time at the cells which have two faces. If they are stinted with regard to time, they give the new cells but half the depth which they ought to have; leaving them imperfect, till they have sketched out the number of cells necessary for the present occasion. The construction of their combs costs them a great deal of labour: they are made by insensible additions; and not cast at once in a mould, as some are apt to imagine. There seems no end of their shaping, finishing, and turning them neatly up. The cells for their young are most carefully formed; those designed for lodging the drones, are larger than the rest; and that for the queen-bee the largest of all. The cells in which the young brood are lodged, serve at different times for containing honey; and this proceeds from an obvious cause: every worm, before it is transformed into an aurelia, hangs its old skin on the partitions of its cell; and thus, while it strengthens the wall, diminishes the capacity of its late apartment. The same cell, in a single summer, is often tenanted by three or four worms in succession; and the next season by three or four more. Each worm takes particular care to fortify the pannels of its cell, by hanging up its spoils there: thus, the partitions being lined six or eight deep, become at last too narrow for a new brood, and are converted into store-houses for honey.

Those cells where nothing but honey is deposited, are much deeper than the rest. When the harvest of honey is so plentiful that they have not sufficient room for it, they either lengthen their combs, or build more; which are much longer than the former. Sometimes they work at three combs at a time; for when there are three work-houses, more bees may be thus employed, without embarrassing each other.

But honey, as was before observed, is not the only food upon which these animals subsist. The meal of flowers, of which their wax is formed, is one of their most favourite repasts. This is a diet which they live upon during the summer; and of which they lay up a large winter provision. The wax of which their combs are made, is no more than this meal digested, and wrought into a paste. When the flowers upon which bees generally feed, are not fully blown, and this meal or dust is not offered in sufficient quantities, the bees pinch the tops of the stamina in which it is contained, with their teeth; and thus anticipate the progress of vegetation. In April and May, the bees are busy, from morning to evening, in gathering this meal; but when the weather becomes too hot in the midst of summer, they work only in the morning.

The bee is furnished with a stomach for its wax, as well as its honey. In the former of the two, their powder is altered, digested, and concocted into real wax, and is thus ejected by the same passage by which it was swallowed. Every comb, newly made, is white: but it becomes yellow as it grows old, and almost black when kept too long in the hive. Beside the wax thus digested, there is a large portion of the powder kneaded up for food in every hive, and kept in separate cells, for winter provision. This is called by the country people, bee-bread; and contributes to the health and strength of the animal during winter. Those who rear bees, may rob them of their honey, and feed them, during the winter, with treacle; but no proper substitute has yet been found for the bee-bread; and, without it, the animals become consumptive, and die.

As for the honey, it is extracted from that part of the flower called the nectareum. From the mouth this delicious fluid passes into the gullet; and then into the first stomach, or honey-bag, which, when filled, appears like

an oblong bladder. Children that live in country places, are well acquainted with this bladder; and destroy many bees, to come at their store of honey. When a bee has sufficiently filled its first stomach, it returns back to the hive, where it disgorges the honey into one of the cells. It often happens that the bee delivers its store to some other, at the mouth of the hive, and flies off for a fresh supply. Some honeycombs are always left open for common use; but many others are stopped up, till there is a necessity of opening them. Each of these is covered carefully with wax; so close, that the covers seem to be made at the very instant the fluid is deposited within them.

Having thus given a cursory description of the insect, individually considered, and of the habitation it forms, we next come to its social habits and institutions: and, in considering this little animal attentively, after the necessary precautions for the immediate preservation of the community, its second care is turned to the continuance of posterity. How numerous soever the multitude of bees may appear in one swarm, yet they all owe their original to a single parent, which is called the *Queen-Bee*. It is indeed surprising that a single insect shall, in one summer, give birth to above twenty thousand young: but, upon opening her body the wonder will cease; as the number of eggs appearing at one time, amounts to five thousand.[1] This animal, whose existence is of so much importance to her subjects, may easily be distinguished from the rest by her size, and the shape of her body. On her safety depends the whole welfare of the commonwealth; and the attentions paid her by all the rest of the swarm, evidently show the dependence her subjects have upon her security. If this insect be carefully observed,

[1] *On the conversion of the larva of a Worker into a Queen.*—Bees, when deprived of their queen, are endowed by nature with the power of remedying this calamity, by converting a worker larva into a royal one; and, by means of a cell of a larger size, and of a peculiar kind of nourishment, of producing a female that shall be, to all intents and purposes, a queen or mother-bee, capable of perpetuating her kind. The discovery of this singular fact is generally attributed to Schirach, and, probably, with justice; for, although the practice of making artificial swarms, which can only be effected by causing the production of artificial queens, is said to have pervailed amongst the modern Greeks and Italians from a very early period, it does not follow, nor does it appear from any authentic documents, that they were aware of the reason why. The manner in which Schirach made the discovery is interesting:—Having used a great quantity of smoke in some of his operations, the bees were so annoyed by it that numbers of them left the hive, and, amongst them, the queen. Knowing the consequences of her loss, he sought for her diligently, but in vain. Next morning he observed a cluster of bees about the size of an apple on the prop of the hive whose queen had fled; here he discovered a queen, and, having carried her to the entrance of the hive which had lost its own, she was immediately surrounded by the bees, and treated in such a manner as plainly announced that she was their queen. "What was my astonishment," he proceeds, "when, wishing to introduce her among the combs, I saw that the bees remaining had already planned and almost finished three royal cells! Struck with the activity and sagacity of these creatures, to save themselves from impending destruction, I was filled with admiration, and adored the infinite goodness of God in the care taken to perpetuate his works. Having carried away two of the cells to ascertain whether the bees would continue their operations, I beheld, next morning, with the utmost surprise, that they had removed all the food from around the third worm left behind, on purpose to prevent its conversion to a queen." The fact of this power possessed by the bees is so extraordinary, that its reality was at first called in question by several eminent naturalists, among others, by the justly celebrated Bonnet. This naturalist was at last, however, convinced of its reality by experiments instituted by himself, and, satisfied that all the working-bees are females of imperfect organisation, expressed his opinion that the evolution of the germ is effected by the action of the prolific matter as a stimulant, as a substantial nutriment suitable for that purpose; and he supposes that a certain quality of food administered more copiously than in ordinary cases, may unfold those organs in the larvæ of bees that never would have appeared without it. He conceived, also, that a habitation, like a queen-cell, considerably more spacious, and differently placed, is absolutely necessary to the complete development of organs, which the new nutriment may cause to grow in all directions. It furnishes a surprising evidence of the slow degrees by which scientific facts make their way, if not essential to general utility, when we consider that to this day, the knowledge of this singularity in the natural history of this insect, is confined almost exclusively to apiarians, and even rejected by some of them. It has, however, been confirmed by so many experiments instituted by many different individuals, that no unprejudiced mind can withhold its assent from its truth.

The proceedings of the bees, in order to supply the loss of their queen, are extremely interesting. In about twenty-four hours they are aware of the misfortune that has befallen them, and, without loss of time, they set about repairing the disaster. They fix upon a worm not more than three days old, demolish the three contiguous cells, and raise around it a regular cylindrical inclosure. At the end of three days, the workers change the direction of the cell, which has hitherto been horizontal, into a perpendicular position, working downwards till it assume the appearance of a stalactite. In due time it is sealed, and the larva undergoes its metamorphosis into a royal nymph. Huber gives a detail of some interesting experiments on this head, the substance only of which we can present to our readers. He deprived a hive of its queen, and put into it some pieces of comb containing worker eggs. The same day several cells were enlarged by the bees, and converted into royal cells, and the larvæ supplied with a profusion of jelly. He then removed these worms from the royal cells, and substituted for them as many common worms from workers' cells. The bees did not seem aware of the change, they watched over the new worms as intently as over those chosen by themselves; they continued enlarging the cells, and closed them at the usual time. At the proper time, two queens were hatched, almost at the same moment, of the largest size, and well formed in every respect. Nothing could be more conclusive than this experiment. It demonstrated that bees have the power of converting the worms of workers into queens, since they succeeded in procuring them by operating on worms not chosen by themselves, but selected for them.—*Naturalist's Library. Edin.* 1840.

she will be seen at times attended with a numerous retinue, marching from cell to cell, plunging the extremity of her body into many of them, and leaving a small egg in each.

The bees which generally compose her train are thought to be males, which serve to impregnate her by turns. These are larger and blacker than the common bees; without stings, and without industry. They seem formed only to transmit a posterity; and to attend the queen, whenever she thinks proper to issue from the secret retreats of the hive, where she most usually resides. Upon the union of these two kinds depends all expectations of a future progeny; for the working bees are of no sex, and only labour for another offspring: yet such is their attention to the queen, that if she happens to die, they will leave off working, and take no further care of posterity. If, however, another queen is, in this state of universal despair, presented them, they immediately acknowledge her for their sovereign, and once more diligently apply to their labour. It must be observed, however, that all this fertility of the queen-bee, and the great attentions paid to her by the rest, are controverted by more recent observers. They assert, that the common bees are parents themselves; that they deposit their eggs in the cells which they have prepared; that the females are impregnated by the males, and bring forth a progeny, which is wholly their own.[1]

However, to go on with their history, as delivered us by Mr Reaumur.—When the queen-bee has deposited the number of eggs necessary in the cells, the working bees undertake the care of the rising posterity. They are seen to leave off their usual employments; to construct proper receptacles for eggs; or to complete those that are already formed. They purposely build little cells, extremely solid, for the young; in which they employ a great deal of wax: those designed for lodging the males, as was already observed, are larger than the rest; and those for the queen-bees the largest of all. There is usually but one egg deposited in every cell; but when the fecundity of the queen is such, that it exceeds the number of cells already prepared, there are sometimes three or four eggs crowded together in the same apartment. But this is an inconvenience that the working bees will by no means suffer. They seem sensible that two young ones, stuffed up in the same cell, when they grow larger, will but embarrass and at last destroy each other: they therefore take care to leave a cell to every egg; and remove or destroy the rest.

The single egg that is left remaining, is fixed to the bottom of the cell, and touches it but in a single point. A day or two after it is deposited, the worm is excluded from the shell of the egg, having the appearance of a maggot rolled up in a ring, and lying softly on a bed of a whitish-coloured jelly; upon which also the little animal begins to feed. In the meantime, the instant it appears, the working bees attend it with the most anxious and parental tenderness; they furnish it every hour with a supply of this whitish substance, on which it feeds and lies; and watch the cell with unremitting care. They are nurses that have a greater affection for the offspring of others, than many parents have for their own children. They are constant in visiting each cell, and seeing that nothing is wanting; preparing the white mixture, which is nothing but a composition of honey and wax, in their own bowels, with which they feed them. Thus attended, and plentifully fed, the worm, in less than six days' time, comes to its full growth, and no longer accepts the food offered it. When the bees perceive that it has no further occasion for feeding, they perform the last offices of tenderness, and shut the little animal up in its cell; walling up the mouth of its apartment with wax: where they leave the worm to itself; having secured it from every external injury.

The worm is no sooner left inclosed, but from a state of inaction, it begins to labour, extending and shortening its body; and by this means lining the walls of its apartment with a silken tapestry, which it spins in the manner of caterpillars, before they undergo their last transformation. When their cell is thus prepared, the animal is soon after transformed into an aurelia; but differing from that of the common caterpillar, as it exhibits not only the legs, but the wings of the future bee, in its present state of inactivity. Thus, in about twenty or one and twenty days after the egg was laid, the bee is completely formed, and fitted to undergo the fatigues of its state. When all its parts have acquired their proper strength and consistence, the young animal opens its prison, by piercing with its teeth the waxen door that confines it. When just freed from its cell, it is as yet moist, and incommoded with the spoils of its former situation: but the officious bees are soon seen to flock round it, and to lick it clean on all sides with their trunks; while another band, with equal assiduity, are observed to feed it with honey: others again begin immediately to cleanse the cell that has been just left; to carry the ordure out of the hive, and to fit the place for a new inhabitant. The young bee soon repays their care by its industry; for as soon as ever its external parts become dry, it discovers its natural appetites for labour, and industriously begins the task, which it pursues unremittingly

[1] See Note at the beginning of the chapter.

through life. The toil of man is irksome to him, and he earns his subsistence with pain ; but this little animal seems happy in its pursuits, and finds delight in all its employments.

When just freed from the cell, and properly equipped by its fellow-bees for duty, it at once issues from the hive, and instructed only by Nature, goes in quest of flowers, chooses only those that yield it a supply, rejects such as are barren of honey, or have been already drained by other adventurers ; and when loaded, is never at a loss to find its way back to the common habitation. After this first sally, it begins to gather the mealy powder that lies on every flower, which is afterwards converted into wax ; and with this, the very first day, it returns with two large balls stuck to its thighs.

When bees first begin to break their prisons, there are generally above a hundred excluded in one day. Thus, in the space of a few weeks, the number of the inhabitants in one hive, of moderate size, becomes so great, that there is no place to contain the new comers ; and they are scarcely excluded from the cell, when they are obliged, by the old bees, to sally forth in quest of new habitations. In other words, the hive begins to swarm, and the new progeny prepares for exile.[1]

While there is room enough in the hive, the bees remain quietly together ; it is necessity alone that compels the separation. Sometimes, indeed, the young brood, with grace-

[1] Those not experienced in the nature of bees, may be greatly deceived in the purchasing of hives for stock. It can only be by a minute examination of the interior of the hive, that a just estimate of its value may be gained ; this, however, is attended with much difficulty, and some danger ; but by the outward appearance and weight of the hive he may perhaps arrive at nearly a correct conjecture. The best season for purchasing is either in February or at the swarming season ; in February it has survived the rigour of winter, and the purchaser has then only to attend to the population of the hive, or its apparent age. Let the purchaser observe with attention the number of bees which enter the hive loaded with the fruits of their industry ; and if an apparently equal number departs in great bustle and hurry, he may then conjecture the hive to be in good health and well populated ; and if a loud humming noise is heard within the hive, it is a certain sign of its strength and prosperity. The weight of a hive in February should never be under fifteen pounds, nor in autumn under thirty ; and care should be taken that the hive is new, for in old hives a quantity of farina or bee-head accumulates, which adds considerably to its weight ; the purchaser should also reject a hive when he observes its straw decayed and rotten, the ligaments loose, and frequent blotches over it, for it will cost him incessant trouble and vexation to keep it in a sufficient state of preservation, so as to maintain the health of his bees.

The apiary, or place where the bee-hives are placed, should in very warm situations be made to face the east, and in colder districts the south-east. It should be well protected from high winds, which not only prevent the bees from leaving the hive in quest of honey, but they also surprise them in the fields, and often kill them by dashing them against the trees and rocks or into rivers. The hives in an apiary should always be placed in a right line ; but should the number of the hives be great, and the situation not capacious enough to admit of their being placed longitudinally it is more advisable to place them over one another on shelves than in double rows on the ground. A bee, on leaving the hive, generally forms an angle of about forty-five with the horizon ; the elevation of the hive should therefore be about two feet from the ground, in order to protect it from humidity. The greater the elevation of the hive, the longer is the flight of the swarm ; and when they are at a certain point of elevation, the swarms are lost for ever to the proprietor. If the hives are to be placed in a double row, the hinder ones should alternate with, and be placed at such a distance from, the front ones, that when the bees take their flight no obstruction is offered to their ascent. Huish recommends placing every hive upon a single pedestal, and at two or three feet distance from each other. By this means, when any thing happens to one hive, the others are less likely to be disturbed than when placed on a shelf in a bee-house ; and the hive may be chained down and locked. It is usual to have three or four legs or supports to the bee-boards ; but those who have tried one will never resort to more, as one is a much better protection from vermin and insects. The space in front of the apiary should be kept clear of high plants for two or three yards.

The variety of bees employed is a matter of some consequence. To the common observer all working bees, as to external appearance, are nearly the same ; but to those who examine them with attention, the difference in size is very distinguishable ; and they are, in their vicious and gentle, indolent and active natures, essentially different. Of the stock which Howison had in 1810, it required 250 to weigh an ounce ; but they were so vicious and lazy that he changed it for a smaller variety, which possessed much better dispositions, and of which it required 296, on an average, to weigh an ounce. Whether size and disposition are invariably connected, is not determined.

The best material and form for hives is a straw thimble or flower-pot placed in an inverted position. Hives made of straw, as now in use, have a great advantage over those made of wood and other materials, from the effectual defence they afford against the extremes of heat in summer and cold in winter.

The size of hives should correspond as nearly as possible with that of the swarms. This has not had that attention paid to it which the subject demands, as much of the success in the management of the bees depends on that circumstance. From blind instinct bees endeavour to fill with combs whatever hive they are put into, before they begin to gather honey. Owing to this, when the hive is too large for its inhabitants, the time for collecting their winter store is spent in unprofitable labour ; and starvation is the consequence. This evil also extends to occasioning late swarming the next summer ; it being long before the hive becomes so filled with young bees as to produce a necessity for emigration, from which cause the season is too far advanced for the young colonies to procure a winter stock. A full-sized straw hive will hold three pecks ; a small-sized from one and a half to two pecks.

The Polish hive appears to be the second in merit to that described, and perhaps it may deserve the preference, if the mode of using it were generally known. It is simply the trunk of a tree, of a foot or fourteen inches in diameter, and about nine feet long. It is scooped out (boring in this country would be better) for about six feet from one end, so as to form a hollow cylinder of that length, and of six or eight inches in diameter within. Part of the circumference of this cylinder is cut out during the greater part of its length, about four inches wide

less obstinacy, refuse to depart, and even venture to resist their progenitors. The young ones are known by being browner than the old, with whiter hair; the old ones are of a lighter colour, with red hair. The two armies are therefore easily distinguishable, and dreadful battles are often seen to ensue. But the victory almost ever terminates with strict political justice in favour of the veterans, and the rebellious offspring are driven off, not without loss and mutilation.

In different countries, the swarms make their appearance at different times of the year, and there are several signs previous to this intended migration. The night before, an unusual buzzing is heard in the hive; in the morning, though the weather be soft and inviting, they seem not to obey the call, being intent on more important meditations within. All labour is discontinued in the hive; every bee is either employed in forcing, or reluctantly yielding, a submission; at length, after some noise and tumult, a queen-bee is chosen to guard, rather than conduct the young colony to other habitations, and then they are marshalled without any apparent conductor. In less than a minute they leave their native abode, and forming a cloud round their protectress, they set off without seeming to know the place of their destination; *the world before them, where to choose their place of rest.* The usual time of swarming is from ten in the morning to three in the afternoon, when the sun shines bright, and invites them to seek their fortunes. They flutter for a while in the air, like flakes of snow, and sometimes undertake a distant journey, but more frequently are contented with some neighbouring asylum: the branch of a tree, a chimney-top, or some other exposed situation. It is, indeed, remarkable, that all those animals, of whatever kind, that have long been under the protection

---

and a slip of wood is made to fit the opening. On the sides of this slip, or segment, notches are made every two or three inches, of sufficient size to allow a single bee to pass. This slip may be furnished with hinges, and with a lock and key; but in Poland it is merely fastened in by a wedge. All that is wanting to complete the hive is a cover at top to throw off the rain; and then it requires only to be placed upright like a strong post in the garden, so as the bottom of the hollow cylinder may be not nearer the ground than two feet, and the opening slip look to the south. When a swarm is to be put in, the tree, with the door or slip opened, is placed obliquely over it; when the bees enter, the door is closed, and the holes stopped with clay till the hive is planted or placed upright. When honey is wanted, the door is opened during the finest part of a warm day, when most of the bees are out; its entire state is seen from top to bottom, and the operator, with a segar in his mouth, or with a lighted rag, to keep off the bees from his hands, cuts out with a crooked knife as much comb as he thinks fit. In this way fresh honey is obtained during the summer, the bees are never cramped for room, nor does it become necessary to kill them. The old comb, however, is annually cut out, to prevent or lessen the tendency to swarming, which, notwithstanding this and the size of their dwelling, they generally do once a year; for the laws of nature are not to be changed. Though it be a fact that a small swarm of bees will not do well in a large hive; yet, if the hive extend in length and not in breadth, it is admitted both by Huber and Huish that they will thrive in it. "If too great a diameter," says Huber, "be not given to the abode of the bee, it may without danger be increased in the elevation; their success in the hollow trees, their natural domicile, incontestably proves the truth of this assertion."

The feeding of bees is generally deferred till winter or spring; but this is a most erroneous practice. Hives should be examined in the course of the month of September, or about the time of killing the drones; and if a large hive does not weigh thirty pounds, it will be necessary to allow it half a pound of honey, or the same quantity of soft sugar made into syrup, for every pound that it is deficient of that weight; and in like proportion to smaller hives. This work must not be delayed, that time may be given for the bees to make the deposit in their empty cells before they are rendered torpid by the cold. Sugar simply dissolved in water (which is a common practice), and sugar boiled with water into a syrup, form compounds very differently suited for the winter store of bees. When the former is wanted for their immediate nourishment, as in spring, it will answer equally as a syrup; but if to be laid up as store, the heat of the hive quickly evaporating the water, leaves the sugar in dry crystals, not to be acted upon by the trunks of the bees. Hives may be killed with hunger while some pounds' weight of sugar remain in this state in their cells. The boiling of sugar into syrup forms a closer combination with the water, by which it is prevented from flying off, and a consistence resembling that of honey retained. Howison had frequent experience of hives, not containing a pound of honey, preserved in perfect health through the winter with sugar so prepared, when given in proper time and in sufficient quantity. The quantity of food which ought to be given to a hive may be calculated in the proportion of two pounds a month; but if the weather be very cold, a less quantity will suffice. When a hive is fed in the spring, it should always be after sunset, when the bees have returned from the fields; otherwise the most disastrous consequences may ensue from the robberies committed by the bees of other hives. If they are fed in the morning, it must be before sunrise, and the entrance instantly stopped to keep out depredators; for as the bees leave the hive on the very first appearance of day-light, a later period would prevent the return of all those who had left the hive previous to the entrance being secured. The following receipt for bees is recommended as beneficial and economical. To two quarts of good ale put one pound of moist sugar; boil them until the sugar is wholly dissolved, carefully skimming it; when it is cold, it will be found of the consistency of honey, and it may be given to the bees in the following manner: If the bees are in the plain cottage hive, an eek of the same diameter as the hive must be provided, and from three to four hands in height. When the sun is set, and the bees have retired, let the hive be gently raised, and the eek placed on the stool: then, having filled a soup-plate with the food, place it on the eek, and put down the hive. To prevent the bees being drowned in the liquid, it is necessary to place some straws over the plate, and over the straws a piece of paper, either thickly perforated or cut into nicks; these nicks, however, must not run parallel with the straws, but either across or diagonally; the entrance must then be closed, and the plate removed on the following morning, and the whole of the liquid will be transferred into the combs.

of man, seem to lose a part of their natural sagacity in providing for themselves. The rabbit, when domesticated, forgets to dig holes, the hen to build a nest, and the bee to seek a shelter that shall protect it from the inclemencies of winter. In those countries where the bees are wild, and unprotected by man, they are always sure to build their waxen cells in the hollow of a tree; but with us, they seem improvident in their choice, and the first green branch that stops their flight, seems to be thought sufficient for their abode through winter. However, it does not appear that the queen chooses the place where they are to alight, for many of the stragglers, who seemed to be pleased with a particular branch, go and settle upon it; others are seen to succeed; and, at last, the queen herself, when she finds a sufficient number there before her, goes to make it the place of her head-quarters. When the queen is settled, the rest of the swarm soon follow; and, in about a quarter of an hour, the whole body seem to be at ease. It sometimes is found, that there are two or three queens to a swarm, and the colony is divided into parties; but it most usually happens, that one of these is more considerable than the others, and the bees, by degrees, desert the weakest, to take shelter under the most powerful protector. The deserted queen does not long survive this defeat; she takes refuge under the new monarch, and is soon destroyed by her jealous rival. Till this cruel execution is performed, the bees never go out to work; and if there should be a queen-bee belonging to the new colony left in the old hive, she always undergoes the fate of the former. However, it must be observed, that the bees never sacrifice any of their queens, when the hive is full of wax and honey; for there is at that time no danger in maintaining a plurality of breeders.

When the swarm is thus conducted to a place of rest, and the policy of government is settled, the bees soon resume their former labours. The making cells, storing them with honey, impregnating the queen, making proper cells for the reception of the rising progeny, and protecting them from external danger, employ their unceasing industry. But soon after, and towards the latter end of summer, when the colony is sufficiently stored with inhabitants, a most cruel policy ensues. The drone bees, which are (as has been said) generally in a hive to the number of a hundred, are marked for slaughter. These, which had hitherto led a life of indolence and pleasure, whose only employment was in impregnating the queen, and rioting upon the labours of the hive, without aiding in the general toil, now share the fate of most voluptuaries, and fall a sacrifice to the general resentment of society.

The working bees in a body declare war against them; and in two or three days' time the ground all round the hive is covered with their dead bodies. Nay, the working bees will even kill such drones, as are yet in the worm state, in the cell, and eject their bodies from the hive among the general carnage.

When a hive sends out several swarms in the year, the first is always the best, and the most numerous. These having the whole summer before them, have the more time for making wax and honey, and consequently their labours are the most valuable to the proprietor. Although the swarm chiefly consists of the youngest bees, yet it is often found that bees of all ages compose the multitude of emigrants, and it often happens that bees of all ages are seen remaining behind. The number of them is always more considerable than that of some populous cities, for sometimes upwards of forty thousand are found in a single hive. So large a body may well be supposed to work with great expedition; and in fact, in less than twenty-four hours they will make combs above twenty inches long, and seven or eight broad. Sometimes they will half fill their hives with wax in less than five days. In the first fifteen days, they are always found to make more wax than they do afterwards during the rest of the year.

Such are the outlines of the natural history of these animals, as usually found in our own country. How they are treated, so as to produce the greatest quantity of honey, belongs rather to the rural economist, than the natural historian; volumes have been written on the subject, and still more remains equally curious and new. One thing, however, it may be proper to observe, that a farm, or a country, may be over-stocked with bees, as well as with any other sort of animal; for a certain number of hives always require a certain number of flowers to subsist on. When the flowers near home are rifled, then are these industrious insects seen taking more extensive ranges: but their abilities may be over taxed; and if they are obliged, in quest of honey, to go too far from home, they are over-wearied in the pursuit, they are devoured by birds, or beat down by the winds and rain.

From a knowledge of this, in some parts of France and Piedmont, they have contrived, as I have often seen, a kind of floating bee-house.

They have on board one barge threescore or a hundred bee-hives, well defended from the inclemency of an accidental storm: and with these the owners suffer themselves to float gently down the river. As the bees are continually choosing their flowery pasture along the banks of the stream, they are furnished with sweets before unrifled; and thus

a single floating bee-house yields the proprietor a considerable income. Why a method similar to this has never been adopted in England, where we have more gentle rivers, and more flowery banks, than in any other part of the world, I know not: certainly it might be turned to advantage, and yield the possessor a secure, though perhaps a moderate income.

Having mentioned the industry of these admirable insects, it will be proper to say something of the effects of their labour of that wax and honey which are turned by man to such various uses. Bees gather two kinds of wax; one coarse, and the other fine. The coarser sort is bitter, and with this, which is called *propolis*, they stop up all the holes and crevices of their hives.[1] It is of a more resinous nature than the fine wax, and is consequently better qualified to resist the moisture of the season, and preserve the works warm and dry within. The fine wax is as necessary to the

[1] It was strongly suspected by Reaumur, that the bees collected the propolis from those trees which are known to produce a similar gummy resin, such as the poplar, the birch, and the willow; but he was thrown into doubt by not being able to detect the bees in the act of procuring it, and by observing them to collect it where none of those trees, nor any other of the same description, grew. His bees also refused to make use of bitumen, and other resinous substances, with which he supplied them, though Mr Knight was more successful.

Huber at length set the question at rest. "For many years," says he, "I had fruitlessly endeavoured to find them on trees producing an analogous substance, though multitudes had been seen returning laden with it. In July, some branches of the wild poplar, which had been cut since spring, with very large buds, full of a reddish, viscous, odoriferous matter, were brought to me, and I planted them in vessels before hives, in the way of the bees going out to forage, so that they could not be insensible of their presence. Within a quarter of an hour they were visited by a bee, which separating the sheath of a bud with its teeth, drew out threads of the viscous substance, and lodged a pellet of it in one of the baskets of its limbs: from another bud it collected another pellet for the opposite limb, and departed to the hive. A second bee took the place of the former in a few minutes, following the same procedure. Young shoots of poplar, recently cut, did not seem to attract these insects, as their viscous matter had less consistence than the former. Different experiments proved the identity of this substance with propolis; and now, having only to discover how the bees applied it to use, we peopled a hive, so prepared as to fulfil our views. The bees, building upwards, soon reached the glass above; but, unable to quit their habitation, on account of rain, they were three weeks without bringing home propolis. Their combs remained perfectly white until the beginning of July, when the state of the atmosphere became more favourable for our observations. Serene warm weather engaged them to forage, and they returned from the fields laden with a resinous gum, resembling a transparent jelly, and having the colour and lustre of the garnet. It was easily distinguished from the farinaceous pellets then collected by other bees. The workers bearing the propolis ran over the clusters suspended from the roof of the hive, and rested on the rods supporting the combs, or sometimes stopped on the sides of their dwelling, in expectation of their companions coming to discumber them of their burden. We actually saw two or three arrive, and carry the propolis from off the limbs of each with their teeth. The upper part of the hive exhibited the most animated spectacle: thither a multitude of bees resorted from all quarters, to engage in the predominant occupation of the collection, distribution, and application of the propolis. Some conveyed that of which they had unloaded the purveyors in their teeth, and deposited it in heaps; others hastened, before its hardening, to spread it out like a varnish, or form it into strings, proportioned to the interstices of the sides of the hive to be filled up. Nothing could be more diversified than the operations carried on.

The bees, apparently charged with applying the propolis within the cells, were easily distinguished from the multitude of workers, by the direction of their heads towards the horizontal pane forming the roof of the hive, and on reaching it, they deposited their burden nearly in the middle of intervals separating the combs: then they conveyed the propolis to the real place of its destination. They suspended themselves by the claws of the hind legs to points of support, afforded by the viscosity of the propolis on the glass; and, as it were, swinging themselves backwards and forwards, brought the heap of this substance nearer to the cells at each impulse. Here the bees employed their fore feet, which remained free, to sweep what the teeth had detached, and to unite the fragments scattered over the glass, which recovered all its transparency when the whole propolis was brought to the vicinity of the cells. After some of the bees had smoothed down and cleaned out the glazed cells, feeling the way with their antennæ, one desisted, and having approached a heap of propolis, drew out a thread with its teeth. This being broken off, it was taken in the claws of the fore feet, and the bee, re-entering the cell, immediately placed it in the angle of two portions that had been smoothed, in which operation the fore feet and teeth were used alternately; but probably proving too clumsy, the thread was reduced and polished; and we admired the accuracy with which it was adjusted when the work was completed. The insect did not stop here: returning to the cell, it prepared other parts of it to receive a second thread, for which we did not doubt that the heap would be resorted to. Contrary to our expectation, however, it availed itself of the portion of the thread cut off on the former occasion, arranged it in the appointed place, and gave it all the solidity and finish of which it was susceptible. Other bees concluded the work which the first had begun; and the sides of the cells were speedily secured with threads of propolis, while some were also put on the orifices; but we could not seize the moment when they were varnished, though it may be easily conceived how it is done."

This is not the only use to which bees apply the propolis. They are extremely solicitous to remove such insects or foreign bodies as happen to get admission into the hive. When so light as not to exceed their powers, they first kill the insect with their stings, and then drag it out with their teeth. But it sometimes happens, as was first observed by Maraldi, and since by Reaumur and others, that an ill-fated snail creeps into the hive: this is no sooner perceived than it is attacked on all sides, and stung to death. But how are the bees to carry out so heavy a burthen? Such a labour would be in vain. To prevent the noxious smell which would arise, from its putrefaction, they immediately embalm it, by covering every part of its body with propolis, through which no effluvia can escape. When a snail with a shell gets entrance, to dispose of it gives much less trouble and expense to the bees. As soon as it receives the first wound from a sting, it naturally retires within its shell. In this case, the bees, instead of pasting it all over with propolis, content themselves with gluing all round the margin of the shell, which is sufficient to render the animal for ever immovably fixed.

animal's preservation as the honey itself. With this they make their lodgings, with this they cover the cells of their young, and in this they lay up their magazines of honey. This is made, as has been already observed, from the dust of flowers, which is carefully kneaded by the little insect, then swallowed, and having undergone a kind of digestion, is formed into the cells, which answer such a variety of purposes. To collect this, the animal rolls itself in the flower it would rob, and thus takes up the vegetable dust with the hair of its body. Then carefully brushing it into a lump, with its fore-paws it thrusts the composition into two cavities behind the thighs, which are made like spoons to receive the wax, and the hair that lines them serves to keep it from falling.

As of wax, there are also two kinds of honey; the white and the yellow. The white is taken without fire from the honey-combs. The yellow is extracted by heat, and squeezed through bags, in a press. The best honey is new, thick, and granulated, of a clear transparent white colour, of a soft and aromatic smell, and of a sweet lively taste. Honey made in mountainous countries is preferable to that of the valley. The honey made in the spring is more highly esteemed than that of autumn, when the flowers begin to fade, and lose their fragrance.

The bees are nearly alike in all parts of the world; yet there are differences worthy our notice. In Guadaloupe, the bee is less by one half than the European, and more black and round. They have no sting, and make their cells in hollow trees; where, if the hole they meet with is too large, they form a sort of waxen house of the shape of a pear, and in this they lodge and store their honey, and lay their eggs. They lay up their honey in waxen vessels, of the size of a pigeon's egg, of a black or deep violet colour; and these are so joined together, that there is no space left between them. The honey never congeals, but is fluid, of the consistence of oil, and the colour of amber. Resembling these, there are found little black bees, without a sting, in all the tropical climates; and though these countries are replete with bees like our own, yet those form the most useful and laborious tribe in that part of the world. The honey they produce is neither so unpalatable nor so surfeiting as ours; and the wax is so soft that it is only used for medicinal purposes, it being never found hard enough to form into candles, as in Europe.

Of insects that receive the name of bees among us, there are several; which, however, differ very widely from that industrious social race we have been just describing. The Humble-bee is the largest of all this tribe, being as large as the first joint of one's middle finger.[1] These are seen in every field, and

Mr Knight, President of the Horticultural Society, discovered by accident an artificial substance, more attractive than any of the resins experimentally tried by Reaumur. Having caused the decorticated part of a tree to be covered with a cement, composed of bees'-wax and turpentine, he observed that this was frequented by hive-bees, who, finding it to be a very good propolis ready made, detached it from the tree by their mandibles, and then, as usual, passed it from the first leg to the second, and so on. When one bee had thus collected its load, another often came behind and despoiled it of all it had collected; a second and a third load were frequently lost in the same manner; and yet the patient insect pursued its operations without manifesting any signs of anger. Probably the latter circumstance, at which Mr Knight seems to have been surprised, was nothing more than an instance of the division of labour so strikingly exemplified in every part of the economy of bees.

[1] The humble-bees of this country are now divided into two generic groups, *Bombus* and *Apathus*. They may be distinguished from the hive-bee, and other races bearing affinity to them, by having the simple eyes arranged in a curve, instead of forming a triangle; by having an impression in the shape of a cross on the forehead; the labrum transverse, and two distinct spines at the apex of the posterior tibiæ. More obvious characters are afforded by their large, comparatively rounded, hirsute bodies, generally adorned with bands of light-yellow or red. Upwards of forty different species are described as inhabitants of Britain; but as the three distinct races of females, males, and workers, belonging to the same species, often bear little resemblance to one another, and as the hair or down covering their bodies, often of the gayest colours, changes with age, like the plumage of birds, it is by no means unlikely that individuals of the same family, and differing only in sex or age, have in some instances, been described as of a different species.

The common humble-bee abounds in our fields and gardens, and is almost equally common throughout all

Europe. It is distinguished above its congeners for strength and activity. It is one of the earliest insects that appear in the spring, and one of the latest to leave us in autumn. It forms its nest, as is well known, in holes in the ground, sometimes excavated laboriously by its own efforts, sometimes previously formed by other animals and taken possession of by the foundress of the colony. The females of this, as of all the other species, are largest in size, the males next, and the workers smallest. Early in spring, when the willows begin to bloom, the female may be seen traversing the gardens by sun-rise with her usual sonorous booming, and busied in collecting honey and pollen from the catkins. The workers do not appear till a somewhat later period, and the males not till autumn, when the thistles are in blossom, upon the flowers of which they are found in great numbers, and in still greater, if possible, upon seeding

perched on every flower. They build their nest in holes in the ground, of dry leaves, mixed with wax and wood, defended with moss from the weather. Each humble-bee makes a separate cell about the size of a small nutmeg, which is round and hollow, containing the honey in a bag. Several of these cells are joined together in such a manner, that the whole appears like a cluster of grapes. The females, which have the appearance of wasps, are very few, and their eggs are laid in cells, which the rest soon cover over with wax. It is uncertain whether they have a queen or not; but there is one much larger than the rest, without wings, and without hair, and all over black, like polished ebony. This goes and views all the works, from time to time, and enters into the cell, as if it wanted to see whether every thing was done right. In the morning the young humble-bees are very idle, and seem not at all inclined to labour, till one of the largest, about seven o'clock, thrusts half its body from a hole designed for that purpose, and seated on the top of the nest, beats its wings for twenty minutes successively, buzzing the whole time, till the whole colony is put in motion. The humble-bees gather honey as well as the common bees; but it is neither so fine nor so good, nor the wax so clean, or so capable of fusion.

Beside the bees already mentioned, there are various kinds among us, that have much the appearance of honey-makers, and yet make only wax. The Wood-Bee is seen in every garden. It is rather larger than the common queen-bee; its body of a bluish black, which is smooth and shining. It begins to appear at the approach of spring, and is seen flying near walls exposed to a sunny aspect. This bee makes its nest in some piece of wood, which it contrives to scoop and hollow for its purpose.[1] This, however, is never done in

leeks and onions, where, on a single flower, may be seen half a dozen at the same moment. At this early period of the year, the female is a solitary being, and her flights are directed in search of a place suitable for a habitation. The females only, of all the former year's colony, have survived the winter, and now dispersing, each seeks a residence for herself, where she may become the foundress of a new community. Having pitched upon a convenient spot, the laborious insect proceeds to excavate first the passage or gallery, then the nest itself, detaching the soil, as it were, grain by grain; she seizes the molecule with the first pair of legs, transfers it instantly to the second, receives it next with the third, and finally pushes it as far as possible behind her. These excavations, situated often above a foot under the surface, are wholly the work of the solitary female. Sometimes, however, the nest is made close to, or even upon the surface when partially hollow, and covered with dry moss; but this is not the usual mode pursued by this species, and in such localities the colony is far less numerous than when at a greater depth.

Having finished the excavation, and carpeted her new dwelling with soft leaves, &c., the insect proceeds to construct brood cells. The wax of which these are formed is secreted, as in the domestic bee, in certain receptacles placed on each side of the middle process of the abdominal scales, and is extracted by the bee in the form of laminæ, moulded to the shape of the insect's body. Unlike the queen of the hive bees, the mother-bee of this family possesses these wax-secreting organs as well as the workers, and produces the substance in greater quantity than her progeny.

[1] We have frequently witnessed, says Mr Rennie, the operations of these ingenious little workers, who are particularly partial to posts, palings, and the wood-work of houses which has become soft by beginning to decay. Wood actually decayed, or affected by dry-rot, they seem to reject as unfit for their purposes; but they make no objections to any hole previously drilled, provided it be not too large; and, like the mason-bees, they not unfrequently take possession of an old nest, a few repairs being all that in this case is necessary. When a new nest is to be constructed, the bee proceeds to chisel sufficient space for it out of the wood with her jaws. We say *her*, because the task in this instance, as in most others of solitary bees and wasps, devolves solely upon the female, the male taking no concern in the affair, and probably being altogether ignorant that such a work is going forward. It is at least certain the male is never seen giving his assistance, and he seldom if ever approaches the neighbourhood. The female carpenter-bee has a task to perform no less arduous than the mason-bee; for though the wood may be tolerably soft, she can only cut out a very small portion at a time. The successive portions which she gnaws off may be readily ascertained by an observer, as she carries them away from the place. In giving the history of a mason-wasp, we remarked the care with which she carried to a distance little fragments of brick, which she detached in the progress of excavation. We have recently watched a precisely similar procedure in the instance of a *carpenter-bee* forming a cell in a

wooden post. The only difference was, that the bee did not fly so far away with her fragments of wood as the wasp did; but she varied the direction of her flight every time; and we could observe, that after dropping the chip of wood which she had carried off, she did not return in a direct line to her nest, but made a circuit of some extent before wheeling round to go back.

"On observing the proceedings of this carpenter-bee next day, we found her coming in with balls of pollen on her thighs; and on tracing her from the nest into the adjacent garden, we saw her visiting every flower which was likely to yield her a supply of pollen for her future progeny. This was not all: we subsequently saw her taking the direction of a clay-quarry frequented by the mason-bees, where we recognized her loading herself with a pellet of clay, and carrying it into her cell in the wooden post. We observed her alternating this labour for several days, at one time carrying clay, and at another pollen; till at length she completed her task, and closed the entrance with a barricado of clay, to prevent the intrusion of any insectivorous depredator, who might make prey of her young; or of some prying parasite, who might introduce its own eggs into the nest she had taken so much trouble to construct.

trees that are standing, for the wood it makes choice of is half rotten. The holes are not made directly forward, but turning to one side, and have an opening sufficient to admit one's middle finger, from whence runs the inner apartment, generally twelve or fifteen inches long. The instruments used in boring these cavities are their teeth; the cavity is usually branched into three or four apartments; and in each of these they lay their eggs, to the number of ten or twelve, each separate and distinct from the rest: the egg is involved in a sort of paste, which serves at once for the young animal's protection and nourishment. The grown bees, however, feed upon small insects, particularly a louse, of a reddish brown colour, of the size of a small pin's head.

Mason-Bees make their cells with a sort of mortar made of earth, which they build against a wall that is exposed to the sun. The mortar, which at first is soft, soon becomes as hard as stone, and in this their eggs are laid. Each nest contains seven or eight cells, an egg in every cell, placed regularly one over the other. If the nests remain unhurt, or want but little repairs, they make use of them the year ensuing; and thus they often serve three or four years successively. From the strength of their houses, one would think these bees in perfect security; yet none are more exposed than they. A worm with very strong teeth is often found to bore into their little fortifications, and devour their young.

The Ground-Bee builds its nest in the earth,

"Some days after it was finished, we cut into the post, and exposed this nest to view. It consisted of six cells of a somewhat square shape, the wood forming the literal walls; and each was separated from the one adjacent by a partition of clay, of the thickness of a playing card. The wood was not lined with any extraneous substance, but was worked as smooth as if it had been chiselled by a joiner. There were five cells, arranged in a very singular manner—two being almost horizontal, two perpendicular, and one oblique. The depth to which the wood was excavated, in this instance, was considerably less than what we have observed in other species which dig perpendicular galleries several inches deep in posts and garden-seats; and they are inferior in ingenuity to the carpentry of a bee described by Reaumur, which has not been ascertained to be a native of Britain, though a single indigenous species of the genus has been doubtingly mentioned, and is figured by Kirby, in his valuable 'Monographia.' If it ever be found here, its large size and beautiful violet-coloured wings will render mistakes impossible.

"The violet carpenter-bee usually selects an upright piece of wood, into which she bores obliquely for about an inch; and then, changing the direction, works perpendicularly, and parallel to the sides of the wood, for twelve or fifteen inches, and half an inch in breadth. Sometimes the bee is contented with one or two of these excavations; at other times, when the wood is adapted to it, she scoops out three or four—a task which sometimes requires several weeks of incessant labour. The tunnel in the wood, however, is only one part of the work; for the little architect has afterwards to divide the whole into cells, somewhat less than an inch in depth. It is necessary, for the proper growth of her progeny, that each should be separated from the other, and be provided with adequate food. She knows, most exactly, the quantity of food which each grub will require, during its growth; and she therefore does not hesitate to cut it off from any additional supply. In constructing her cells, she does not employ clay, like the bee which we have mentioned above, but the sawdust, if we may call it so, which she has collected in gnawing out the gallery. It would not, therefore, have suited her design to scatter this about, as our carpenter-bee did. The violet bee, on the contrary, collects her gnawings into a little store-heap for future use, at a short distance from her nest. She proceeds thus:—At the bottom of her excavation she deposits an egg, and over it fills a space nearly an inch high with the pollen of flowers, made into a paste with honey. She then covers this over with a ceiling composed of cemented sawdust, which also serves for the floor of the next chamber above it. For this purpose, she cements round the wall a ring of wood chips, taken from her store-heap; and within this ring forms another, gradually contracting the diameter till she has constructed a circular plate, about the thickness of a crown-piece, and of considerable hardness. This plate of course exhibits concentric circles, somewhat similar to the annual circles in the cross section of a tree. In the same manner she proceeds till she has completed ten or twelve cells; and then she closes the main entrance with a barrier of similar materials.

"Let us compare the progress of this little joiner with a human artisan—one who has been long practised in his trade, and has the most perfect and complicated tools for his assistance. The bee has learned nothing by practice; she makes her nest but once in her life, but it is then as complete and finished as if she had made a thousand. She has no pattern before her—but the Architect of all things has impressed a plan upon her own mind, which she can realize without scale or compasses. Her two sharp teeth are the only tools with which she is provided for her laborious work; and yet she bores a tunnel, twelve times the length of her own body, with greater ease than the workman who bores into the earth for water, with his apparatus of augers adapted to every soil. Her tunnel is clean and regular; she leaves no chips at the bottom, for she is provident of her materials. Further, she has an exquisite piece of joinery to perform, when her ruder labour is accomplished. The patient bee works her rings from the circumference to the centre, and she produces a shelf, united with such care with her natural glue, that a number of fragments are as solid as one piece.

"The violet carpenter-bee, as may be expected, occupies several weeks in these complicated labours; and during that period she is gradually depositing her eggs, each of which is successively to become a grub, a pupa, and a perfect bee. It is obvious, therefore, as she does not lay all her eggs in the same place—as each is separated from the other by a laborious process—that the egg which is first laid will be the earliest hatched; and that the first perfect insect, being older than its fellows in the same tunnel, will strive to make its escape sooner, and so on of the rest. The careful mother provides for this contingency. She makes a lateral opening at the bottom of the cells; for the teeth of the young bees would not be strong enough to pierce the outer wood, though they can remove the cemented rings of saw-dust in the interior. Reaumur observed these holes, in several cases; and he further noticed another external opening opposite to the middle cell, which he supposed was formed, in the first instance, to shorten the distance for the removal of the fragments of wood in the lower half of the building."—*Insect Architecture.*

wherein it makes round holes, five or six inches deep; the mouth being narrow, and only just sufficient to admit the little inhabitant.

It is amusing enough to observe the patience and assiduity with which they labour. They carry out all the earth, grain by grain, to the mouth of the hole, where it forms a little hillock; an Alps, compared to the power of the artist by which it is raised. Sometimes the walks of a garden are found undermined by their labours: some of the holes running directly downward, others horizontally beneath the surface. They lay up in these cavities provisions for their young, which consist of a paste that has the appearance of corn, and is of a sweetish taste.

The Leaf-cutting Bees make their nest and

lay their eggs among bits of leaves, very artificially placed in holes in the earth, of about the length of a tooth-pick case. They make the bits of leaves of a roundish form, and with them line the inside of their habitations. This tapestry is still further lined by a reddish kind of paste, somewhat sweet or acid. These bees are of various kinds; those that build their nests with chestnut leaves are as big as drones, but those of the rose-tree are smaller than the common bee.[1]

The Wall-Bees are so called because they make their nests in walls, of a kind of silky membrane with which they fill up the vacuities between the small stones which form the sides of their habitation. Their apartment consists of several cells placed end to end, each in the shape of a woman's thimble. Though the web which lines this habitation is thick and warm, yet it is transparent, and of a whitish colour. This substance is supposed to be spun from the animal's body. The males and females are of a size, but the former are without a sting.—To these varieties of the bee kind might be added several others, which are all different in their nature, but not sufficiently distinguished to excite curiosity.[2]

[1] A species of the leaf-cutting or upholsterer bee is called the *poppy-bee*, from its selecting the scarlet petals of the poppy as tapestry for its cells. Kirby and Spence express their doubts whether it is indigenous to this country: but Mr Rennie is almost certain that he saw the nests in Scotland. The poppy-bee may be known by its being rather more than a third of an inch long, of a black colour, studded on the head and back with reddish gray hairs; the belly being gray and silky, and the rings margined with gray above, the second and third having an impressed transversal line.

[2] The Rev. Mr Kirby has discovered that there are no less than *two hundred and twenty-one* distinct species of bees. He divides the Linnæan genus into *mellitta* and *apis*, distinguishing them by their tongues; the insects of the first having short flattish inflected tongues.

We shall here merely specify the *Carding-Bee*, as one of peculiar interest, and no ways uncommon about our villages. This bee is yellow, with the hair of the throat somewhat fawn-coloured. The carding-bees nearly all perish in winter; a few of the females only survive. These usually make their appearance early in spring, as soon as the catkins of the willows are in blossom; upon which, at this time, they may commonly be seen collecting honey from the female, and pollen from the male catkins. The neuters do not appear till the spring is somewhat advanced, and the males are most common in autumn, when the thistles are in blossom, upon the flowers of which they are abundant, sometimes appearing to be asleep or torpid, and at other times acting as if they were intoxicated with the sweets they have been imbibing. When these insects of any sex are walking on the ground, if a finger be moved to them, they lift up three legs on one side, by way of defence, which give them a very grotesque appearance. Their nests are usually formed in meadows and pastures, sometimes in groves and hedge-rows, where the soil is entangled with roots; but now and then these are found in heaps of stones. When they do not meet with an accidental cavity ready made, they excavate one themselves with great labour. This they cover with a thick convex vault of moss, sometimes casting the interior surface with a kind of coarse wax, to keep out the wet. At the lower part of the nest there is an opening for the inhabitants to go in and out at. This entrance is often through a long gallery or covered way, a foot or upwards in length, by which the nest is more effectually concealed from observation. The mode in which they transport the moss which they employ in the formation of their nest is singular. When they have discovered a parcel fitted to that purpose, and conveniently situated, they place themselves in a line, with their backs turned towards the nest. The foremost lays hold of some with their jaws, and clears it, bit by bit, with her fore-feet. When this is sufficiently disentangled, she drives it with her feet under her belly, and as far as possible beyond, to the second bee. The second, in like manner, pushes it on to the third, and so on. Thus small heaps of prepared moss are conveyed to the nest by a file of four or five insects, where they are wrought with the greatest dexterity by those that remain within. The nests are often six or seven inches in diameter, and elevated to the height of four or five inches above the surface of the ground.

[3] The Wasps (*Vespa*), like the ants and bees, live in society. They are comparable to the latter for their in-

CHAP. III.

OF THE WASP.

However similar many insects may be in appearance, this does not imply a similitude in their history. The bee and the wasp resemble each other very strongly, yet, in examining their manner and their duration, they differ very widely: the bee labours to lay up honey, and lives to enjoy the fruits of its industry: the wasp appears equally assiduous: but only works for posterity, as the habitation is scarcely completed when the inhabitant dies.

The wasp[3] is well known to be a winged

insect with a sting;—to be longer in proportion to its bulk than the bee, to be marked with bright yellow circles round its body, and to be the most swift and active insect of all the fly kind. On each side of the mouth this animal is furnished with a long tooth, notched like a saw, and with these it is enabled to cut any substance, not omitting meat itself, and

dustry, and approximate to the former in the extent of their ravages. The bee, continually occupied with its labours, lives only on what it gathers from flowers, and the sting with which it is armed, is merely a defensive weapon, never unsheathed but for the protection of itself or its country. But the wasp, on the contrary, is ferocious, and subsists only on rapine and destruction. Its sting is an offensive weapon, a means of overpowering animals more feeble than itself. Nevertheless it is not less ingenious than the others, nor less attached to its offspring. United in a single republic, the wasps spare neither care nor labour. The works which they perform evince their dexterity, their patience, and the delicacy of their instinct. The peculiar style of their architecture is worthy of admiration.

Among them we particularly distinguish two species, the *hornet* (*vespa crabro*), and the *common wasp* (*vulgaris*). The first makes its nests sheltered from winds and heavy rains, either in barns or the holes of old walls, but most frequently in the large trunks of trees, the interior of which is rotten. There these insects form a large cavity, by detaching fragments of the wood, which is ready to fall into dust. It is in spring that the females, after having passed the winter in a lethargic state, and now reanimated by the heat of the atmosphere, issue from their retreat, to find out a suitable place in which to establish their nest. This place once found, they lay there the first foundations of the edifice, which consist of a thick and solid pillar of the same material as the rest of the nest, but much harder, and more compact. The material of which the wasps makes use, is the bark of the slender branches of the ash, which they detach in filaments. Then they grind and bruise it with their mandibles, so as to form a paste, which hardens after it has been employed in building. They collect, at the same time, a clear and saccharine fluid, which drops from the places which have been recently gnawed from the branch which they have been despoiling. This pillar is always placed in the most elevated part of the vault, and the hornets attach to it a sort of cap or covering of the same material, which is to serve as a roof to the edifice, and prevent the dirt, &c., detached from the upper part of the ground cavity, from falling on the combs. Within this cavity or vault they place a second pillar, which is in some sort only a continuation of the first. This is to serve for a base to the first comb of the cells. These cells are hexagonal, and their aperture is turned downwards. The mother constructs some of them. As none but females are found in spring, it is probable that they have been fecundated previously to the winter. What is certain is, that the females commence laying as soon as they have constructed a few cells in which to deposit their eggs. These eggs soon disclose the young, and the mother feeds the young larvæ which issue from them, with the products of the chase. When the latter have acquired their full growth, they line their cells with silk, and stop them with a covercle of the same material. Beneath this envelope they undergo their metamorphoses. They do not come forth from it until they are perfect insects. The wasps which are first born are workers. Analogy leads us to the belief that, as among the *bees*, they are only females destitute of the ovariæ. They are designed for the occupation of constructing the nest, and nursing the larvæ. As the female continues to lay, the family increases, and the lodging becomes too small. Then the workers increase the covering and the comb, and when the latter is pushed to the edge of this envelope, they construct another immediately. This last is attached to the first by one or many pillars. Speedily the covering is finished, and filled with new combs. Then there remains but a single aperture to the nest. This aperture corresponds to that of the hole which is the gate through which the wasps arrive at their nest. It is often no more than an inch in diameter.

It is only towards the commencement of autumn that the young females and young males come forth from their nymph state. All the larvæ which could not become perfect insects until the month of October, usually are put to death before this period, especially when the cold begins to be sensibly perceptible. The wasps, instead of continuing to nourish the larvæ, are then solely occupied in plucking them out of their cells, and flinging them out of the nest. The nymphs, or pupæ, meet with no more mercy. The males and workers are daily perishing, from the growing inclemency of the season; so that at the end of the winter, none but some females remain, which have passed that season in a state of lethargy, at the bottom of the nest.

In autumn, males and females are to be met with on trees, from which acid and saccharine fluids exude. They return no more to the nest, and perish miserably on the first approach of cold. Thus invariably finishes this society, whose largest population but little exceeds one hundred, or one hundred and fifty individuals.

The *common wasp* makes its nest in the ground, usually at the depth of about half a foot. The entrance to it is a conduit of about an inch in diameter, and very seldom in a straight line. The edges which are at the surface of the earth look as if they were ploughed.

The most usual form of the vespiary is that of a ball. It is thirteen or fourteen inches in diameter: its envelope is a sort of paper or paste-board, which is sometimes more than an inch in thickness. Its colour is a gray of different shades, disposed in bands. This envelope is rough, and appears formed of pieces, in the form of valves of shells placed one upon the other, so that nothing is seen but their convex exterior. When finished, this envelope has two gates, which are two round holes, through which the wasps enter and go out. The interior of the nest is occupied by several combs, parallel, and pretty nearly horizontal: they resemble those of the bees in form, but are composed of a very different material. The vespiary sometimes contains fifteen or sixteen combs of a diameter proportioned to that of the envelope. All these combs are, as it were, so many floors, disposed in stories, which furnish the means of lodging a great number of inhabitants. Free passages are left between them. In these intervals are sorts of columns, which serve to support the combs. The foundations of the edifice, (if we may use such a solecism) are, at its highest part, for the wasps, unlike other builders, begin their work at the top, and descend as they go on with it: these pillars, formed of the same material as the combs and envelope, are massive; their base and capital are of greater diameter than the rest.

These wasps, which work under ground, are concealed from our inspection; they must therefore be drawn, that we may observe the manner in which they construct their nest. When a nest is procured, which is easily done, there is no fear that they will abandon it. It may then be placed under a glass hive, where we can have the pleasure of seeing these insects at their work.

As soon as they are lodged, they begin by repairing the disorders which the vespiary may have suffered, after having attached it solidly to the hive, and they increase the thickness of its envelope.

This envelope deserves a description a little more detailed. Its thickness, which is often more than an inch,

to carry it to its nest. Wasps live, like bees, in community, and sometimes ten or twelve thousand are found inhabiting a single nest.

Of all other insects the wasp is the most fierce, voracious, and most dangerous, when enraged. They are seen wherever flesh is cutting up, gorging themselves with the spoil, and then flying to their nests with their reeking prey. They make war also on every other fly, and the spider himself dreads their approaches.

Every community among bees is composed of females, or queens, drones or males, and neutral or working bees. Wasps have similar

is not massive. It is formed of several layers, which have vacancies between them: each layer is as thin as a sheet of paper. In proportion as the wasps thicken this envelope, they build another layer on those which are already formed. The number of these layers sometimes exceeds fifteen or sixteen.

Nothing can be more amusing than to see these wasps working for the purpose of extending or thickening this envelope. Several of them are engaged at this work, which they perform with the greatest celerity, and without the least confusion. They proceed into the country to find the necessary materials: she that has collected some, returns loaded with a little ball composed of a soft paste; she holds it between her jaws. Arrived at the vespiary, she takes it to the place where she intends to labour, and immediately applies it there. She walks backwards; at each step which she makes, she leaves before her a portion of the ball, without detaching it from the rest, which she holds between her two fore feet. When she has thus applied it all, she unites and smooths it, by repassing over it several times. The materials which she employs are filaments of wood, which she tears off with her mandibles: she moistens and kneads them well previously to use.

These vespiaries contain males, females, and workers: these last, as among the bees and other social insects, are charged with all the labours of the society. Those that go in search of provision are continually employed in the chase; some seize on insects by main force, which they bring back almost entire to the nest; others pillage the shops of butchers, where each one attaches herself to the piece of meat which she prefers, and when she is satiated, cuts off a piece, sometimes larger than herself, to carry it home. Others again plunder the fruits of gardens and orchards: they gnaw or suck them, and bring back the juice. All share their spoils with the males and females, and even with the other workers; and the division is made with the most perfect good will on all sides.

The mothers do not fly into the country, excepting in spring and autumn. During the summer, they are shut up in the interior of the vespiary, occupied in laying, and especially in nursing their larvæ.

A vespiary which has all its combs usually contains fifteen or sixteen thousand cells, each of which is filled by an egg or a nymph. It is the larvæ principally that occupy the attention of the wasps. The latter feed them in the same manner in which birds feed their young, giving them from time to time the *bill-full*, after having softened in their mouth the aliments which the larvæ could not otherwise digest.

Twenty days having elapsed since the eggs were laid, the larvæ are now ready to be metamorphosed into nymphs. Like those of the hornet, they inclose themselves in their cells, and become perfect insects eight or nine days after they have been changed into nymphs. The cell which a young wasp has quitted does not remain a long time vacant. An old wasp cleans it out and renders it fit for the reception of a new egg.

The cells destined for the eggs which produce the workers are never placed among those which contain the eggs destined to give birth to males and females. The edifice built by the wasps, and which occupies them during some months, is to last no longer than a year. This habitation, so populous during summer, is almost deserted in the winter, and entirely abandoned in the spring: most of its inhabitants have perished the preceding autumn. Some females destined to perpetuate the species pass the winter in a state of numbness, and in the following spring each of them becomes the foundress of a new republic, and the mother of all the individuals which compose it. The workers, as being the most useful, are the first who are born: the males and females do not appear until towards the end of summer, or the commencement of autumn: they couple in the vespiary itself in which they were born.

The occupation of the males in the vespiary is limited to cleaning it out and removing the dead bodies: they are smaller than the females, and larger than the workers, which are the smallest of the three kinds of individuals which compose the society. Like the males of the bees, they are destitute of a sting. The mothers and the workers are alone provided with this organ. The sting of the females is longer than that of the workers, and the wound which the wasps inflict is more severe, and causes a sharper pain than that made by the bees. The violent smarting which it produces is, however, caused in the same manner, by a poisonous fluid, which is introduced into the wound.

Peace does not always reign in the societies of the wasps. Combats often take place among the workers, or between them and the males. The last individuals are more cowardly or weaker than the others; but these combats are rarely fatal.

When the cold weather first approaches, the workers snatch from their cells the larvæ which are not yet metamorphosed, and assisted by the males, turn them neck and heels out of the nest. It appears that they know that the little ones could not support cold and hunger during the winter season, when at this early period they can scarcely find wherewithal to nourish them. To cause them thus to perish is, therefore, an act of mercy, not of cruelty. It is the quick prevention of a long and lingering state of misery.

Notwithstanding all the admirable industry of the wasps, agriculturists are not the less desirous to get rid of these insects, which do most particular damage to fruits, even previously to their maturity. Many means have been pointed out for destroying the species which live in a social state, especially the common wasp. When the places which they inhabit can be discovered, it is easy to dispatch thousands of them in a little time. Some have adopted the plan of putting glue on blades of straw, and placing them in the neighbourhood of the nest, but this method is long and troublesome. Boiling water cast into the hole may be used with success. But when the nests are remote from houses, a sufficient quantity cannot well be obtained to destroy the wasps: sulphur matches are far more efficacious. The aperture of the hole which conducts to the vespiary must be widened a little, and lighted matches introduced into the hole, after which its entrance must be closed with small stones, so that the wasps cannot get out without mining, which they cannot do in a little time: they will then assuredly be suffocated by the vapour of the sulphur. Care must be taken, however, not to close the hole so exactly as to prevent all access of air, and give no issue to the smoke, for then the matches would be too soon extinguished.—*Supplement to the English edition of the Animal Kingdom, by Baron Cuvier.*

occupations; the two first are for propagating the species, the last for nursing, defending, and supporting the rising progeny. Among bees, however, there is seldom above a queen or two in a hive; among wasps there are above two or three hundred.

As soon as the summer begins to invigorate the insect tribes, the wasps are the most of the number, and diligently employed either in providing provisions for their nest, if already made; or in making one, if the former habitation be too small to receive the increasing community. The nest is one of the most curious objects in natural history, and contrived almost as artificially as that of the bees themselves. Their principal care is to seek out a hole that has been begun by some other animal, a field-mouse, a rat, or a mole, to build their nests in. They sometimes build upon the plain, where they are sure of the dryness of their situation; but most commonly on the side of a bank, to avoid the rain or water that would otherwise annoy them. When they have chosen a proper place, they go to work with wonderful assiduity. Their first labour is to enlarge and widen the hole, taking away the earth, and carrying it off to some distance. They are perfectly formed for labour, being furnished with a trunk above their mouths, two saws on each side, which play to the right and left against each other, and six strong muscular legs to support them. They cut the earth into small parcels with their saws, and carry it out with their legs or paws. This is the work of some days; and at length the outline of their habitation is formed, making a cavity of about a foot and a half every way. While some are working in this manner, others are roving the fields to seek out materials for their building. To prevent the earth from falling down and crushing their rising city into ruin, they make a sort of roof with their gluey substance, to which they begin to fix the rudiments of their building, working from the top downwards, as if they were hanging a bell; which, however, at length they close up at the bottom. The materials with which they build their nests are bits of wood and glue. The wood they get where they can from the rails and posts which they meet with in the fields and elsewhere. These they saw and divide into a multitude of small fibres, of which they take up little bundles in their claws, letting fall upon them a few drops of gluey matter, with which their bodies are provided, by the help of which they knead the whole composition into a paste, which serves them in their future building. When they have returned with this to the nest, they stick their load of paste on that part where they make their walls and partitions; they tread it close with their feet, and trowl it with their trunks, still going backwards as they work. Having repeated this operation three or four times, the composition is at length flatted out until it becomes a small leaf of a gray colour, much finer than paper, and of a pretty firm texture. This done, the same wasp returns to the field to collect a second load of paste, repeating the same several times, placing layer upon layer, and strengthening every partition in proportion to the wants or convenience of the general fabric. Other working wasps come quickly after to repeat the same operation, laying more leaves upon the former, till at length, after much toil, they have finished the large roof, which is to secure them from the tumbling in of the earth. This dome being finished, they make another entrance to their habitation, designed either for letting in the warmth of the sun, or for escaping, in case one door be invaded by plunderers. Certain however, it is, that by one of these they always enter, by the other they sally forth to their toil; each hole being so small that they can pass but one at a time. The walls being thus composed, and the whole somewhat of the shape of a pear, they labour at their cells, which they compose of the same paper-like substance that goes to the formation of the outside works. Their combs differ from those of bees not less in the composition than the position which they are always seen to obtain. The honey-comb of the bee is edge-ways with respect to the hive; that of the wasp is flat, and the mouth of every cell opens downwards. Thus is their habitation contrived, story above story, supported by several rows of pillars, which give firmness to the whole building, while the upper story is flat-roofed, and as smooth as the pavement of a room, laid with squares of marble. The wasps can freely walk upon these stories between the pillars to do whatever their wants require. The pillars are very hard and compact, being larger at each end than in the middle, not much unlike the columns of a building. All the cells of the nest are only destined for the reception of the young, being replete with neither wax nor honey.

Each cell is like that of the bee, hexagonal: but they are of two sorts; the one larger, for the production of the male and female wasps; the other less, for the reception of the working part of the community. When the females are impregnated by the males, they lay their eggs, one in each cell, and stick it in with a kind of gummy matter to prevent its falling out. From this egg proceeds the insect in its worm state, of which the old ones are extremely careful, feeding it from time to time till it becomes large, and entirely fills up its cell. But the wasp community differs from that of

the bee in this; that among the latter the working bees take the parential duties upon them, whereas among the wasps the females alone are permitted to feed their young, and to nurse their rising progeny. For this purpose the female waits with great patience till the working-wasps have brought in their provisions, which she takes from them, and cuts into pieces. She then goes with great composure from cell to cell, and feeds every young one with her mouth. When the young worms have come to a certain size they leave off eating, and begin to spin a very fine silk, fixing their first end to the entrance of the cell: then turning their heads, first on one side, then on the other, they fix the thread to different parts, and thus they make a sort of door, which serves to close up the mouth of the cell. After this they divest themselves of their skins after the usual mode of transformation; the aurelia, by degrees, begins to emancipate itself from its shell; by little and little it thrusts out its legs and wings, and insensibly acquires the colour and shape of its parent.

The wasp thus formed, and prepared for depredation, becomes a bold, troublesome, and dangerous insect: there are no dangers which it will not encounter in pursuit of its prey, and nothing seems to satiate its gluttony. Though it can gather no honey of its own, no animal is more fond of sweets. For this purpose it will pursue the bee and the humble-bee, destroy them with its sting, and then plunder them of their honey-bag, with which it flies triumphantly loaded to its nest to regale its young. Wasps are ever fond of making their nests in the neighbourhood of bees, merely to have an opportunity of robbing their hives, and feasting on the spoil. Yet the bees are not found always patiently submissive to their tyranny, but fierce battles are sometimes seen to ensue, in which the bees make up by conduct and numbers what they want in personal prowess. When there is no honey to be had, they seek for the best and sweetest fruits, and they are never mistaken in their choice. From the garden they fly to the city, to the grocer's shops, and butcher's shambles. They will sometimes carry off bits of flesh half as big as themselves, with which they fly to their nests for the nourishment of their brood. Those who cannot drive them away, lay for them a piece of ox's liver, which being without fibres, they prefer to other flesh; and whenever they are found, all other flies are seen to desert the place immediately. Such is the dread with which these little animals impress all the rest of the insect tribes, which they seize and devour without mercy, that they vanish at their approach. Wherever they fly, like the eagle or the falcon, they form a desert in the air round them. In this manner the summer is passed in plundering the neighbourhood, and rearing up their young: every day adds to their numbers; and from their strength, agility, and indiscriminate appetite for every kind of provision, were they as long-lived as the bee, they would soon swarm upon the face of nature, and become the most noxious plague of man; but providentially their lives are measured to their mischief, and they live but a single season.

While the summer heats continue, they are bold, voracious, and enterprising; but as the sun withdraws, it seems to rob them of their courage and activity. In proportion as the cold increases, they are seen to become more domestic; they seldom leave the nest; they make but short adventures from home, they flutter about in the noon-day heats, and soon after return chilled and feeble.

As their calamities increase, new passions soon begin to take place; the care for posterity no longer continues; and as the parents are no longer able to provide their growing progeny a supply, they take the barbarous resolution of sacrificing them all to the necessity of the times. In this manner, like a garrison upon short allowance, all the useless hands are destroyed; the young worms, which a little before they fed and protected with so much assiduity, are now butchered, and dragged from their cells. As the cold increases, they no longer find sufficient warmth in their nests, which grow hateful to them, and they fly to seek it in the corners of houses, and places that receive an artificial heat. But the winter is still insupportable; and before the new year begins, they wither and die; the working-wasps first, the males soon following, and many of the females suffer in the general calamity. In every nest, however, one or two females survive the winter, and having been impregnated by the male during the preceding season, she begins in spring to lay her eggs in a little hole of her own contrivance. This bundle of eggs, which is clustered together like grapes, soon produces two worms, which the female takes proper precaution to defend and supply, and these, when hatched, soon give assistance to the female, who is employed in hatching two more; these also gathering strength, extricate themselves out of the web that enclosed them, and become likewise assistants to their mother; fifteen days after, two more make their appearance; thus is the community every day increasing, while the female lays in every cell, first a male and then a female. These soon after become breeders in turn, till from a single female, ten thousand wasps are seen produced before the month of June. After the female has thus produced her progeny, which are distributed in different districts, they assemble from all parts in

the middle of summer, and provide for themselves the large and commodious habitation which has been described above.[1]

Such is the history of the social wasp; but, as among bees, so also among these insects, there are various tribes that live in solitude; these lay their eggs in a hole for the purpose, and the parent dies long before the birth of its offspring. In the principal species of the Solitary-Wasps, the insect is smaller than the working-wasp of the social kind. The filament by which the corselet is joined to the body, is longer and more distinctly seen, and the whole colour of the insect is blacker than in the ordinary kinds. But it is not their figure, but the manners of this extraordinary insect, that claim our principal regard.

From the end of May to the beginning of July, this wasp is seen most diligently employed. The whole purpose of its life seems to be in contriving and fitting up a commodious apartment for its young one, which is not to succeed it till the year ensuing. For this end it is employed, with unwearied assiduity, in boring a hole in the finest earth some inches deep, but not much wider than the diameter of its own body. This is but a gallery leading to a wider apartment destined for the convenient lodgment of its young. As it always chooses a gravelly soil to work in, and where the earth is almost as hard as stone itself, the digging and hollowing this apartment is an enterprise of no small labour: for effecting its operations, this insect is furnished with two teeth, which are strong and firm, but not sufficiently hard to penetrate the substance through which it is resolved to make its way. In order therefore to soften that earth which it is unable to pierce, it is furnished with a gummy liquor, which it emits upon the place, and which renders it more easily separable from the rest, and the whole becoming a kind of soft paste, is removed to the mouth of the habitation. The animal's provision of liquor in these operations is, however, soon exhausted; and it is then seen taking up water either from some neighbouring flower or stream, in order to supply the deficiency.

At length, after much toil, a hole some inches deep is formed, at the bottom of which is a large cavity; and to this no other hostile insect would venture to find its way, from the length and the narrowness of the defile through which it would be obliged to pass. In this the solitary wasp lays its egg, which is destined to continue the species; there the nascent animal is to continue for about nine months, unattended and immured, and at first appearance the most helpless insect of the creation. But when we come to examine, new wonders offer; no other insect can boast so copiously luxurious a provision, or such confirmed security.

As soon as the mother wasp has deposited her egg at the bottom of the hole, her next care is to furnish it with a supply of provisions, which may be offered to the young insect as soon as it leaves the egg. To this end she procures a number of little green worms, generally from eight to twelve, and these are to serve as food for the young one the instant it awakens into life. When this supply is regularly arranged and laid in, the old one then, with as much assiduity as it before worked out its hole, now closes the mouth of the passage; and thus leaving its young one immured in perfect security, and in a copious supply of animal food, she dies, satisfied with having provided for a future progeny.

When the young one leaves the egg, it is scarcely visible, and is seen immured among a number of insects, infinitely larger than itself, ranged in proper order around it, which, however, give it no manner of apprehension. Whether the parent, when she laid in the insect provision, contrived to disable the worms from resistance, or whether they were at first incapable of any, is not known. Certain it is, that the young glutton feasts upon the living spoil without any control: his game lies at his hand, and he devours one after the other as the calls of appetite incite him. The life of the young animal is therefore spent in the most luxurious manner, till its whole stock of worms is exhausted, when the time of its transforma-

[1] "One of the most remarkable of our native social wasps is the *Vespa Britannica*, or tree-wasp, which is not uncommon in the northern, but seldom to be met with in the southern parts of the island. Instead of burrowing in the ground like the common wasp, or in the hollows of trees like the hornet, it boldly swings its nest from the extremity of a branch, where it exhibits some resemblance, in size and colour, to a Welsh wig, hung out to dry. We have seen more than one of these nests on the same tree, at Catrine, in Ayrshire, and at Wemyss Bay, in Renfrewshire. The tree which the Britannic wasp prefers is the silver fir, whose broad flat branch serves as a protection to the suspended nest both from the sun and the rain.

"Reaumur has given a very interesting account of the wasps of Cayenne, which hang their nests on trees. Like the bird of Africa called the Loxia, they fabricate a perfect house, capable of containing many hundreds of their community, and suspend it on high out of the reach of attack. But the Cayenne wasp is a more expert artist than the bird. He is a card-maker;—and travellers of veracity agree that the card with which he forms the exterior covering of his abode is so smooth, so strong, so uniform in its texture, and so white, that the most skilful manufacturer of this substance might be proud of the work.

"The nest of the card-making wasp is impervious to water. It hangs upon the branch of a tree; and those rain-drops which penetrate through the leaves never rest upon its hard and polished surface. A small opening for the entrance of the insects terminates its funnel-shaped bottom. It is impossible to unite more perfectly the qualities of lightness and strength."—*Insect Architecture.*

tion begins to approach; and then spinning a silken web, it continues fixed in its cell till the sun calls it from its dark abode the ensuing summer.

The wasps of Europe are very mischievous, yet they are innocence itself when compared to those of the tropical climates, where all the insect tribes are not only numerous but large, voracious, and formidable. Those of the West Indies are thicker, and twice as long, as the common bee; they are of a gray colour, striped with yellow, and armed with a very dangerous sting. They make their cells in the manner of a honey-comb, in which the young ones are hatched and bred. They generally hang their nests by threads, composed of the same substance with the cells, to the branches of trees, and the eaves of houses. They are seen every where in great abundance, descending like fruit, particularly pears, of which shape they are, and as large as one's head. The inside is divided into three round stories full of cells, each hexagonal, like those of a honey-comb. In some of the islands these insects are so very numerous, that their nests are stuck up in this manner, scarce two feet asunder, and the inhabitants are in continual apprehension from their accidental resentment. It sometimes happens that no precautions can prevent their attacks, and the pain of their sting is almost insupportable. Those who have felt it, think it more terrible than even that of a scorpion; the whole visage swells, and the features are so disfigured, that a person is scarcely known by his most intimate acquaintance.

CHAP. IV.

OF THE ICHNEUMON FLY.

Every rank of insects, how voracious soever, have enemies that are terrible to them, and that revenge upon them the injuries done upon the rest of the animated creation. The wasp as we have seen, is very troublesome to man, and very formidable to the insect tribe; but the ichneumon fly (of which there are many varieties) fears not the wasp itself; it enters its retreats, plunders its habitations, and takes possession of that cell for its own young, which the wasp had laboriously built for a dearer posterity.

Though there are many different kinds of this insect, yet the most formidable, and that best known, is called the common ichneumon, with four wings, like the bee, a long, slender, black body, and a three-forked tail, consisting of bristles; the two outermost black, and the middlemost red. This fly receives its name from the little quadruped, which is found to be so destructive to the crocodile, as it bears a strong similitude in its courage and rapacity.

Though this instrument is, to all appearance, slender and feeble, yet it is found to be a weapon of great force and efficacy. There is scarcely any substance which it will not pierce; and indeed it is seldom seen but employed in penetration. This is the weapon of defence; this is employed in destroying its prey; and still more, by this the animal deposits her eggs wherever she thinks fit to lay them. As it is an instrument chiefly employed for this purpose, the male is unprovided with such a sting, while the female uses it with great force and dexterity, brandishing it when caught, from side to side, and very often wounding those who thought they held her with the greatest security.

All the flies of this tribe are produced in the same manner, and owe their birth to the destruction of some other insect, within whose body they have been deposited, and upon whose vitals they have preyed, till they come to maturity. There is no insect whatever, which they will not attack, in order to leave their fatal present in its body; the caterpillar, the gnat, and even the spider himself, so formidable to others, is often made the unwilling fosterer of this destructive progeny.

About the middle of the summer, when other insects are found in great abundance, the ichneumon is seen flying busily about, and seeking proper objects upon whom to deposit its progeny. As there are various kinds of this fly, so they seem to have various appetites. Some are found to place their eggs within the aurelia of some nascent insect, others place them within the nest, which the wasp had curiously contrived for its own young: and as both are produced at the same time, the young of the ichneumon not only devours the young wasp, but the whole supply of worms which the parent had carefully provided for its provision. But the greatest number of the ichneumon tribe are seen settling upon the back of the caterpillar, and darting, at different intervals, their stings into its body. At every dart they deposit an egg, while the wounded animal seems scarcely sensible of the injury it sustains. In this manner they leave from six to a dozen of their eggs within the fatty substance of the reptile's body, and then fly off to commit further depredations. In the meantime, the caterpillar, thus irreparably injured, seems to feed as voraciously as before; does not abate of its usual activity; and to all appearance, seems no way affected by the internal enemies that are preparing its destruction in their darksome abode. But they soon burst from their egg state, and begin to prey upon the substance of their prison. As they

grow larger, they require a greater supply; till at last the animal, by whose vitals they are supported, is no longer able to sustain them, but dies; its whole inside being almost eaten away. It often happens, however, that it survives their worm-state, and then they change into a chrysalis, inclosed in the caterpillar's body till the time of their delivery approaches, when they burst their prisons, and fly away. The caterpillar, however, is irreparably destroyed, it never changes into a chrysalis, but dies shortly after from the injuries it had sustained.

Such is the history of this fly, which, though very terrible to the insect tribe, fails not to be of infinite service to mankind. The millions which it kills in a single summer are inconceivable; and without such a destroyer, the fruits of the earth would only rise to furnish a banquet for the insect race, to the exclusion of all the nobler ranks of animated nature.

CHAP. V.

OF THE ANT.

Though the number of two-winged flies be very great, and the naturalists have taken much pains to describe their characters and varieties; yet there is such a similitude in their forms and manners, that in a work like this, one description must serve for all. We now, therefore, come to a species of four-winged insects, that are famous from all antiquity for their social and industrious habits, that are marked for their spirit of subordination, that are offered as a pattern of parsimony to the profuse, and of unremitting diligence to the sluggard.

In the experiments, however, which have been more recently made, and the observations which have been taken, much of their boasted frugality and precaution seems denied them: the treasures they lay up are no longer supposed intended for future provision; and the choice they make in their stores, seems no way dictated by wisdom. It is indeed somewhat surprising, that almost every writer of antiquity should describe this insect, as labouring in the summer, and feasting upon the produce during the winter. Perhaps, in some of the warmer climates where the winter is mild, and of short continuance, this may take place; but in France and England, these animals can have no manner of occasion for a supply of winter provisions, as they are actually in a state of torpidity during that season.

The common ants of Europe are of two or three different kinds: some red, some black; some with stings, and others without; such as have stings, inflict their wounds in that manner; such as are unprovided with these weapons of defence, have a power of spurting from their hinder parts an acid pungent liquor, which, if it lights upon the skin, inflames and burns it like nettles.[1]

[1] The *formica rufa*, or wood-ant, is the largest of our British ants. It is called the Hill-ant by Gould, the Fallow-ant by the English translator of Huber, and popularly the Pismire. It invariably lives in or near woods and forests. It may be readily distinguished from other ants by the dusky black colour of its head and hinder parts, and the rusty brown of its middle. The structures reared by this species are often of considerable magnitude, and bear no small resemblance to a rook's nest thrown upon the ground, bottom upwards. The exterior of the nest is composed of almost every transportable material which the colonists can find in their vicinity; but the greater portion consists of withered grass and short twigs of trees, piled up in apparent confusion, but with sufficient regularity to render the whole smooth, conical, and sloping towards the base, for the purpose, we may infer, of carrying off rain water. When within reach of a corn-field, they often also pick up grains of wheat, barley, or oats, and carry them to the nest as building materials, and not for food as was believed by the ancients. The coping which forms the exterior of the wood-ant's nest, though only a small portion of the structure, which consists of a great number of interior chambers and galleries, with funnel-shaped avenues leading to them, is one of the most essential parts, and we cannot follow a more delightful guide than the younger Huber, in detailing its formation.

"The labourers," he says, "of which the colony is composed, not only work continually on the outside of their nest, but, differing very essentially from other species, who willingly remain in the interior, sheltered from the sun, they prefer living in the open air, and do not hesitate to carry on, even in our presence, the greater part of their operations. To have an idea how the straw or stubble roof is formed, let us take a view of the ant-hill at its origin, when it is simply a cavity in the earth. Some of its future inhabitants are seen wandering about in search of materials fit for the exterior work, with which, though rather irregularly, they cover up the entrance; whilst others are employed in mixing the earth, thrown up in hollowing the interior, with fragments of wood and leaves, which are every moment brought in by their fellow-assistants; and this gives a certain consistence to the edifice, which increases in size daily. Our little architects leave here and there cavities, where they intend constructing the galleries which are to lead to the exterior, and as they remove in the morning the barriers placed at the entrance of their nest the preceding evening, the passages are kept open during the whole time of its construction. We soon observed the roof to become convex; but we should be greatly deceived did we consider it solid. This roof is destined to include many apartments or stories. Having observed the motions of these little builders through a pane of glass, adjusted against one of their habitations, I am thence enabled to speak with some degree of certainty upon the manner in which they are constructed. I ascertained, that it is by excavating or mining the under portion of their edifice, that they form their spacious halls, low, indeed, and of heavy construction, yet sufficiently convenient for the use to which they are appropriated, that of receiving, at certain hours of the day, the larvæ and pupæ. These halls have a free communication by galleries, made in the same manner. If the materials of which the ant-hill is composed were only interlaced, they would fall into a confused heap every time the ants

The body of an ant is divided into the head, breast, and belly. In the head the eyes are placed, which are entirely black, and under their eyes there are two small horns or feelers, composed of twelve joints, all covered with a fine silky hair. The mouth is furnished with two crooked jaws, which project outwards, in each of which are seen incisors, that look like

attempted to bring them into regular order. This, however, is obviated by their tempering the earth with rain-water, which, afterwards hardened in the sun, so completely and effectually binds together the several substances, as to permit the removal of certain fragments from the ant-hill without any injury to the rest; it, moreover, strongly opposes the introduction of the rain. I never found, even after long and violent rains, the interior of the nest wetted to more than a quarter of an inch from the surface, provided it had not been previously out of repair, or deserted by its inhabitants. The ants are extremely well sheltered in their chambers, the largest of which is placed nearly in the centre of the building; it is much loftier than the rest, and traversed only by the beams that support the ceiling; it is in this spot that all the galleries terminate, and this forms, for the most part, their usual residence. As to the underground portion, it can only be seen when the ant-hill is placed against a declivity; all the interior may be then readily brought in view, by simply raising up the straw-roof. The subterranean residence consists of a range of apartments, excavated in the earth, taking a horizontal direction."

There is this remarkable difference in the nest of the wood-ants, that they do not construct a long covert way as if for concealment, as the yellow and the brown ants do. The wood-ants are not, like them, afraid of being surprised by enemies, at least during the day, when the whole colony is either foraging in the vicinity or employed on the exterior. But the proceedings of the wood-ants at night are well worthy of notice; and when M. Huber began to study their economy, he directed his entire attention to their night proceedings. "I remarked," says he, "that their habitations changed in appearance hourly, and that the diameter of those spacious avenues, where so many ants could freely pass each other during the day, was, as night approached, gradually lessened. The aperture, at length, totally disappeared, the dome was closed on all sides, and the ants retired to the bottom of their nest. In further noticing the apertures of these ant-hills, I fully ascertained the nature of the labour of its inhabitants, of which I could not before even guess the purport; for the surface of the nest presented such a constant scene of agitation, and so many insects were occupied in carrying materials in every direction, that the movement offered no other image than that of confusion. I saw then clearly that they were engaged in stopping up passages; and for this purpose, they at first brought forward little pieces of wood, which they deposited near the entrance of those avenues they wished to close; they placed them in the stubble; they then went to seek other twigs and fragments of wood, which they disposed above the first, but in a different direction, and appeared to choose pieces of less size in proportion as the work advanced. They, at length, brought in a number of dried leaves, and other materials of an enlarged form, with which they covered the roof; an exact miniature of the art of our builders, when they form the covering of any building? Nature, indeed, seems everywhere to have anticipated the inventions of which we boast, and this is doubtless one of the most simple. Our little insects, now in safety in their nest, retire gradually to the interior before the last passages are closed, one or two only remain without, or concealed behind the doors on guard, whilst the rest either take their repose, or engage in different occupations in the most perfect security. I was impatient to know what took place in the morning upon these ant-hills, and therefore visited them at an early hour. I found them in the same state in which I had left them the preceding evening. A few ants were wandering about on the surface of the nest, some others issued from time to time from under the margin of their little roofs formed at the entrance of the galleries; others afterwards came forth, who began removing the wooden bars that blockaded the entrance, in which they readily succeeded. This labour occupied them several hours. The passages were at length free, and the materials with which they had been closed, scattered here and there over the ant-hill. Every day, morning and evening, during the fine weather, I was a witness to similar proceedings. On days of rain the doors of all the ant-hills remained closed. When the sky was cloudy in the morning, or rain was indicated, the ants, who seemed to be aware of it, opened but in part their several avenues, and immediately closed them when the rain commenced."

The galleries and chambers which are roofed in as thus described, are very similar to those of the mason-ants, being partly excavated in the earth, and partly built with the clay thence procured. It is in these they pass the night, and also the colder months of the winter, when they become torpid or nearly so, and of course require not the winter granaries of corn with which the ancients fabulously furnish them.

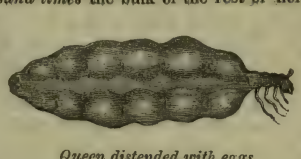
The *Carpenter-Ants*, or ants that work in wood, perform much more extensive operations than any of the other carpenter insects. Their only tools, like those of bees and wasps, are their jaws or mandibles; but though these may not appear so curiously constructed as the ovipositor file of the tree-hopper, or the rasp and saw of the saw-flies, they are no less efficient in the performance of what is required. Among the carpenter-ants the emmet or jet-ant holds the first rank, and is easily known by being rather less in size than the wood-ant, and by its fine shining black colour. It is less common in Britain than the others, though its colonies may occasionally be met with in the trunks of decaying oak or willow trees in hedges.

Among the foreign ants, we may mention a small yellow ant of South America, described by Dampier, which seems, from his account, to construct a nest of green leaves. "Their sting," he says, "is like a spark of fire; and they are so thick among the boughs in some places, that one shall be covered with them before he is aware. These creatures have nests on great trees, placed on the body between the limbs; some of their nests are as big as a hogshead. This is their winter habitation; for in the wet season they all repair to these their cities, where they preserve their eggs. In the dry season, when they leave their nests, they swarm all over the woodlands, for they never trouble the savannahs. Great paths, three or four inches broad, made by them, may be seen in the woods. They go out light, but bring home heavy loads on their backs, all of the same substance, and equal in size. I never observed any thing besides pieces of green leaves, so big that I could scarcely see the insect for his burden; yet they would march stoutly, and so many were pressing forward that it was a very pretty sight, for the path looked perfectly green with them.

Ants observed in New South Wales, by the gentlemen in the expedition under Captain Cook, are still more interesting. "Some," we are told, "are as green as a leaf, and live upon trees, where they build their nests of various sizes, between that of a man's head and his fist. These nests are of a very curious structure: they are formed by bending down several of the leaves, each of which is as broad as a man's hand, and glueing the points

teeth. The breast is covered with a fine silky hair, from which project six legs, that are pretty strong and hairy, the extremities of each armed with two small claws, which the animal uses in climbing. The belly is more reddish than the rest of the body, which is of a brown chestnut colour, shining as glass, and covered with extremely fine hair.

---



of them together so as to form a purse. The viscous matter used for this purpose is an animal juice which nature has enabled them to elaborate. Another sort are quite black. Their habitations are the inside of the branches of a tree which they contrive to excavate, by working out the pith almost to the extremity of the slenderest twig, the tree at the same time flourishing as if it had no such inmate. A third kind we found nested in the root of a plant, which grows on the bark of trees in the manner of misletoe, and which they had perforated for that use. This root is commonly as big as a large turnip, and sometimes much bigger. When we cut it we found it intersected by innumerable winding passages, all filled with these animals, by which, however, the vegetation of the plant did not appear to have suffered any injury. We never cut one of these roots that was not inhabited, though some were not bigger than a hazel-nut. The animals themselves are very small, not more than half as big as the common red ant in England. They had stings, but scarcely force enough to make them felt; they had, however, a power of tormenting us in an equal, if not in a greater degree; for the moment we handled the root, they swarmed from innumerable holes, and running about those parts of the body that were uncovered, produced a titillation more intolerable than pain, except it is increased to great violence."

The species called *Sugar-Ants* in the West Indies are particularly destructive to the sugar-cane, as well as to lime, lemon, and orange-trees, by excavating their nests at the roots, and so loosening the earth that they are frequently uprooted and blown down by the winds. If this does not happen the roots are deprived of due nourishment, and the plants become sickly and die.

But the most extraordinary of ants is the *White-Ants* or Termites, inhabiting the plains of East India, Africa, and South America. Mr Smeathman has given in the Philosophical Transactions a very complete account of these wonderful creatures. He says that they are naturally divided into three orders: first, the working insects, which he distinguishes by the name of *labourers;* second, the fighters, or *soldiers*, which perform no other labour than such as is necessary in defence of the nest; and third, the winged or perfect insects, which are male and female, and capable of multiplying the species. The latter he denotes the *nobility* or *gentry*, because they neither labour nor fight. In their nest or hill, for they build on the surface of the ground, the labourers are always the most numerous, there being at least a hundred labourers for one of the fighting insects, or soldiers. In this state they are about a quarter of an inch in length. The second order, or soldiers, differ in figure from the labourers. These appear to be such insects as have undergone one change towards their perfect state. They are now nearly half an inch in length, and equal in size to about fifteen of the labourers. The shape of the head is likewise greatly changed. In the former state the mouth is evidently formed for gnawing, or for holding bodies; but in this state the jaws being shaped like two sharp awls, a little jagged, are destined solely for piercing or wounding. For these purposes they are well calculated, being as hard as a crab's claw, and placed in a strong horny head, which is larger than all the rest of the body. The insect of the third order, or in its perfect state, is still more remarkable. The head, the thorax, and the abdomen, differ almost in the same parts in the labourers and soldiers. The animals are also now furnished with four large brownish transparent wings, by which they are enabled, at the proper season, to emigrate, and to establish new settlements. They are likewise greatly altered in their size as well as figure, and have acquired the powers of propagating the species. Their bodies now measure nearly three quarters of an inch in length; their wings, from tip to tip, above two inches and a half; and their bulk is equal to that of thirty labourers, or two soldiers. Instead of active, industrious, and rapacious little animals, when they arrive at their perfect state, they become innocent, helpless, and dastardly.

Their numbers are great, but their enemies are still more numerous. They are devoured by birds, by every species of ants, by carnivorous reptiles, and even by the inhabitants of many parts of Africa. After such devastation, it seems surprising that even a single pair should escape. Some, however, are so fortunate; and being found by some of the labouring insects, that are continually running about the surface of the ground under their covered galleries, are elected kings and queens over new states; all those who are not so elected and preserved, certainly perish. The manner in which these labourers protect the happy pair from their innumerable enemies, not only on the day of the massacre of almost all their race, but for a long time after, justifies the use of the term election. The little industrious creatures immediately enclose them in a small chamber of clay suitable to their size, into which at first they leave but one entrance, large enough for themselves and soldiers to go in and out at, but too little for either of the royal pair to use; and when necessity obliges them to make more entrances, they are never larger, so that of course, the voluntary subjects charge themselves with the task of providing for the offspring of their sovereigns, as well as of working and fighting for them, until they have raised a progeny capable at least of dividing the task with them.

About this time a most extraordinary change takes place in the queen; the abdomen begins to extend and enlarge to such an enormous size, that an old queen will sometimes have it so much increased, as to be nearly *two thousand times* the bulk of the rest of her body. It

Queen distended with eggs.

is now of an irregular, oblong shape, and is become one vast matrix full of eggs. When these are perfectly formed, they begin to be protruded, and they come forth so quickly, that about sixty in a minute, or upwards of eighty thousand in twenty-four hours, are deposited. The eggs are immediately taken away by the attendants, and carried to the nurseries: here they are hatched. The young ones are attended and provided with every thing necessary, until they are able to shift for themselves, and take their share in the labours of the community.

The nests, or rather hills of these ants, (for they are often elevated ten or twelve feet above the surface of the ground,) are nearly of a conical shape; and sometimes so numerous, as at a little distance to appear like little villages of the Negroes. (See a representation of ant-hills in plate I. fig. 1.) Jobson, in his history of Gambia, says that some of them are twenty feet high, and that he and his companions have often hidden themselves behind them, for the purpose of shooting deer and other wild animals. Each hill is composed of an exterior and interior part. The exterior cover is a large clay shell, shaped like a dome, of strength and magnitude sufficient

From such a formation, this animal seems bolder and more active, for its size, than any other of the insect tribe, and fears not to attack a creature often above ten times its own magnitude.

As soon as the winter is past, in the first fine day in April, the ant-hill, that before seemed a desert, now swarms with new life, and myriads of these insects are seen just awaked from their annual lethargy, and pre-

to enclose and protect the interior building from the injuries of the weather, and to defend its numerous inhabitants from the attacks of natural or accidental enemies. Different species of termites construct nests of very different forms. In the plate referred to, among others, are represented turret-nests, the figures of which resemble a pillar, with a large mushroom for a capital. These turrets are composed of well-tempered black earth, and stand nearly three feet high. One nest is represented cut through with the upper part lying on the ground. When one of these turrets is completed, the insects do not enlarge them, when they become too small, but build another at a short distance. They are so strongly built that they will sooner tear up from the roots than break.

The royal chamber is always situated as near the centre of the building as possible, is generally on a level with the surface of the ground, and of an obtuse oval shape within. In the infant state of the colony it is not above an inch in length: but in time it becomes enlarged to six or eight inches, or more. The entrance into the royal chamber not admitting any animal larger than the labourers or soldiers, it follows that the king and queen can never possibly get out. This chamber is surrounded by a hundred of others, of different sizes, figures, and dimensions; all of them arched either in a circular or an elliptical form. These either open into each other, or have communicating passages, which being always clear, are evidently intended for the convenience of the soldiers and attendants, of whom great numbers are necessary. The latter apartments are joined by the magazines and nurseries. The magazines are chambers of clay, and are at all times well stored with provisions, which to the naked eye seem to consist of the raspings of wood and plants, but, when examined by the microscope, they are found to consist chiefly of the gums or inspissated juices of plants thrown together in small irregular masses.

The magazines are always intermixed with the nurseries, buildings totally different from the rest of the apartments. These are composed entirely of wooden materials, which seem to be cemented with gum. They are invariably occupied by the eggs, and the young ones, which first appear in the shape of labourers. These buildings are exceedingly compact, and are divided into a number of small irregular-shaped chambers, not one of which is half an inch wide. They are placed all around, and as near as possible to the royal apartments. When a nest is in an infant state, the nurseries are close to the royal apartment. But as in process of time the body of the queen enlarges, it becomes necessary, for her accommodation, to augment the dimensions of her chamber. She then likewise lays a greater number of eggs, and requires more attendants: of course it is necessary that both the number and dimensions of the adjacent apartments should be augmented. For this purpose, the small first built nurseries are taken to pieces, rebuilt a little farther off, and made a size larger, and their number at the same time is increased. Thus the animals are continually employed in pulling down, repairing, or rebuilding their apartments; and these operations they perform with wonderful sagacity, regularity, and foresight. The nurseries are enclosed in chambers of clay, like those which contain the provisions; but they are much larger. In the early state of the nest they are not bigger than a hazel-nut; but in great hills they are oftentimes four or five inches across.

The royal chamber, as before observed, is situated as nearly under the apex of the hill as possible, and is sur-

rounded on all sides, both above and below, by what Mr Smeathman calls the *royal apartments*, which contain only those labourers and soldiers that are employed in defence of the common parents. These apartments compose an intricate labyrinth, which extends a foot or more in diameter from the royal chamber on every side. Here the nurseries and magazines of provisions begin; and, being separated by small empty chambers and galleries, which surround them, and communicate with each other, are continued on all sides to the outward shell, and reach up within two-thirds, or three-fourths of its height, leaving an open area in the middle under the dome. This is surrounded by large pointed arches, which are sometimes two or three feet high next to the front of the area, but diminish rapidly as they recede, and are soon lost among the innumerable chambers and nurseries behind them. The inferior building, or assemblage of nurseries, chambers, and passages, has a flattish floor, without any perforation. By this contrivance, if by accident water should penetrate the external dome, the apartments below are preserved from injury. The area has also a flattish floor, which is situated above the royal chamber; it is likewise water-proof, and so constructed, that if water gets admittance, it runs off by subterraneous passages, which are cylindrical, and some of them so much as even thirteen inches in diameter. These subterraneous passages are thickly lined with the same kind of clay of which the hill is composed; they ascend the internal part of the external shell in a spiral form, and winding round the whole building up to the top, intersect and communicate with each other at different heights. From every part of these large galleries, a number of pipes, or smaller galleries, leading to different apartments of the building, proceed. There are likewise a great many which lead downward, by sloping descents, to a considerable depth under the surface of the ground. Other galleries ascend and lead out horizontally on every side, and are also carried under ground, but near the surface, to great distances, for the purpose of foraging.

When a breach is made in one of the walls by an axe or other instrument, the first object that attracts attention is the behaviour of the soldiers or fighting insects. Immediately after the blow is given, a soldier comes out, walks about the breach, and seems to examine the nature of the enemy, or cause of the attack. He then goes into the hill, gives the alarm, and in a short time large bodies rush out as fast as the breach will permit. It is not easy to describe the fury that actuates these fighting insects. In their eagerness to repel the enemy, they frequently tumble down the sides of the hill, but quickly recover themselves, and bite everything they encounter. This biting, joined to the striking of their forceps upon the building, makes a crackling or vibrating noise, which is somewhat shriller and quicker than the ticking of a watch, and may be heard at the distance of several feet. While the attack proceeds they are in the most violent bustle and agitation. If they seize hold of any part of a man's body, they instantly make a wound which gives some pain. When they attack the leg, the stain of blood upon the stocking extends more than an inch in width. They make their hooked jaws meet at the first stroke, and never quit their hold, but suffer themselves to be pulled away piece after piece, without any attempt to escape. On the other hand, if a person keeps out of their reach, and gives them no further disturbance, in less than half an hour they retire into the nest, as if they supposed the monster that damaged their castle had fled. Before the whole of the soldiers have got in, the labouring

paring for the pleasure and fatigues of the season. For the first day they never offer to leave the hill, which may be considered as their citadel, but run over every part of it, as if to examine its present situation, to observe what injuries it has sustained during the rigours of winter,[1] while they slept, and to meditate and settle the labours of the day ensuing.

At the first display of their forces, none but the wingless tribe appears, while those furnished with wings remain at the bottom. These are the working ants that first appear, and that are always destitute of wings; the males and females, that are furnished with four large wings each, are more slow in making their appearance.

Thus, like bees, they are divided into males, females, and the neutral or the working tribe. These are all easily distinguished from each other; the females are much larger than the males; the working ants are the smallest of all. The two former have wings; which, however, they sometimes are divested of; the latter never have any, and upon them are devolved all the labours that tend to the welfare of the community. The female, also, may be distinguished by the colour and structure of her breast, which is a little more brown than that of the common ant, and a little brighter than that of the male.

In eight or ten days after their first appearance, the labours of the hill are in some forwardness; the males and females are seen mixed with the working multitude, and pursued or pursuing each other. They seem no way to partake in the common drudgeries of the state; the males pursue the females with great assiduity, and in a manner force them to compliance. They remain coupled for some time; while the males, thus united, suffer themselves to be drawn along by the will of their partners.

In the meantime, the working body of the state take no part in their pleasures; they are seen diligently going from the ant-hill in pursuit of food for themselves and their associates, and of proper materials for giving a comfortable retreat to their young, or safety to their habitation. In the fields of England, ant-hills are formed with but little apparent regularity. In the more southern provinces of Europe, they are constructed with wonderful contrivance, and offer a sight highly worthy a naturalist's curiosity. These are generally formed in the neighbourhood of some large tree and a stream of water. The one is considered by the animals as the proper place for getting food; the other for supplying them with moisture, which they cannot well dispense with. The shape of the ant-hill is that of a sugar-loaf, about three feet high, composed of various substances; leaves, bits of wood, sand, earth, bits of gum, and grains of corn. These are all united into a compact body, perforated with galleries down to the bottom, and winding ways within the body of the structure. From this retreat, to the water, as well as to the tree, in different directions, there are many paths worn by constant assiduity, and along these the busy insects are seen passing and repassing continually; so that from May, or the beginning of June, according to the state of the season, they work continually, till the bad weather comes on.

The chief employment of the working ants is in sustaining not only the idlers at home, but also finding a sufficiency of food for themselves. They live upon various provisions, as well of the vegetable as of the animal kind. Small insects they will kill and devour: sweets of all kinds they are particularly fond of. They seldom, however, think of their community, till they themselves are first satiated. Having found a juicy fruit, they swallow what they can, and then tearing it in pieces, carry home their load. If they meet with an insect above their match, several of them will fall upon it at once, and, having

---

insects are all in motion, and hastening towards the breach, each of them having a quantity of tempered mortar in his mouth. This mortar they stick upon the breach as fast as they arrive, and perform the operation with so much despatch and facility, that, notwithstanding the immensity of their number, they never stop or embarrass one another. During this scene of apparent hurry and confusion, the spectator is agreeably surprised, by observing a regular wall rising and gradually filling up the chasm. While the labourers are thus employed, almost all the soldiers remain within, except here and there one, who saunters about among six hundred or a thousand labourers, but never touches the mortar. One soldier, however, invariably takes his station close to the wall which the labourers are building. This soldier turns himself leisurely on all sides, and, at intervals of a minute or two, raises his head, beats upon the building with his forceps, and makes the vibrating noise formerly mentioned. A loud hiss instantly issues from the inside of the dome, and all the subterraneous caverns and passages. That this hiss proceeds from the labourers is apparent; for, at every signal of this kind, they work with redoubled quickness and alacrity. A renewal of the attack, however, instantly changes the scene. "On the first stroke," Mr Smeathman remarks, "the labourers run into the many pipes and galleries with which the building is perforated, which they do so quickly, that they seem to vanish; for in a few seconds, all are gone, and the soldiers rush out as numerous and as vindictive as before. On finding no enemy, they return again leisurely into the hill; and, soon after, the labourers appear loaded as at first, as active, and as sedulous, with soldiers here and there among them, who act just in the same manner, one or other of them giving the signal to hasten the business. Thus the pleasure of seeing them out to fight or to work alternately may be obtained as often as curiosity excites, or time permits; and it will certainly be found, that the one order never attempts to fight, nor the other to work, let the emergency be ever so great."

[1] Memoires pour servir a l'Histoire des Insectes par Charles de Geer.

mangled it, each will carry off a part of the spoil. If they meet, in their excursions, any thing that is too heavy for one to bear, and yet which they are able to divide, several of them will endeavour to force it along, some dragging and others pushing. If any one of them happens to make a lucky discovery, it will immediately give advice to others, and then, at once the whole republic will put themselves in motion. If in these struggles one of them happens to be killed, some kind survivor will carry him off to a great distance, to prevent the obstructions his body might give to the general spirit of industry.

But while they are thus employed in supporting the state in feeding abroad, and carrying in provisions to those that continue at home, they are not unmindful of posterity. After a few days of fine weather, the female ants begin to lay their eggs, and those are as assiduously watched and protected by the working ants, who take upon themselves to supply whatever is wanting to the nascent animal's convenience or necessity. They are carried, as soon as laid, to the safest situation, at the bottom of their hill, where they are carefully defended from cold and moisture. We are not to suppose, that those white substances which we so plentifully find in every ant-hill, are the eggs as newly laid. On the contrary, the ant's egg is so very small, that, though laid upon a black ground, it can scarcely be discerned. The little white bodies we see are the young animals in their maggot state, endued with life, long since freed from the egg, and often involved in a cone, which it has spun round itself, like the silk-worm. The real egg when laid, if viewed through a microscope, appears smooth, polished, and shining, while the maggot is seen composed of twelve rings, and is often larger than the ant itself.—It is impossible to express the fond attachment which the working ants show to their rising progeny. In cold weather they take them in their mouths, but without offering them the smallest injury, to the very depths of their habitation, where they are less subject to the severity of the season. In a fine day they remove them with the same care nearer the surface, where their maturity may be assisted by the warm beams of the sun. If a formidable enemy should come to batter down their whole habitation, and crush them by thousands in the ruin, yet these wonderful insects, still mindful of their parental duties, make it their first care to save their offspring. They are seen running wildly about, and different ways, each loaded with a young one, often bigger than the insect that supports it. I have kept, says Swammerdam, several of the working ants in my closet, with their young in a glass filled with earth. I took pleasure in observing, that in proportion as the earth dried on the surface, they dug deeper and deeper to deposit their eggs; and when I poured water thereon, it was surprising to see with what care, affection, and diligence, they laboured, to put their brood in safety, in the driest place. I have seen also, that when water has been wanting for several days, and when the earth was moistened after it a little, they immediately carried their young ones to have a share, who seemed to enjoy and suck the moisture.

When the young maggot is come to its full growth, the breast swells insensibly, it casts its skin, and loses all motion. All the members which were hidden before, then begin to appear; an aurelia is formed, which represents very distinctly all the parts of the animal, though they are yet without motion, and, as it were, wrapped up in swaddling clothes. When at length the little insect has passed through all its changes, and acquired its proper maturity, it bursts this last skin, to assume the form it is to retain ever after. Yet this is not done by efforts of the little animal alone, for the old ones very assiduously break open, with their teeth, the covering in which it is enclosed. Without this assistance the aurelia would never be able to get free, as M. de Geer often found, who tried the experiment by leaving the aurelias to themselves. The old ones not only assist them, but know the very precise time for lending their assistance; for, if produced too soon, the young one dies of cold: if retarded too long, it is suffocated in its prison.

When the female has done laying, and the whole brood is thus produced, her labours, as well as that of the male, become unnecessary; and her wings, which she had but a short time before so actively employed, drop off. What becomes of her when thus divested of her ornaments is not well known, for she is seen in the cells for some weeks after. The males, on the other hand, having no longer any occupation at home, make use of those wings with which they have been furnished by nature, and fly away, never to return or be heard of more. It is probable they perish with the cold, or are devoured by the birds, which are particularly fond of this petty prey.

In the meantime, the working ants, having probably deposed their queens, and being deserted by the males, that served but to clog the community, prepare for the severity of the winter, and bury their retreats as deep in the earth as they conveniently can. It is now found that the grains of corn, and other substances with which they furnish their hill, are only meant as fences to keep off the rigours of the weather, not as provisions to support them during its continuance. It is found generally

to obtain, that every insect that lives a year after it is come to its full growth, is obliged to pass four or five months without taking any nourishment, and will seem to be dead all that time. It would be to no purpose, therefore, for ants to lay up corn for the winter, since they lie that time without motion, heaped upon each other, and are so far from eating, that they are utterly unable to stir. Thus, what authors have dignified by the name of a magazine, appears to be no more than a cavity, which serves for a common retreat when the weather forces them to return to their lethargic state.

What has been said with exaggeration of the European ant, is however true, if asserted of those of the tropical climates. They build an ant-hill with great contrivance and regularity, they lay up provisions, and as they probably live the whole year, they submit themselves to regulations entirely unknown among the ants of Europe.

Those of Africa are of three kinds, the red, the green, and the black; the latter are above an inch long, and in every respect a most formidable insect. Their sting produces extreme pain, and their depredations are sometimes extremely destructive. They build an ant-hill of a very great size, from six to twelve feet high; it is made of viscous clay, and tapers into a pyramidal form. This habitation is constructed with great artifice; and the cells are so numerous and even, that a honeycomb scarce exceeds them in number and regularity.

The inhabitants of this edifice seem to be under a very strict regulation. At the slightest warning they will sally out upon whatever disturbs them; and if they have time to arrest their enemy, he is sure to find no mercy. Sheep, hens, and even rats, are often destroyed by these merciless insects, and their flesh devoured to the bone. No anatomist in the world can strip a skeleton so completely as they; and no animal, how strong soever, when they have once seized upon it, has power to resist them.

It often happens that these insects quit their retreat in a body, and go in quest of adventures. "During my stay," says Smith, "at Cape Corse Castle, a body of these ants came to pay us a visit in our fortification. It was about day-break when the advanced guard of this famished crew entered the chapel, where some negro servants were asleep upon the floor. The men were quickly alarmed at the invasion of this unexpected army, and prepared, as well as they could, for a defence. While the foremost battalion of insects had already taken possession of the place, the rear-guard was more than a quarter of a mile distant. The whole ground seemed alive, and crawling with unceasing destruction. After deliberating a few moments upon what was to be done, it was resolved to lay a large train of gunpowder along the path they had taken: by this means, millions were blown to pieces; and the rear-guard perceiving the destruction of their leaders, thought proper instantly to return and make back to their original habitation."

The order which these ants observe, seems very extraordinary; whenever they sally forth, fifty or sixty larger than the rest are seen to head the band, and conduct them to their destined prey. If they have a fixed spot where their prey continues to resort, they then form a vaulted gallery, which is sometimes a quarter of a mile in length; and yet they will hollow it out in the space of ten or twelve hours.

CHAP. VI.

OF THE BEETLE, AND ITS VARIETIES.

Hitherto we have been treating of insects with four transparent wings, we now come to a tribe with two transparent wings, with cases that cover them close while at rest, but which allow them their proper play when flying. The principal of these are the Beetle, the May-bug, and the Cantharis. These are all bred like the rest of their order, first from eggs, then they become grubs, then a chrysalis, in which the parts of the future fly are distinctly seen; and, lastly, the animal leaves its prison, breaking forth as a winged animal in full maturity.

Of the Beetle there are various kinds; all, however, concurring in one common formation of having cases to their wings, which are the more necessary to those insects, as they often live under the surface of the earth, in holes which they dig out by their own industry. These cases prevent the various injuries their real wings might sustain, by rubbing or crushing against the sides of their abode. These, though they do not assist flight yet keep the internal wings clean and even, and produce a loud buzzing noise when the animal rises in the air.

If we examine the formation of all animals of the beetle kind, we shall find, as in shell-fish, that their bones are placed externally and their muscles within. These muscles are formed very much like those of quadrupeds, and are endued with such surprising strength, that, bulk for bulk, they are a thousand times stronger than those of a man.—The strength of these muscles is of use in digging the animal's subterraneous abode, where it is most usually hatched, and to which it most fre-

quently returns, even after it becomes a winged insect capable of flying.

Beside the difference which results from the shape and colour of these animals, the size also makes a considerable one; some beetles being not larger than the head of a pin, while others, such as the elephant beetle, are as big as one's fist. But the greatest difference among them is, that some are produced in a month, and in a single season go through all the stages of their existence; while others take near four years to their production, and live as winged insects a year more. To give the history of all these animals, that are bred pretty much in the same way, would be insipid and endless; it will suffice to select one or two from the number, the origin of which may serve as specimens of the rest. I will, therefore, offer the history of the May-bug to the reader's attention; premising that most other beetles, though not so long lived, are bred in the same manner.

The May-bug, or dorr-beetle, as some call it, has, like all the rest, a pair of cases to its wings, which are of a reddish brown colour, sprinkled with a whitish dust, which easily comes off. In some years their necks are seen covered with a red plate, and in others with a black; these, however, are distinct sorts, and their difference is by no means accidental. The fore-legs are very short, and the better calculated for burrowing in the ground, where this insect makes its retreat. It is well known, for its evening buzz, to children; but still more formidably introduced to the acquaintance of husbandmen and gardeners; for, in some seasons, it has been found to swarm in such numbers as to eat up every vegetable production.

The two sexes in the May-bug are easily distinguished from each other, by the superior length of the tufts, at the end of the horns, in the male. They begin to copulate in summer; and at that season they are seen joined together a considerable time. The female being impregnated, quickly falls to boring a hole into the ground where to deposit her burden. This is generally about half a foot deep, and in it she places her eggs, which are of an oblong shape, with great regularity, one by the other. They are of a bright yellow colour, and no way wrapped up in a common covering, as some have imagined. When the female is lightened of her burden she again ascends from her hole, to live as before upon leaves and vegetables, to buzz in the summer evening, and to lie hid among the branches of trees in the heat of the day.

In about three months after these eggs have been thus deposited in the earth, the contained insect begins to break its shell, and a small grub or maggot crawls forth, and feeds upon the roots of whatever vegetable it happens to to be nearest.

All substances of this kind seem equally grateful, yet it is probable the mother insect has a choice among what kind of vegetables she shall deposit her young. In this manner these voracious creatures continue in the worm state, for more than three years, devouring the roots of every plant they approach, and making their way under ground, in quest of food, with great dispatch and facility. At length they grow to above the size of a walnut, being a great thick white maggot with a red head, which is seen most frequently in new-turned earth, and which is so eagerly sought after by birds of every species. When largest, they are found an inch and a half long, of a whitish yellow colour, with a body consisting of twelve segments or joints, on each side of which there are nine breathing-holes, and three red feet. The head is large in proportion to the body, of a reddish colour, with a pincer before, and a semi-circular lip, with which it cuts the roots of plants, and sucks out their moisture. As this insect lives entirely under ground, it has no occasion for eyes, and accordingly it is found to have none; but is furnished with two feelers, which, like the crutch of a blind man, serve to direct its motion. Such is the form of this animal, that lives for years in the worm state under ground, still voracious, and every year changing its skin.

It is not till the end of the fourth year, that this extraordinary insect prepares to emerge from its subterraneous abode, and even this is not effected but by a tedious preparation. About the latter end of autumn, the grub begins to perceive the approach of its transformation; it then buries itself deeper and deeper in the earth, sometimes six feet beneath the surface, and there forms itself a capacious apartment, the walls of which it renders very smooth and shining by the excretions of its body, its abode being thus formed, it begins, soon after, to shorten itself, to swell, and to burst its last skin, in order to assume the form of a chrysalis. This, in the beginning, appears of a yellowish colour, which heightens by degrees, till at last it is seen nearly red. Its exterior form plainly discovers all the vestiges of the future winged insect, all the foreparts being distinctly seen; while behind, the animal seems as if wrapped in swaddling clothes.

The young May-bug continues in this state for about three months longer; and it is not till the beginning of January, that the aurelia divests itself of all its impediments, and becomes a winged insect, completely formed. Yet still the animal is far from attaining its natural strength, health and appetite. It undergoes a kind of infant imbecility; and, un-

like most other insects, that the instant they become flies are arrived at their state of full perfection, the May-bug continues feeble and sickly. Its colour is much brighter than in the perfect animal, all its parts are soft, and its voracious nature seems, for a while, to have entirely forsaken it. As the animal is very often found in this state, it is supposed, by those unacquainted with its real history, that the old ones of the former season have buried themselves for the winter, in order to revisit the sun the ensuing summer. But the fact is, the old one never survives the season, but dies, like all the other winged tribe of insects, from the severity of cold in winter.

About the latter end of May, these insects, after having lived for four years under ground, burst from the earth, when the first mild evening invites them abroad. They are at that time seen rising from their long imprisonment, from living only upon roots, and imbibing only the moisture of the earth, to visit the mildness of the summer air, to choose the sweetest vegetables for their banquet, and to drink the dew of the evening. Wherever an attentive observer then walks abroad, he will see them bursting up before him in his pathway, like ghosts on a theatre. He will see every part of the earth, that had its surface beat into hardness, perforated by their egression. When the season is favourable for them, they are seen by myriads buzzing along, hitting against every object that intercepts their flight. The mid-day sun, however, seems too powerful for their constitutions; they then lurk under the leaves and branches of some shady tree; but the willow seems particularly their most favourite food; there they lurk in clusters, and seldom quit the tree till they have devoured all its verdure. In those seasons which are favourable to their propagation, they are seen in an evening as thick as flakes of snow, and hitting against every object with a sort of capricious blindness. Their duration, however, is but short, as they never survive the season. They begin to join shortly after they have been let loose from their prison, and when the female is impregnated, she cautiously bores a hole in the ground, with an instrument fitted for that purpose, which she is furnished with at the tail, and there deposits her eggs, generally to the number of threescore. If the season and the soil be adapted to their propagation, these soon multiply as already described, and go through the noxious stages of their contemptible existence. This insect, however, in its worm state, though prejudicial to man, makes one of the chief repasts of the feathered tribe, and is generally the first nourishment with which they supply their young. Rooks and hogs are particularly fond of these worms, and devour them in great numbers. The inhabitants of the county of Norfolk, some time since, went into the practice of destroying their rookeries, but in proportion as they destroyed one plague, they were pestered with a greater; and these insects multiplied in such an amazing abundance, as to destroy not only the verdure of the fields, but even the roots of vegetables not yet shot forth. One farm in particular was so injured by them in the year 1751, that the occupier was not able to pay his rent, and the landlord was content not only to lose his income for that year, but also gave money for the support of the farmer and his family. In Ireland they suffered so much by these insects, that they came to a resolution of setting fire to a wood of some miles in extent, to prevent their mischievous propagation.[1]

---

[1] *Grubs.*—We frequently, (says Mr Rennie, in his interesting work on Insect Transformations,) hear farmers and gardeners complaining that their produce is destroyed by "*the* grub;" they might with equal propriety accuse "*the* bird" when their ripe seeds are devoured by sparrows, chaffinches, linnets, and other seed-eaters. Instead of one sort of grub, as the expression seems to indicate, we are far under the mark in reckoning a thousand species indigenous to Britain, each peculiar in its food and its manners. We shall, however, adhere as nearly as possible to the terms in common use; but as the larvæ of the crane-flies (*Tipulidæ* Leach), being without legs, cannot be accurately ranked with the legged grubs of beetles, we shall consider them as maggots, though they are usually termed grubs by the farmers.

The most destructive, perhaps, of the creatures usually called grubs, are the larvæ of the may-bug or cockchafer (*Melolontha vulgaris*), but too well known, particularly in the southern and midland districts of England, as well as in Ireland, where the grub is called the Connaught worm; but fortunately not abundant in the north. We only once met with the cockchafer in Scotland, at Sorn, in Ayrshire. Even in the perfect state, this insect is not a little destructive to the leaves of both forest and fruit trees. In 1823, we remember to have observed almost all the trees about Dulwich and Camberwell defoliated by them; and Salisbury says, the leaves of the oaks in Richmond Park were so eaten by them, that scarcely an entire leaf was left. But it is in their previous larvæ state that they are most destructive, as we shall see by tracing their history.

The mother cockchafer, when about to lay her eggs, digs into the earth of a meadow or corn-field to the depth of a span, and deposits them in a cluster at the bottom of the excavation. Rösel, in order to watch their proceedings, put some females into glasses half-filled with earth, covered with a tuft of grass, and a piece of thin muslin. In a fortnight, he found some hundreds of eggs deposited, of an oval shape and a pale yellow colour. Placing the glass in a cellar, the eggs were hatched towards autumn, and the grubs increased remarkably in size. In the following May they fed so voraciously that they required a fresh turf every second day; and even this proving too scanty provender, he sowed in several garden pots a crop of peas, lentils, and salad, and when the plants came up, he put a pair of grubs in each pot; and in this manner he fed them through the second and third years. During this period, they cast their skins three or four times, going for this purpose deeper into the earth, and burrowing out a hole where they might effect their change undisturbed; and they do the same in winter, during which they become torpid and do not eat.

Of all the beetle kind this is the most numerous, and therefore deserves the chief attention of history. The numerous varieties of other kinds might repay the curiosity of the diligent observer, but we must be content in general to observe, that in the great outlines of their history, they resemble those of which we have just been giving a description; like them

---

When the grub changes into a pupa, in the third autumn after it is hatched, it digs a similar burrow about a yard deep; and when kept in a pot, and prevented from going deep enough, it shows great uneasiness and often dies. The perfect beetle comes forth from the pupa in

Transformations of the cockchafer (*Melolontha vulgaris*). *a*, newly hatched larvæ. *b*, larvæ, one year old. *c*, the same larvæ at the second year of its growth. *d*, the same three years old. *e*, section of a bank of earth, containing the chrysalis of the fourth year. *f*, the chafer first emerging from the earth. *g*, the perfect chafer in a sitting posture.

The following (*h*) represents the insect flying.

January or February; but it is then as soft as it was whilst still a grub, and does not acquire its hardness and colour for ten or twelve days, nor does it venture above ground before May, on the fourth year from the time of its hatching. At this time, the beetles may be observed issuing from their holes in the evening, and dashing themselves about in the air as if blind.

During the three summers then of their existence in the grub state, these insects do immense injury, burrowing between the turf and the soil, and devouring the roots of grass and other plants; so that the turf may easily be rolled off, as if cut by a turfing spade, while the soil underneath for an inch or more is turned into soft mould like the bed of a garden. Mr Anderson of Norwich, mentions having seen a whole field of fine flourishing grass so undermined by these grubs, that in a few weeks it became as dry, brittle, and withered as hay. Bingley also tells us that "about sixty years ago, a farm near Norwich was so infested with cockchafers, that the farmer and his servants affirmed they gathered eighty bushels of them; and the grubs had done so much injury, that the court of the city, in compassion to the poor fellow's misfortune, allowed him twenty-five pounds." In the year 1785, a farmer, near Blois, in France, employed a number of children and poor persons to destroy the cockchafers at the rate of two liards a hundred, and in a few days they collected fourteen thousand.

"I remember," says Salisbury, "seeing, in a nursery near Bagshot, several acres of young forest trees, particularly larch, the roots of which were completely destroyed by it, so much so, that not a single tree was left alive." We are doubtful, however, whether this was the grub of the cockchafer, and think it more likely to have been that of the green rose beetle (*Cetonia aurata*), which feeds on the roots of trees.

The grub of an allied genus, the midsummer chafer (*Zantheumia Solstitialis*, Leach), has for the last two years been abundant on Lewisham Hill, Blackheath, doing considerable injury to herbage and garden plants. This beetle may be known from being smaller and paler than the cockchafer, and from its not appearing before midsummer. The grub is very similar.

The best way of preventing the ravages of these insects would be to employ children to collect the perfect insects when they first appear, before they lay their eggs; but when a field is once overrun with the larvæ, nothing can be done with it, except paring and burning the surface, or ploughing it up, and turning in a flock of ducks or other poultry, or a drove of pigs, which are said to eat these grubs, and to fatten on the fare. Drenching the field with stable urine by means of reservoir carts, like those used for watering roads, would, if sufficiently done, both kill the grubs, and beneficially manure the land.

The grub called the *wire worm*, though not very appropriately, is the larvæ of one of the spring or click beetles (*Hemirhipus lineatus*, and *H. obscurus*, Latreille) known by their long flattish body, and their power of springing with a clicking sound out of the hand when caught. In some works on agriculture, the larvæ of a common crane fly (*Tipula oleracea* or *T. crocata*) is called the *wire worm*,—we suppose by mistake. The grubs of the click beetles, just alluded to, are said by Bierscander and by Mr Paul of Starston, Norfolk, who watched their transformations, to continue five years before producing the perfect insect. During this time the grub feeds chiefly on the roots of wheat, rye, oats, barley, and grass; but seems also sometimes to attack the larger roots of potatoes, carrots, and salads. Its ravages are often so extensive as to cut off entire crops of grain. It appears to be most partial to land newly broken up; and has not been found so abundant in meadows and pastures,

all other beetles are bred from the egg, which is deposited in the ground, or sometimes, though seldom, in the barks of trees, they change into a worm; they subsist in that state by living upon the roots of vegetables, or the succulent parts of the bark round them. They generally live a year at least before they change into an aurelia; in that state they are not entirely mo-

unless in fields recently laid down with grass. "The wire worm," says Spence, "is particularly destructive for a few years in gardens recently converted from pasture ground. In the botanic garden at Hull, thus circumstanced, a great proportion of the annuals sown in 1813 were destroyed by it. A very simple and effectual remedy, in such cases, was mentioned to me by Sir Joseph Banks. He recommended that slices of potatoes stuck upon skewers, should be buried near the seeds sown, examined every day, and the wire-worms, which collect upon them in great numbers, destroyed."

The wire worm is long, slender, and very tough and hard; but otherwise it has no resemblance to wire, being whitish in colour, of a flattish form, and jointed or ringed. Its breathing spiracles, two in number, are on the back of its last ring.

An insect of this family (*Elater noctilucus*, Linn.) is exceedingly destructive in the West Indies to the sugar-cane; the grub, according to Humboldt and Bonpland, feeding on its roots and killing the plants. . . . . The insect most destructive to our peas is the pulse beetle (*Bruchus granarius*, Linn.), which sometimes lays an egg on every pea in a pod, which the grub, when hatched, destroys. In the same way, clover seed is often attacked by two or more species of small weevil (*Apion*, Herbst), known by the yellow colour of their thighs or their feet; and when the farmer expects to reap considerable profit, he finds nothing but empty husks.

Great ravages are committed in granaries by the caterpillars of small moths; but these are rivalled in the work of destruction by several species of grubs. One of these grubs is called by the French cadelle (*Trogosita mauritanica*, Olivier), and is reported to have done more damage to housed grain than any other insect.* The pest of the granaries, which is but too well known in this country, is the grain weevil (*Calandra granaria*, Clairville), the same, probably, which is mentioned by Virgil,

> ——— Populatque ingentem farris acervum
> Curculio. *Georg.* i. 87.
>
> ——— The high stacks of corn
> Are wasted by the weevil. *Trapp.*

Kirby and Spence calculate that a single pair of weevils may produce in one season 6000 descendants; and they were told by an extensive brewer that he had collected and destroyed them by bushels,—meaning, no doubt, insects and damaged grain together.

Another beetle grub, popularly called the meal worm, the larvæ of *Tenebrio molitor*, Linn., which lives in that state two years, does no little damage to flour, as well as to bread, cakes, biscuit, and similar articles. Accounts are also given of the ravages committed by the grubs of other beetles, of several species, apparently not well ascertained, upon different sorts of provisions, such as bacon, ham, dried tongues, ship-biscuit, &c. Sparrman tells us, that he has witnessed the ground peas on ship-board so infested with these grubs, that they were seen in every spoonful of the soup. In the case of soup, or of other food which has been exposed to heat, the only inconvenience is the disgust which must ensue; but, unfortunately, there may sometimes occur circumstances of a more serious nature,—from either the eggs or the insects themselves being incautiously swallowed alive. We do not wish, however, to create, so much as to allay, the fears entertained by those who are unacquainted with the habits of insects; and nothing, we are persuaded, will do this more effectually than a statement of facts well ascertained. "Several people," says Abbé de la pluche, "never eat fruit because they believe that spiders and other insects scatter their eggs upon it at random; but even if it were so, as it is not, it would be impossible for the young, should they be hatched in the stomach, to live there for an instant."

Adhering (continues Mr Rennie) to the distinction of terming those larvæ which are destitute of feet, *maggots*, we shall notice here a very destructive one, which is sometimes popularly called *the* grub, and sometimes confounded with the wire worm. We allude to the larva of one or two common species of crane flies (*Tipulidæ*), well known by the provincial names of father-long-legs, Jenny-spinners, and tailors. These insects are so common in some meadows, that, being very shy and fearful of danger, they rise in swarms at every step—some of them flying high, others only skipping over the grass, and others running and using their long legs as the inhabitants of marshy countries use stilts, and employing their wings like the ostrich to aid their limbs.

These flies deposit their eggs in the earth; sometimes in grass fields or moist meadows, and sometimes in the tilled ground of gardens and farms. For this purpose the female is provided with an ovipositor well adapted to the operation, consisting of a sort of pincer or forceps of a horny consistence, and sharp at the point. By pressure, as Réaumur says, the eggs may be extruded from this in the same way as the stone can be easily squeezed out of a ripe cherry.

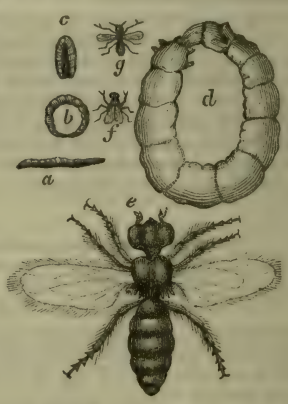
The eggs are exceedingly small and black, like grains of gunpowder, and each female lays a good many hundreds. The position which she assumes appears somewhat awkward, for she raises herself perpendicularly on her two hind legs, using her ovipositor as a point of support, and resting with her fore legs upon the contiguous herbage. She then thrusts her ovipositor into the ground as far as the first ring of her body, and leaves one or more eggs in the hole; and next moves onwards to another place, but without bringing herself into a horizontal position. The maggot, when hatched from the egg, immediately attacks the roots of the grass and other herbage which it finds nearest to it; and of course the portion of the plant above ground withers for lack of nourishment. In many districts of England these insects cut off a large proportion of the wheat crop, particularly, it would appear, when it has been sown on clover leys.

The maggot of a minute fly of the same family, known by the name of the wheat fly, (*Cecidomyia Tritici*, Kirby), is frequently productive of great damage in the crops of wheat. The parent fly is very small, not unlike a midge (*Culicoides punctata*, Latr.), of an orange colour, and wings rounded at the tip, and fringed with hairs. The female is furnished with a retractile ovipositor, four times as long as the body, and as fine as a hair, for depositing her eggs, which she does in the glumes of the florets of the grain.

The *Hessian fly* of America is a little larger than our wheat fly, more slender in the body, has longer legs, and is not orange, but black and fulvous. The female deposits from one to eight or more eggs on a single plant of wheat, between the sheath of the inner leaf and the stem nearest the roots; in which situation, with its head towards the root or first joint, the young larva passes the winter, eating into the stem, and causing it to break.

The devastation committed by the Hessian fly seems to have been first observed in 1776, and it was erroneously supposed that the insect was conveyed among straw by the Hessian troops from Germany. It was first

* Oliver, ii. 19.



tionless, nor entirely swaddled up without form.

It would be tedious and endless to give a description of all; and yet it would be an unpardonable omission not to mention the particularities of some beetles, which are singular rather from their size, their manners, or their formation. That beetle, which the Americans call the Tumble-dung, particularly demands our attention; it is all over of a dusky black, rounder than those animals are generally found to be, and so strong, though not much larger than the common black beetle, that if one of them be put under a brass candlestick, it will cause it to move backwards and forwards, as if it were by an invisible hand, to the admiration of those who are not accustomed to the sight; but this strength is given it for much more useful purposes than those of exciting human curiosity, for there is no creature more laborious, either in seeking subsistence, or in providing a proper retreat for its young. They are endowed with sagacity to discover subsistence by their excellent smelling, which directs them in flights to excrements just fallen from man or beast, on which they instantly drop, and fall unanimously to work in forming round balls or pellets thereof, in the middle of

noticed in the wheat fields of Long Island, from which it spread gradually at the rate of fifteen or twenty miles round; and in 1789 it had advanced two hundred miles from its original station in Long Island. Other accounts state that it did not travel more than seven miles annually, and did little serious damage before 1788. Their numbers seem almost incredible. The houses in the infested districts swarmed with them to so great a degree, that every vessel was filled with them; five hundred were actually counted on a glass tumbler which had been set down for a few minutes with a little beer in it. They were observed crossing the Delaware river like a cloud; and even mountains do not seem to interrupt their progress. We can well understand, therefore, that so formidable a ravager should have caused a very great alarm; and even our own government was in fear lest the insect should be imported. The privy council, indeed, sat day after day in deep consultation what measures should be adopted to ward off the danger of a calamity more to be dreaded, as they well knew, than the plague or the pestilence. Expresses were sent off in all directions to the officers of the customs at the different outports respecting the examination of cargoes,—despatches were written to the ambassadors in France, Austria, Prussia, and America, to gain information,—and so important altogether was the business deemed, that the minutes of council, and the documents collected from all quarters, fill upwards of two hundred pages.

The cheese fly (*Piophila Casei*, Fallen) is very small and black, with whitish wings margined with black. It was one of those experimented upon by Redi to prove that insects, in the fabric of which so much art, order, contrivance, and wisdom appear, could not be the production of chance or rottenness, but the work of the same Omnipotent hand which created the heavens and the earth. This tiny little fly is accordingly furnished with an admirable instrument for depositing its eggs, in an ovipositor, which it can thrust out and extend to a great length, so that it can penetrate to a considerable depth into the cracks of cheese, where it lays its eggs, 256 in number. "I have seen them myself," says Swammerdam, "thrust out their tails for this purpose to an amazing length, and by that method bury the eggs in the deepest cavities. I found in a few days afterwards a number of maggots which had sprung from those eggs, perfectly resembling those of the first brood that had produced the mother fly. I cannot but also take notice that the rottenness of cheese is really caused by these maggots; for they both crumble the substance of it into small particles and also moisten it with some sort of liquid, so that the decayed part rapidly spreads. I once observed a cheese which I had purposely exposed to this kind of fly grow moist in a short time in those parts of it where eggs had been deposited, and had afterwards been hatched into maggots; though, before, the cheese was perfectly sound and entire."

The cheese-hopper is furnished with two horny claw-shaped mandibles, which it uses both for digging into the cheese and for moving itself, being destitute of feet. Its powers of leaping have been observed by every one; and Swammerdam says, "I have seen one, whose length did not exceed the fourth of an inch, leap out of a box six inches deep, that is, twenty-four times the length of its own body: others leap a great deal higher." For this purpose it first erects itself on its tail, which is furnished with two wart-like projections, to enable it to maintain its balance. It then bends itself into a circle, catches the skin near its tail with its hooked mandibles, and after strongly contracting itself from a circular into an oblong form, it throws itself with a jerk into a straight line, and thus makes the leap.

Cheese hoppers (*Piophila casei*, Fallen). *a*, the maggot extended; *b*, in a leaping position; *d*, the same magnified; *e*, the fly magnified; *f*, *g*, the fly, natural size.

One very surprising provision is remarkable in the breathing-tubes of the cheese maggot, which are not placed, as in caterpillars, along the sides, but a pair near the head and another pair near the tail. Now, when burrowing in the moist cheese, these would be apt to be obstructed; but to prevent this, it has the power of bringing over the front pair a fold of the skin, breathing in the meanwhile through the under pair. Well may Swammerdam denominate these contrivances "surprising miracles of God's power and wisdom in this abject creature."

Like the other destructive insects above mentioned, the multiplication of the cheese fly is checked by some insect, whose history, so far as we are aware, is not yet known. Swammerdam found many of the maggots with other larvæ in their bodies; but he did not trace their transformations. If they were the larva of an ichneumon it must be exceedingly minute.

which they lay an egg. These pellets, in September, they convey three feet deep in the earth, where they lie till the approach of spring; when the eggs are hatched the nests burst, and the insects find their way out of the earth. They assist each other with indefatigable industry, in rolling these globular pellets to the place where they are to be buried. This they are to perform with the tail foremost, by raising up their hinder part, and shoving along the ball with their hind-feet. They are always accompanied with other beetles of a larger size, and of a more elegant structure and colour. The breast of this is covered with a shield of a crimson colour, and shining like metal; the head is of the like colour, mixed with green, and on the crown of the head stands a shining black horn, bended backwards. These are called the kings of the beetles; but for what reason is uncertain, since they partake of the same dirty drudgery with the rest.[1]

[1] The scientific name for beetles is *Coleoptera*. They are readily distinguished, (says Mr Duncan, in the Naturalist's Library,) from other insects, by having the inferior wings covered and protected by a hard case or shell. This peculiarity of structure has suggested the name, which is composed of two Greek words, and signifies *wings in a sheath* (κολεος, a *sheath*, and πτερα, *wings*). The term was first used by Aristotle, and as the character to which it refers forms a very obvious mark of distinction, it has been almost universally adopted by subsequent writers. In several instances, however, it fails to be an accurate definition of the order, for there are some beetles without either wings or sheath, and many others in which the latter only is present. To the other characters more recently added, such as the transverse folding of the wings, and the straight sutural line down the middle of the wingcases, separating them into two equal portions, there are likewise exceptions; but these are too few and unimportant to invalidate materially the general correctness of the definition.

The insects to which these characters apply, constitute one of the most numerous orders of their class. In this country alone, they amount, by the latest and most accurate *census*, to upwards of 3600, thus forming nearly a third part of our entire insect population. This is considerably more than double the number of phanogamous or flowering plants indigenous to Britain, and greatly exceeds the whole amount of our native vertebrate animals. When compared with the two other orders that are next to it in extent in this country, it will be found that the Coleoptera are nearly one half more numerous than the Lepidoptera, and that they stand much in the same relation to the Diptera or two winged flies. Of the latter, indeed, all the species ascertained to inhabit Europe scarcely exceed the amount of British Coleoptera; for the most accurate enumeration of the European Diptera which we possess makes them about 3760. The native Coleoptera of Sweden, according to the enumeration of them given by Gyllenhal, in his admirable *Insecta Suecica*, are about 4700 in number. In advancing southwards, these insects increase in a ratio similar to what is observed in other departments of nature; and in countries under the tropics, so redundant in every kind of animal life, they may be said absolutely to swarm. We are without sufficient data, however, from which to form an accurate estimate of their total amount. Some years since, the collection of the Count de Jean at Paris, one of the most extensive that exists, contained no fewer than 20,000 species. Many others are no doubt to be found in different collections; and when we take into account the discoveries daily made by the numerous cultivators of this branch of zoology, and the extent and fertility of the countries with the insect productions of which we are wholly unacquainted, there seems reason to believe that it cannot be much short of 30,000—that is, 10,000 above the estimate formed by Ray nearly a century and a half ago, as the probable amount of the whole class of insects!

The Elephant-Beetle is the largest of this kind hitherto known, and is found in South America, particularly Guiana and Surinam, as well as about the river Oroonoko. It is of

This order comprehends some of the largest as well as the most minute insects with which we are acquainted. Certain *orthopterous* species belonging to the genus *Phasma* surpass them in length, and several gigantic moths are of greater superficial extent; but in many beetles length of body is combined with a proportionate breadth and thickness, which renders them the most bulky and massive of their class. A fine specimen of Prionus giganteus measures nearly half a foot in length, the breadth is about two inches, and the expansion of the wings is nine inches. A handsome and scarce species of the same family (*Prionus armillatus*) is about five inches long and one inch and three quarters broad, and the antennæ, which are very strong and rigid, are upwards of six inches in length. The Hercules beetle (*Dynastes Hercules*), and Scarabæus Actæon, measure respectively about four and a half inches in length including the horns. The largest coleopterous insects inhabiting Britain are the *Hydröus piceus*, and the Stag-beetle (*Lucanus cervus*). The latter is nearly two inches in length, including the mandibles; and the former is not much short of the same dimensions, besides being of considerably greater breadth. These may be regarded as the giants of this order of insects, occupying one extremity of the scale. At the opposite extremity may be placed some species of the genera Trichopteryx, Atomaria, and Agathidium, which are so minute as not to exceed one-eighth part of a line in length;* or, to adopt an illustration sometimes employed, they are absolutely not bigger than the full stop that closes this period.

The structure of these minute beings is perhaps even more calculated to excite our admiration than that of the larger animals. In the latter, most of the parts are of sufficient size to come within the direct cognisance of our senses, and there is no apparent discrepancy between their dimensions and the functions which they perform; but when we reflect that a mere animated point, almost invisible to the naked eye, possesses all the attributes which belong to the largest of its race—that it is furnished with an external covering made up of many parts adjusted to each other with the nicest accuracy—that it is supplied with all the requisite organs of sense and motion, and has a nervous and respiratory system of greater complexity than many of the larger animals—that the various processes of digestion, assimilation, and secretion, are continually going forward—that not a limb can be put in motion without calling into play a multitude of muscles—and that this atomic being is moreover endowed with instincts which regulate with almost unerring certainty all its habits and economy—we can scarcely fail to regard it as affording a more striking instance of consummate skill than if it had occupied a much larger space.

> "The shapely limb, and lubricated joint,
> Within the small dimensions of a point,
> Muscle and nerve miraculously spun,
> His mighty work, who speaks and it is done;
> The invisible in things scarce seen revealed,
> To whom an atom is an ample field."

* A line is the twelfth part of a French inch.

a black colour, and the whole body is covered with a very hard shell, full as thick and as strong as that of a small crab. Its length, from the hinder part to the eyes, is almost four inches, and from the same part to the end of the proboscis, or trunk, four inches and three quarters. The transverse diameter of the body is two inches and a quarter, and the breadth of each elytron, or case for the wings, is an inch and three-tenths. The antennæ, or feelers, are quite horny ; for which reason the proboscis, or trunk, is movable at its insertion into the head, and seems to supply the place of feelers. The horns are eight-tenths of an inch long, and terminate in points. The proboscis is an inch and a quarter long, and turns upwards, making a crooked line, terminating in two horns, each of which is near a quarter of an inch long ; but they are not perforated at the end like the proboscis of other insects. About four-tenths of an inch above the head, on that side next the body, is a prominence or small horn, which, if the rest of the trunk were away, would cause this part to resemble the horn of a rhinoceros. There is indeed a beetle so called, but then the horns or trunk has no fork at the end, though the lower horn resembles this. The feet are all forked at the end, but not like lobster's claws.

To this class we may also refer the Glow-worm, that little animal which makes such a distinguished figure in the descriptions of our poets. No two insects can differ more than the male and female of this species from each other. The male is in every respect a beetle, having cases to its wings, and rising in the air at pleasure ; the female, on the contrary, has none, but is entirely a creeping insect, and is obliged to wait the approaches of her capricious companion. The body of the female has eleven joints, with a shield breast-plate, the shape of which is oval ; the head is placed over this, and is very small, and the three last joints of her body are of a yellowish colour ; but what distinguishes it from all other animals, at least in this part of the world, is the shining light which it emits by night, and which is supposed by some philosophers to be an emanation which she sends forth to allure the male to her company. Most travellers who have gone through sandy countries, must well remember the little shining sparks with which the ditches are studded on each side of the road. If incited by curiosity to approach more nearly, he will find this light sent forth by the glow-worm ; if he should keep the little animal for some time, its light continues to grow paler, and at last appears totally extinct. The manner in which this light is produced has hitherto continued inexplicable ; it is probable the little animal is supplied with some electrical powers, so that by rubbing the joints of its body against each other, it thus supplies a stream of light, which if it allures the male, as we are told, serves for very useful purposes.[1]

If superiority in certain qualities must be conceded to some other tribes of insects, the Coleoptera certainly surpass them all, as well as the higher races of animals, in variety of form and singularity of structure. Among butterflies, the *Hymenoptera*, and two-winged flies, nearly as great a uniformity of outline prevails as in the case of birds and serpents. But there appears to be no general type of form according to which beetles have been modelled. They differ as widely among themselves in outward appearance, as separate classes of other animated beings do from each other. Even the great deep, which has ever been regarded as the fertile mother of all monstrous and all prodigious things, seldom produces an "odd fish" equal in eccentricity to some species of beetles. If we are less struck with the strange proportion of their parts, than with any unusual figure among the larger animals, it is on account of their small size, which is generally too inconsiderable to arrest our attention, and leads us to consider them in a great measure abstractedly from the idea of physical power with which we are accustomed to regard animated beings of large dimensions. But for this circumstance, they would excite the astonishment of the most careless observer, and lead us to fear lest they should realize the anticipations of the poet,—

> "Their shape would make them, had they bulk and size,
> More hideous foes then fancy can devise,
> With helmet-heads, and dragon-scales adorned,
> The mighty myriads, now securely scorned,
> Would mock the majesty of man's high birth,
> Despise his bulwarks, and unpeople earth."

—*Naturalist's Library, Vol. II. Beetles. By James Duncan. Edinburgh*, 1835.

[1] We boast of our candles, our wax-lights, and our Argand-lamps, and pity our fellow-men who, ignorant of our methods of producing artificial light, are condemned to pass their nights in darkness. We regard these inventions as the results of a great exertion of human intellect, and never conceive it possible that other animals are able to avail themselves of modes of illumination equally efficient; and are furnished with the means of guiding their nocturnal evolutions by actual lights, similar in their effect to those which we make use of. Yet many insects are thus provided. Some are forced to content themselves with a single candle, not more vivid than the rush-light which glimmers in the peasant's cottage ; others exhibit two or four, which cast a stronger radiance ; and a few can display a lamp little inferior in brilliancy to some of ours. Not that these insects are actually possessed of candles and lamps. You are aware that I am speaking figuratively. But Providence has supplied them with an effectual substitute—a luminous preparation or secretion, which has all the advantages of our lamps and candles, without their inconveniences ; which gives light sufficient to direct their motions, while it is incapable of burning ; and whose lustre is maintained without needing fresh supplies of oil or the application of the snuffers.

Of the insects thus singularly provided, the common glow-worm (*Lampyris noctiluca*) is the most familiar instance. Who that has ever enjoyed the luxury of a summer evening's walk in the country, in the southern parts of our island, but has viewed with admiration these "stars of the earth and diamonds of the night?" And if, living like me in a district where it is rarely met with, the first time you saw this insect, chanced to be, as it was in my case, one of those delightful evenings which

The Cantharis is of the beetle kind, from whence come cantharides, well known in the shops by the name of Spanish flies, and for their use in blisters. They have feelers like bristles, flexible cases to the wings, a breast pretty plain, and the sides of the belly wrinkled. Cantharides differ from each other in their size, shape, and colour; those used in the

---

an English summer seldom yields, when not a breeze disturbs the balmy air, and "every sense is joy," and hundreds of these radiant worms, studding their mossy couch with mild effulgence, were presented to your wondering eye in the course of a quarter of a mile—you could not help associating with the name of glow-worm the most pleasing recollections. No wonder that an insect, which chiefly exhibits itself on occasions so interesting, and whose economy is so remarkable, should have afforded exquisite images and illustrations to those poets who have cultivated natural history.

If you take one of these glow-worms home with you for examination, you will find that in shape it somewhat resembles a caterpillar, only that it is much more depressed; and you will observe that the light proceeds from a pale-coloured patch that terminates the underside of the abdomen. It is not, however, the larva of an insect, but the perfect female of a winged beetle, from which it is altogether so different, that nothing but actual observation could have inferred the fact of their being the sexes of the same insect. In the course of your inquiries, you will find that sexual differences even more extraordinary exist in the insect world.

It has been supposed by many that the males of the different species of *Lampyris* do not possess the property of giving out any light; but it is now ascertained that this supposition is inaccurate, though their light is much less vivid than that of the female. Ray first pointed out this fact with respect to *L. noctiluca*. Geoffroy also observed that the male of this species has four small luminous points, two on each of the two last segments of the belly; and his observation has been recently confirmed by Muller. This last entomologist, indeed, saw only two shining spots; but from the insect's having the power of withdrawing them out of sight, so that not the smallest trace of light remains, he thinks it is not improbable that at times two other points still smaller may be exhibited, as Geoffroy has described. In the males of *L. splendidula* and of *L. hemiptera* the light is very distinct, and may be seen in the former while flying. The females have the same faculty of extinguishing or concealing their light—a very necessary provision to guard them from the attacks of the nightingale and other nocturnal birds. Mr White even thinks that they regularly put it out between eleven and twelve every night; and they have also the power of rendering it for awhile more vivid than ordinary.

Authors who have noticed the luminous parts of the common female glow-worm, having usually contented themselves with stating that the light issues from the three last ventral segments of the abdomen. I shall give you the result of some observations I once made upon this subject. One evening, in the beginning of July, meeting with two of these insects, I placed them on my hand. At first their light was exceedingly brilliant, so as to appear even at the junctions of the upper or dorsal segments of the abdomen. Soon after I had taken them, one withdrew its light altogether, but the other continued to shine. While it did this, it was laid upon its back, the abdomen forming an angle with the rest of its body, and the last or anal segment being kept in constant motion. This segment was distinguished by two round and very vivid spots of light; which, in the specimen that had ceased to shine, were the last that disappeared, and they seem to be the first parts that become luminous, when the animal is disposed to yield its light. The penultimate and antepenultimate segments each exhibited a middle transverse band of yellow radiance, terminated towards the trunk by an obtusely-dentated line; a greener and fainter light being emitted by the rest of the segment.

Though many of the females of the different species of *Lampyris* are without wings, and even elytra, (in which circumstance they differ from all other apterous *Coleoptera*,) this is not the case with all. The female of *L. Italica*, a species common in Italy, and which, if we may trust to the accuracy of the account given by Mr Waller in the *Philosophical Transactions* for 1684, would seem to have been taken by him in Hertfordshire, is winged; and when a number of these moving stars are seen to dart through the air in a dark night, nothing can have a more beautiful effect. Dr Smith tells us that the beaus of Italy are accustomed in an evening to adorn the heads of the ladies with these artificial diamonds, by sticking them into their hair; and a similar custom prevails amongst the ladies of India.

Besides the different species of the genus *Lampyris*, all of which are probably more or less luminous, another insect of the beetle tribe, *Elater noctilucus*, is endowed with the same property, and that in a much higher degree. This insect, which is an inch long, and about one-third of an inch broad, gives out its principal light from two transparent eye-like tubercles placed upon the thorax; but there are also two luminous patches concealed under the elytra, which are not visible except when the insect is flying, at which time it appears adorned with four brilliant gems of the most beautiful golden-blue lustre; in fact, the whole body is full of light, which shines out between the abdominal segments when stretched. The light emitted by the two thoracic tubercles alone is so considerable, that the smallest print may be read by moving one of these insects along the lines; and in the West India Islands, particularly in St Domingo, where they are very common, the natives were formerly accustomed to employ these living lamps, which they called *Cucuij*, instead of candles in performing their evening household occupations. In travelling at night, they used to tie one to each great toe; and in fishing and hunting required no other flambeau. Southey has happily introduced this insect in his "*Madoc*," as furnishing the lamp by which Coatal rescued the British hero from the hands of the Mexican priests.

> "She beckoned and descended, and drew out
> From underneath her vest a cage, or net
> It rather might be called, so fine the twigs
> Which knit it, where confined, two fire-flies gave
> Their lustre. By that light did Madoc first
> Behold the features of his lovely guide."

The brilliant nocturnal spectacle presented by these insects to the inhabitants of the countries where they abound, cannot be better described than in the language of the poet above referred to, who has thus related its first effect upon the British visitors of the New World:—

> "Sorrowing we beheld
> The night come on; but soon did night display
> More wonders than it veil'd: innumerous tribes
> From the wood cover swarm'd, and darkness made
> Their beauties visible: one while they streamed
> A bright blue radiance upon flowers that closed
> Their gorgeous colours from the eye of day;
> Now motionless and dark, eluded search,
> Self-shrouded; and anon, starring the sky,
> Rose like a shower of fire."

With regard to the immediate source of the luminous properties of these insects, Mr Macartney, to whom we are indebted for the most recent investigation on the

shops also do the same. The largest in these parts are about an inch long, and as much in circumference, but others are not above three quarters of an inch. Some are of a pure azure colour, others of a pure gold, and others again have a mixture of pure gold and azure colours; but they are all very brilliant, and extremely beautiful. These insects, as is well known,

subject, has ascertained that in the common glow-worm, and in *Elater noctilucus* and *ignitus*, the light proceeds from masses of a substance not generally differing, except in its yellow colour, from the instertitial substance (*corps graisseux*) of the rest of the body, closely applied underneath those transparent parts of the insect's skin which afford the light. In the glow-worm, besides the last-mentioned substance, which, when the season for giving light is passed, is absorbed, and replaced by the common instertitial substance, he observed on the inner side of the last abdominal segment two minute oval sacs formed of an elastic spirally-wound fibre similar to that of the tracheæ, containing a soft yellow substance of a closer texture than that which lines the adjoining region, and affording a more permanent and brilliant light. This light he found to be less under the control of the insect, than that from the adjoining luminous substance, which it has the power of voluntarily extinguishing, not by retracting it under a membrane, as Carradori imagined, but by some inscrutable change dependent upon its will; and when the latter substance was extracted from living glow-worms, it afforded no light, while the two sacs in like circumstances shone uninterruptedly for several hours. Mr Macartney conceives, from the radiated structure of the instertitial substance surrounding the oval yellow masses immediately under the transparent spots in the thorax of *Elater noctilucus*, and the sub-transparency of the adjoining crust, that the instertitial substance in this situation has also the property of shining—a supposition which, if De Geer and other authors be correct in stating that this insect has two luminous patches under its elytra, and that the incisures between the abdominal segments shine when stretched, may probably be extended to the *whole* of the instertitial substance of its body. What peculiar organization contributes to the production of light in the hollow projections of *Fulgora laternaria* and *candelaria*, the hollow antennæ of *Pausus sphærocerus*, and under the whole integument of *Scolopendra electrica*, Mr Macartney was unable to ascertain. Respecting this last he remarks, what I have myself observed, that there is an apparent effusion of a luminous fluid on its surface, that may be received upon the hand, which exhibits a phosphoric light for a few seconds afterwards; and that it will not shine unless it have been previously exposed for a short time to the solar light.*

With respect to the remote cause of the luminous property of insects, philosophers are considerably divided in opinion. The disciples of modern chemistry have, in general, with Dr Darwin, referred it to the slow combustion of some combination of phosphorus secreted from their fluids by an appropriate organization, and entering into combination with the oxygen supplied in respiration. This opinion is very plausibly built upon the ascertained existence of phosphoric acid as an animal secretion; the great resemblance between the light of phosphorus in slow combustion and animal light; the remarkably large spiracula in glow-worms; and upon the statement that the light of the glow-worm is rendered more brilliant by the application of heat and oxygen gas, and is extinguished by cold and by hydrogen and carbonic acid gases. From these last facts, Spallanzani was led to regard the luminous matter as a compound of hydrogen and carbonated hydrogen gas. Carradori having found that the luminous portion of the belly of the Italian glow-worm (*Lampyris italica*) shone in vacuo, in oil, in water, and when under other circumstances where the pressure of oxygen gas was precluded, with Brugnatelli ascribed the property in question to the imbibition of light separated from the food or air taken into the body, and afterwards secreted in a sensible form. Lastly, Mr Macartney having ascertained by experiment that the light of a glow-worm is not diminished by immersion in water, or increased by the application of heat; that the substance affording it, though poetically employed for lighting the fairies' tapers, is incapable of inflammation if applied to the flame of a candle or red-hot iron; and when separated from the body, exhibits no sensible heat on the thermometer's being applied to it—rejects the preceding hypothesis as unsatisfactory, but without substituting any other explanation; suggesting, however, that the facts he observed are more favourable to the supposition of light being a quality of matter than a substance.

Which of these opinions is the more correct, I do not pretend to decide. But though the experiments of Mr Macartney seem fairly to bear him out in denying the existence of any ordinary combination of phosphorus in luminous insects, there exists a contradiction in many of the statements, which requires reconciling before final decision can be pronounced. The different results obtained by Forster and Spallanzani, who assert that glow-worms shine more brilliantly in oxygen gas, and by Beckerheim, Dr Hulme, and Sir H. Davy, who could perceive no such effect, may perhaps be accounted for by the supposition that in the latter instances the insects having been taken more recently, might be less sensible to the stimulus of the gas than in the former, where possibly their irritability was, as Brown would say, accumulated by a longer abstinence: but it is not so easy to reconcile the experiment of Sir H. Davy, who found the light of the glow-worm not to be sensibly diminished in hydrogen gas, with those of Spallanzani and Dr Hulme, who found it to be extinguished by the same gas, as well as by carbonic acid, nitrous and sulphurated hydrogen gases. Possibly some of these contradictory results were occasioned by not adverting to the faculty which the living insect possesses of extinguishing its lights at pleasure; or different philosophers may have experimented on different species of Lampyris.

The general use of this singular provision is not much more satisfactorily ascertained than its nature. I have before conjectured—and in an instance I then related it seemed to be so—that it may be a means of defence against their enemies. In different kinds of insects, however, it may probably have a different object. Thus, in the lantern-flies (*Fulgora*) whose light precedes them, it may act the part that their name imports, enabling them to discover their prey, and to steer themselves safely in the night. In the fire-flies, (*Elater*) if we consider the infinite numbers that in certain climates and situations present themselves every where in the night, it may distract the attention of their enemies or alarm them. And in the glow-worm—since their light is usually most brilliant in the female; in some species, if not all, present only in the season when the sexes are destined to meet; and strikingly more vivid at the very moment when the meeting takes place—besides the above uses, it is most probably intended to conduct the sexes to each other. This seems evidently the design in view in those species in which, as in the common glow-worm, (*L. noctiluca, L.*) the females are apterous. The torch which the wingless female, doomed to crawl upon the grass, lights up at the approach of night, is a beacon which unerringly guides the vagrant male to her

* *Phil. Trans.* 1810, p. 281.—Mr Macartney's statement on this point is not very clear. He probably means that the insect will not shine in a dark place in the *day time*, unless previously exposed to the solar light: for it is often seen to shine at night when it could have had no *recent* exposure to the sun.

are of the greatest benefit to mankind, making a part in many medicines conducive to human preservation. They are chiefly natives of Spain, Italy, and Portugal; but they are to be met with also about Paris in the summer time, upon the leaves of the ash, the poplar, and the rose-trees, and also among wheat, and in meadows. It is very certain, that these insects are fond of ash-leaves, insomuch that they will sometimes strip one of these trees quite bare. Some affirm that these flies delight in sweet smelling herbs; and it is very certain, that they are fond of honey-suckles, lilac, and wild-cherry shrubs; but some that have sought after them declare they never could find them on elder-trees, nut-trees, and among wheat. We are told that the country people expect the return of these insects every seven years. It is very certain, that such a number of these insects have been seen together in the air, that they appeared like swarms of bees; and that they have so disagreeable a smell, that it may be perceived a great way off, especially about sun-set, though they are not seen at that time. This bad smell is a guide for those who make it their business to catch them. When they are caught they dry them, after which they are so light, that fifty will hardly weigh a drachm. Those that gather them tie them in a bag, or a piece of linen cloth, that has been well worn, and then they kill them with the vapours of hot vinegar, after which they dry them in the sun, and keep them in boxes. These flies, thus dried, being chemically analysed, yield a great deal of volatile caustic salt, mixed with a little oil, phlegm, and earth. Cantharides are penetrating, corrosive, and, applied to the skin, raise blisters, from whence proceeds a great deal of serosity. They are made use of both inwardly and outwardly. However, it is somewhat strange that the effects of these flies should fall principally upon the urinary passages; for though some authors have endeavoured to account for this, we are still in the dark, for all they have said amounts to no more than that they affect these parts in a manner which may be very learnedly described, but very obscurely comprehended.

An insect of great, though perhaps not equal use in medicine, is that which is known by the name of the Kermes; it is produced in the excrescence of an oak, called the berry-bearing ilex, and appears at first wrapped up in a membranaceous bladder, of the size of a pea, smooth and shining, of a brownish-red colour, and covered with a very fine ash-coloured powder. This bag teems with a number of reddish eggs or insects, which being rubbed with the fingers pour out a crimson liquor. It is only met with in warm countries in the months of May and June. In the month of April this insect becomes of the size and shape of a pea, and its eggs some time after burst from the womb, and soon turning worms, run about the branches and leaves of the tree. They are of two sexes, and the females have been hitherto described; but the males are very distinct from the former, and are a sort of small flies like gnats, with six feet, of which the four forward are short, and the two backward long, divided into four joints and armed with three crooked nails. There are two feelers on the head, a line and a half long, which are movable, streaked, and articulated. The tail, at the back part of the body, is half a line long, and forked. The whole body is covered with two transparent wings, and they leap about in the manner of fleas. The harvest of the kermes is greater or less in proportion to the severity of the winter, and the women gather them before sun-rising, tearing them off with their nails, for fear there should be any loss from the hatching of the insects. They sprinkle them with vinegar, and lay them in the sun to dry, where they acquire a red colour.

An insect, perhaps, still more useful than either of the former, is the Cochineal, which has been variously described by authors; some have supposed it a vegetable excrescence from the tree upon which it is found; some have described it as a louse; some, as a bug; and some, as a beetle. As they appear in our shops when brought from America, they are of an irregular shape, convex on one side, and a little concave on the other; but are both marked with transverse streaks or wrinkles. They are of a scarlet colour within, and without of a blackish red, and sometimes of a white, reddish, or ash colour, which are accounted the best, and are brought us from Mexico. The cochineal insect is of an oval form, of the size of a small pea, with six feet, and a snout or trunk. It brings forth its

---

"love-illumined form," however obscure the place of her abode. It has been objected, however, to this explanation, that—since both larva and pupa, as De Geer observed, and the males shine as well as the females—the meeting of the sexes can scarcely be the object of their luminous provision. But this difficulty appears to me easily surmounted. As the light proceeds from a peculiarly organized substance, which probably must in part be elaborated in the larva and pupa states, there seems nothing inconsistent in the fact of *some* light being then emitted, with the supposition of its being destined solely for use in the perfect state: and the circumstance of the male having the same luminous property, no more proves that the superior brilliancy of the female is not intended for conducting him to her, than the existence of nipples and sometimes of milk in man, proves that the breast of woman is not meant for the support of her offspring. We often see, without being able to account for the fact, except on Sir E. Home's idea, that the sex of the ovum is undetermined, traces of an organization in one sex indisputably intended for the sole use of the other.—*Introduction to Entomology, by Kirby and Spence.*

young alive, and is nourished by sucking the juice of the plant. Its body consists of several rings, and when it is once fixed on the plant, it continues immovable, being subject to no change. Some pretend there are two sorts, the one domestic, which is best; and the other wild, that is of a vivid colour; however, they appear to be the same, only with this difference, that the wild feeds upon uncultivated trees, without any assistance, whereas the domestic is carefully, at a stated season, removed to cultivated trees, where it feeds upon a purer juice. Those who take care of these insects, place them on the prickly pear-plant in a certain order, and are very industrious in defending them from other insects; for if any other kind come among them, they take care to brush them off with foxes' tails. Towards the end of the year, when the rains and cold weather are coming on, which are fatal to these insects, they take off the leaves or branches covered with cochineal, that have not attained their utmost degree of perfection, and keep them in their houses till winter is past. These leaves are very thick and juicy, and supply them with sufficient nourishment, while they remain within doors. When the milder weather returns, and these animals are about to exclude their young, the natives make them nests, like those of birds, but less of tree moss, or soft hay, or the down of cocoa-nuts, placing twelve in every nest. These they fix on the thorns of the prickly-pear plant, and in three or four days' time they bring forth their young, which leave their nests in a few days, and creep upon the branches of the plant, till they find a proper place to rest in, and take in their nourishment; and until the females are fecundated by the males, which, as in the former tribe, differ very widely from the females, being winged insects, whereas the others only creep, and are at most stationary. When they are impregnated, they produce a new offspring, so that the propagator has a new harvest thrice a-year. When the native Americans have gathered the cochineal, they put them into holes in the ground, where they kill them with boiling water, and afterwards dry them in the sun, or in an oven, or lay them upon hot plates. From the various methods of killing them, arise the different colours which they appear in when brought to us. While they are living they seem to be sprinkled over with a white powder, which they lose as soon as the boiling water is poured upon them. Those that are dried upon hot plates are the blackest. What we call the cochineal are only the females, for the males are a sort of fly, as already observed in the kermes. They are used both for dying and medicine, and are said to have much the same virtue as the kermes, though they are now seldom used alone, but are mixed with other things for the sake of the colour.[1]

---

[1] To the beetle kind also belong those animals which cause such alarm to the superstitious by their ticking noise, which is vulgarly called the death-watch. Various species of this insect are to be found in Britain.

The *Death-watch* or *Ptinus*, is a dusky or somewhat hairy insect, with irregular brownish spots, about a quarter of an inch in length. Notwithstanding its smallness, this creature is often the cause of serious alarm among the lower classes of people, from the noise that it makes at a certain time of the year, resembling the ticking of a watch. From this it has its name; for, whenever this faculty is exerted, it is esteemed portentive of death to some one of the family in the house where it is heard. It is chiefly in the advanced state of spring that this insect commences its noise, which is no more than a call or signal by which they are mutually attracted to each other; and it may be considered as analogous to the call of birds. This noise does not arise from the voice, but from the insect's beating on any hard substance with the shield or fore-part of the head. The general number of successive distinct strokes is from seven to nine, or eleven. These are given in pretty quick succession, and are repeated at uncertain intervals; and in old houses, where the insects are numerous, they may be heard, if the weather be warm, every hour in the day. The noise exactly resembles that made by beating with the nail upon a table. The insect being difficult to discover, from its obscure grayish brown colour, nearly resembling that of decayed wood, it is not always easy to say from what exactly the sound proceeds.

Mr Stackhouse observed carefully the manner of its beating. He says the insect raises itself on its hinder legs, and with the body somewhat inclined, beats its head with great force and agility against the place on which it stands. One of them, on a sedge-bottomed chair, exerted so much force, that its strokes were impressed and visible in the exterior coat of the sedge, for a space equal to that of a silver penny. Mr Stackhouse took this insect and put it into a box. On the following day he opened the box, and set it in the sun. It seemed very brisk, and crept about with great activity on the bits of sedge and rotten wood, till at last getting to the end of the pieces, it extended its wings, and was about to take flight; he shut down the lid, when it withdrew them, and remained quiet. He kept it by him about a fortnight.

Strange as it may appear, this little animal is capable of being tamed. Dr Derham kept a male and female together in a box for about three weeks; and by imitating their noise, (beating with his nail, or the point of a pen, on a table or board,) he made them beat whenever he pleased, and they would not only answer very readily, but even continued their beatings as long as required. At the end of this time one of them died, soon after which the other gnawed its way out and escaped.

The *Death-watch Termes*.—This insect, which is sometime mistaken for the ptinus just mentioned, is of a very different tribe, and about a tenth of an inch long. At first sight it has greatly the appearance of a louse: its mouth, however, with a glass, is seen to be reddish, and its eyes are yellow. The antennæ are sharply pointed, and somewhat long. It is sometimes, though very rarely, observed to have wings.

This insect is usually found in old wood, decayed furniture, museums, and neglected books; and both the male and female have the power of making a ticking noise, not unlike that of a watch, to attract each other. The female lays her eggs in dry and dusty places, where they are likely to meet with the least disturbance: these are exceedingly small, and are not unlike the nits or eggs of lice. When they are disturbed, they are

I shall end this account of the beetle tribe with the history of an animal which cannot properly be ranked under this species, and yet cannot be more methodically ranged under any other. This is the insect that forms and resides in the gall-nut, the spoils of which are converted to such useful purposes. The gall-insects are bred in a sort of bodies adhering to a kind of oak in Asia, which differ with regard to their colour, size, roughness, smoothness, and shape, and which we call galls. They are not fruit, as some have imagined, but preternatural tumours, owing to the wounds given to the buds, leaves, and twigs of the tree, by a kind of insects that lay their eggs within them. This animal is furnished with an implement, by which the female penetrates into the bark of the tree, or into that spot which just begins to bud, and there sheds a drop of corrosive fluid into the cavity. Having thus formed a receptacle for her eggs, she deposits them in the place, and dies soon after. The heart of the bud being thus wounded, the circulation of the nutritive juice is interrupted, and the fermentation thereof, with the poison injected by the fly, burns the parts adjacent, and then alters the natural colour of the plant. The juice or sap, turned back from its natural course, extravasates, and flows round the egg. After which it swells and dilates by the assistance of some bubbles of air, which get admission through the pores of the bark, and which run in the vessels with the sap. The external coat of this excrescence is dried by the air, and grows into a figure, which bears some resemblance to the bow of an arch, or the roundness of a kernel. This little ball receives its nutriment, growth, and vegetation, as the other parts of the tree, by slow degrees, and is what we call the *gall-nut*. The worm that is hatched under this specious vault, finds in the substance of the ball, which is as yet very tender, a substance suitable to its nature; gnaws and digests it till the time comes for its transformation to a nymph, and from that state of existence changes into a fly. After this, the insect, perceiving itself duly provided with all things requisite, disengages itself soon from its confinement, and takes its flight into the open air. The case, however, is not similar with respect to the gall-nut that grows in autumn. The cold weather frequently comes on before the worm is transformed into a fly, or before the fly can pierce through its inclosure. The nut falls with the leaves, and although you may imagine that the fly which lies within is lost, yet in reality it is not so; on the contrary, its being covered up so close, is the means of its preservation. Thus it spends the winter in a warm house, where every crack and cranny of the nut is well stopped up; and lies buried, as it were, under a heap of leaves, which preserves it from the injuries of the weather. This apartment, however, though so commodious a retreat in the winter, is a perfect prison in the spring. The fly, roused out of its lethargy by the first heats, breaks its way through, and ranges where it pleases. A very small aperture is sufficient, since at this time the fly is but a diminutive creature. Besides, the ringlets whereof its body is composed, dilate, and become pliant in the passage.

---

very shy in making their tickings; but if they can be viewed without being alarmed by noise, or moving the place where they are, they will not only beat freely, but even answer any person's beating with his nail. At every stroke their body shakes, or seems affected as by a sudden jerk; and these jerks succeed each other so quickly, that it requires great steadiness to perceive with the naked eye that the body has any motion. They are scarcely ever heard to beat before July, and never later than the sixteenth of August. It appears strange that so small an insect should be able to make a noise so loud as is frequently to be heard from this; sometimes equal to that of the strongest beating watch. Dr Derham, who examined and first described this species, says, he had often heard the noise, and in pursuing it found nothing but these insects, which he supposed incapable of producing it; but one day, by finding that the noise proceeded from a piece of paper loosely folded, and lying in a good light in his study window, he viewed it through, and with a microscope observed, to his great astonishment, one of them in the very act of beating. In some years they are more numerous than in others, and their ticking is of course more frequently heard. We are informed by the above naturalist, that, during the month of July, in one particular summer, they scarcely ever ceased, either in the day or night.

CHAP. VII.

OF THE GNAT TIPULA.

THERE are two insects which entirely resemble each other in their form, and yet widely differ in their habits, manners, and propagation. Those who have seen the tipula, or long-legs, and the larger kind of gnat, have most probably mistaken the one for the other; they have often accused the tipula, a harmless insect, of depredations made by the gnat, and the innocent have suffered for the guilty; indeed the differences in their form are so very minute, that it often requires the assistance of a microscope to distinguish the one from the other: they are both mounted on long legs, both furnished with two wings and a slender body; their heads are large, and they seem to be hump-backed; the chief and only difference, therefore, is, that the tipula wants a trunk, while the gnat has a large one, which it often exerts to very mischievous purposes. The tipula is a harmless peaceful insect, that offers injury to nothing; the gnat is sanguinary and predaceous, ever seeking out for a

place in which to bury its trunk, and pumping up the blood from the animal in large quantities.

The gnat proceeds from a little worm, which is usually seen at the bottom of standing waters. The manner in which the insect lays its eggs is particularly curious: after having laid the proper number on the surface of the water, it surrounds them with a kind of unctuous matter, which prevents them from sinking, but at the same time fastens them with a thread to the bottom, to prevent their floating away, at the mercy of every breeze, from a place, the warmth of which is proper for their production, to any other, where the water may be too cold, or the animals' enemies too numerous. Thus the insects, in their egg state resemble a buoy, which is fixed by an anchor. As they come to maturity they sink deeper; and at last when they leave the egg as worms, they creep to the bottom.[1] They now make themselves lodgments of cements, which they fasten to some solid body at the very bottom of the water, unless by accident they meet with a piece of chalk, which being of a soft and pliant nature, gives them an opportunity of sinking a retreat for themselves, where nothing but the claws of a cray-fish can possibly molest them. The worm afterwards changes its form. It appears with a large head, and a tail invested with hair, and moistened with an oleaginous liquor, which she makes use of as a cork to sustain her head in the air, and her tail in the water, and to transport her from one place to another. When the oil with which her tail is moistened, begins to grow dry, she discharges out of her mouth an unctuous humour, which she sheds all over her tail, by virtue whereof she is enabled to transport herself where she pleases, without being either wet or anywise incommoded by the water. The gnat, in her second state, is, properly speaking, in her form a nymph, which is an introduction or entrance into a new life. In the first place, she divests herself of her second skin; in the next, she resigns her eyes, her antennæ, and her tail; in short, she actually seems to expire. However, from the spoils of the amphibious animal, a little winged insect cuts the air, whose every part is active to the last degree, and whose whole structure is the just object of our admiration. Its little head is adorned with a plume of feathers, and its whole body invested with scales and hair, to secure it from any wet or dust. She makes trial of the activity of her wings, by rubbing them either against her body, or her broad side-bags, which keep her in an equilibrium. The furbelow, or little border of fine feathers, which graces her wings, is very curious, and strikes the eye in the most agreeable manner. There is nothing, however, of greater importance to the gnat than her trunk, and that weak implement may justly be deemed one of nature's master-pieces. It is so very small, that the extremity of it can scarcely be discerned through the best microscope that can be procured. That part which is at first obvious to the eye, is nothing but a long scaly sheath under the throat. At near the distance of two-thirds of it, there is an aperture, through which the insect darts out four stings, and afterwards retracts them. One of which, however sharp and active it may be, is no more than the case in which the other three lie concealed, and run in a long groove. The sides of these stings are sharpened like two-edged swords; they are likewise barbed, and have a vast number of cutting teeth towards the point, which turns up like a hook, and is fine beyond expression. When all these darts are stuck into the flesh of animals, sometimes one after another, and sometimes all at once, the blood and humours of the adjacent parts must unavoidably be extravasated; upon which a tumour must consequently ensue, the little orifice whereof is closed up by the compression of the external air. When the gnat, by the point of her case,

[1] We are hardly acquainted with any other than the aërial life of the gnat, yet its aquatic life is also very interesting. It is upon or under the water that the gnat is in its stages of egg, *larva*, and nymph, that is, during almost the whole of its existence, and that an existence which in no way annoys man.

The eggs of this insect have the lengthened form of an olive; their own weight is sufficient to sink them, but 250 or 300 united, and stuck together with a natural glue in the shape of a boat, float on the surface of the water till the *larvæ* come out of them. The part of this agglomeration which touches the water is convex, its upper part concave; and this skiff is so well balanced, that the most furious tempest would not upset it. The learned Kirby made the experiment himself, by placing a dozen of these little boats in a glass half full of water; he then violently troubled the water in the glass, by pouring in water from a pitcher, without being able to succeed in sinking these little boats, of which not one contained a single drop of water when he had ended his experiments.

The manner in which the gnat constructs this floating apparatus is very singular. This insect, as every one knows, is provided with six legs; it places its four front-feet on a dead leaf, a twig, or any other floating substance; its body thus remains horizontally on the surface of the water, with the exception of the last segment of its *abdomen*, which it keeps a little raised; it then extends its long hind legs, and crosses them in the shape of the letter X, and thus forms a support for the first eggs it is about to lay. Each egg, when laid, is enclosed in a kind of glue; the female supports the first in a vertical position till the second egg is placed by its side, and glued to it; the third forms a triangle, and so on. When the boat is completed, the gnat leaves it on the water, and flies away, to end, in a short time, that existence of which it has fulfilled the most important task.

Boat of gnat's eggs.

which she makes use of as a tongue, has tasted any fruit, flesh, or juice, that she has found out; if it be a fluid, she sucks it up, without playing her darts into it; but in case she finds the least obstruction by any flesh whatever, she exerts her strength, and pierces through it, if possibly she can. After this she draws back her stings into their sheath, which she applies to the wound in order to extract, as through a reed, the juices which she finds inclosed. This is the implement with which the gnat performs her work in the summer, for during the winter she has no manner of occasion for it. Then she ceases to eat, and spends all that tedious season either in quarries or in caverns, which she abandons at the return of summer, and flies about in search after some commodious ford, or standing water, where she may produce her progeny, which would be soon washed away and lost, by the too rapid motion of any running stream. The little brood are sometimes so numerous, that the very water is tinged according to the colour of the species, as green, if they be green, and of a sanguine hue, if they be red.

These are circumstances sufficiently extraordinary in the life of this little animal; but it offers something still more curious in the method of its propagation. However similar insects of the gnat kind are in their appearance, yet they differ widely from each other in the manner in which they are brought forth, for some are oviparous, and are produced from eggs: some are viviparous, and come forth in their most perfect form; some are males, and unite with the female; some are females, requiring the impregnation of the male; some are of neither sex, yet still produce young, without any copulation whatsoever. This is one of the strangest discoveries in all natural history! A gnat separated from the rest of its kind, and inclosed in a glass vessel, with air sufficient to keep it alive, shall produce young, which also, when separated from each other, shall be the parents of a numerous progeny. Thus, down for five or six generations, do these extraordinary animals propagate without the use of copulation, without any congress between the male and the female, but in the manner of vegetables, the young bursting from the body of their parents, without any previous impregnation. At the sixth generation, however, their propagation stops; the gnat no longer produces its like, from itself alone, but it requires the access of the male to give it another succession of fecundity.

The gnat of Europe gives but little uneasiness; it is sometimes heard to hum about our beds at night, and keeps off the approaches of sleep by the apprehension it causes; but it is very different in the ill-peopled regions of America, where the waters stagnate, and the climate is warm, and where they are produced in multitudes beyond expression. The whole air is there filled with clouds of those famished insects, and they are found of all sizes, from six inches long to a minuteness that even requires the microscope to have a distinct perception of them.[1] The warmth of the mid-day sun is too powerful for their constitutions; but when the evening approaches, neither art nor

[1] Under the common names of *gnat* and *musquito*, a numerous family are confounded, as if there were only one or two species; whereas Mr Stephen has enumerated twenty-two species of the genera *Culex* and *Anopheles*, found in Britain alone; and hence, it is probable, the foreign musquitoes are also of several species, though to common observers they do not appear to differ from the common gnat.

The *Musquito-fly* is very common in the woody and marshy parts of all hot climates. It also abounds, during their short summer, throughout Lapland, Norway, and Finland, and other countries equally near the pole. The female bites, and sucks the blood in such a severe manner, as to swell and blister the skin very severely, and sometimes leave obstinate sores. These insects are found in such swarms, in the woods, that whoever enters them is sure to have his face covered, and he is scarcely able to see his way before him. A swelling and disagreeable itch instantly follows the puncture, and these are succeeded by small white ulcers; so that the face of a person coming from the country is scarcely to be recognised, and it appears full of blotches. Even gloves are not always found a protection against these troublesome insects, as they often pass their stings through the seams. It is the female only that bites; the buzzing, however, of both males and females is so very loud, as to be alone sufficient to disturb the rest of persons at night.

The *Ox Gad-fly* has brown unspotted wings; and the abdomen is marked with a black band in the middle, and has dusky yellow hairs at the tip. The front is white, and covered with down; and the thorax is yellowish before, black in the middle, and cinereous behind. The female differs from the male in having a black style at the end of the abdomen. This insect deposits its eggs in the back of the ox, and the larvæ live beneath the skin, between this and the cellular membrane. Its sac or abscess is somewhat larger than the insect, and by narrowing upwards, it opens externally to the air by a small aperture. The Ox Gad-fly is the largest of the European species, and is very beautiful: it is, however, the terror of cattle, as it inflicts great pain when depositing its eggs.

The *Horse Gad-fly* is distinguished from the rest of its tribe by having a black band in the middle and two dots at the tip of its whitish wings. The abdomen is yellow brown, with black spots at the divisions of the segments. The female is more brown than the male, and has her abdomen elongated with a cleft terminal style. The larvæ are those odd-looking grubs which are commonly found in the stomachs of horses, and sometimes, though much less frequently, in the intestines. Here they hang in clusters of from half a dozen to more than a hundred, adhering to the inner membrane of the stomach, by means of two small hooks or tentaculæ at their heads, whose points turn outward. When they are removed from the stomach, they will attach themselves to any loose membrane, even to the skin of the hand. To effect this they draw back their hooks, which have a joint near their base, almost entirely within their skin; till the two points come close to each other; then, keeping them parallel, they pierce through the membrane, and immediately afterwards expand in a lateral direction; and by these means they become perfectly fixed.

flight can shield the wretched inhabitants from their attacks; though millions are destroyed, still millions more succeed, and produce unceasing torment. The native Indians, who anoint their bodies with oil, and who have from their infancy been used to their depredations, find them much less inconvenient than those who are newly arrived from Europe; they sleep in their cottages covered all over with thousands of the gnat kind upon their bodies, and yet do not seem to have their slumbers disturbed by their cruel devourers. If a candle happens to be lighted in one of those places, a cloud of insects at once light upon the flame and extinguish it: they are therefore obliged to keep their candles in glass lanterns; a miserable expedient to prevent an unceasing calamity!

HISTORY OF ZOOPHYTES.

BOOK V.

OF THE ZOOPHYTES.

CHAP. I.

OF ZOOPHYTES IN GENERAL.

We now come to the last link in the chain of animated nature, to a class of beings so confined in their powers, and so defective in their formation, that some historians have been at a loss whether to consider them as a superior rank of vegetables, or the humblest order of the animated tribe. In order, therefore, to give them a denomination agreeable to their existence, they have been called Zoophytes, a name implying vegetable nature endued with animal life; and, indeed, in some the marks of the animal are so few, that it is difficult to give their place in nature with precision, or to tell whether it is a plant or an insect that is the object of our consideration.

Should it be asked what it is that constitutes the difference between animal and vegetable life; what it is that lays the line that separates those two great kingdoms from each other, it would be difficult, perhaps we should find it impossible, to return an answer. The power of motion cannot form this distinction, since some vegetables are possessed of motion, and many animals are totally without it. The sensitive plant has obviously a greater variety of motions than the oyster or the pholas. The animal that fills the acorn-shell is immovable, and can only close its lid to defend itself from external injury, while the flower which goes by the name of the fly-trap, seems to close upon the flies that light upon it, and that attempt to rifle it of its honey. The animal in this instance seems to have scarce a power of self-defence; the vegetable not only guards its possessions, but seizes upon the robber that would venture to invade them. In like manner, the methods of propagation give no superiority to the lower rank of animals. On the contrary, vegetables are frequently produced more conformably to the higher ranks of the creation, and though some plants are produced by cuttings from others, yet the general manner of propagation is from seeds, laid in the womb of the earth, where they are hatched into the similitude of the parent plant or flower. But a most numerous tribe of animals have lately been discovered, which are propagated by cuttings, and this in so extraordinary a manner, that, though the original insect be divided into a thousand parts, each, however small, shall be formed into an animal, entirely resembling that which was at first divided; in this respect, therefore, certain races of animals seem to fall beneath vegetables, by their more imperfect propagation.[1]

[1] There is much less of acumen and solidity in these remarks of our author than might have been expected. That there is, to a certain extent, community of feature and character between vegetable bodies and the zoophyte tribes, is at once admitted, for the very name of the latter implies the junction of animal and vegetable characteristics in the same individual. But there is never wanting a broad and striking distinction between the zoophyte and the mere vegetable. We may indeed produce plants possessing motion, and seemingly indued with sensibility, but attentive examination and reflection uniformly convince us that such motion and apparent sensitiveness are mere mechanical properties, in nowise the result of a voluntary principle. We may, again, instance zoophytes in which, at first view, the vegetable character is so predominant, and the animal powers so limited, that they scarcely appear to fall within the lowest orders of animated existences. On close examination, however, we discover that their motions are undoubtedly influenced by volition, or will; and that they have instincts approximating to those of more perfect animals. We readily admit that it requires long and patient observation to distinguish, in many cases, between vegetables and zoophytes; but we believe no instance could be brought forward in which the question of animality might not be determined by the presence or absence of a *will*.

What, therefore, is the distinction between them?—or are the orders so intimately blended as that it is impossible to mark the boundaries of each? To me it would seem, that all animals are possessed of one power, of which vegetables are totally deficient; I mean, either the actual ability, or an awkward attempt at self-preservation. However vegetables may seem possessed of this important quality, yet it is with them but a mechanical impulse, resembling the raising one end of the lever when you depress the other; the sensitive plant contracts and hangs its leaves, indeed, when touched, but this motion no way contributes to its safety: the fly-trap flower acts entirely in the same manner; and though it seems to seize the little animal that comes to annoy it, yet, in reality, only closes mechanically upon it, and this inclosure neither contributes to its preservation nor its defence. But it is very different with insects, even of the lowest order; the earth-worm not only contracts, but hides itself in the earth, and escapes with some share of swiftness from its pursuers. The polypus hides its horns; the star-fish contracts its arms upon the appearance even of distant dangers; they not only hunt for their food, but provide for their safety; and however imperfectly they may be formed, yet still they are in reality placed many degrees above the highest vegetable of the earth, and are possessed of many animal functions, as well as those that are more elaborately formed.

But though these be superior to plants, they are far beneath their animated fellows of existence. In the class of zoophytes, we may place all those animals which may be propagated by cuttings; or in other words, which, if divided into two or more parts, each part in time becomes a separate and perfect animal; the head shoots forth a tail, and, on the contrary, the tail produces a head; some of these will bear dividing but into two parts, such as the earth-worm; some may be divided into more than two, and of this kind are many of the star-fish; others still may be cut into a thousand parts, each becoming a perfect animal; they may be turned inside out, like the finger of a glove; they may be moulded into all manner of shapes, yet still their vivacious principle remains, still every single part becomes perfect in its kind, and, after a few days' existence, exhibits all the arts and industry of its contemptible parent! We shall, therefore, divide zoophytes according to their several degrees of perfection, namely, into worms, star-fish, and polypi; contenting ourselves with a short review of those nauseous and despicable creatures, that excite our curiosity chiefly by their imperfections; it must not be concealed, however, that much has of late been written on this part of natural history. A new mode of animal production, could not fail of exciting not only the curiosity, but the astonishment of every philosopher; many found their favourite systems totally overthrown by the discovery; and it was not without a wordy struggle, that they gave up what had formerly been their pleasure and their pride. At last, however, conviction became too strong for argument; and a question, which owed its general spread rather to its novelty than to its importance, was given up in favour of the new discovery.

CHAP. II.

OF WORMS.[1]

The first in the class of zoophytes, are animals of the worm kind, which, being entirely

[1] "The characters of insects are so distinct and intelligible, those of worms, on the contrary, so vague, and so far from positive, that the shortest way of defining the latter might perhaps be as animals with white blood, not insects; differing from them by the deficiency as well of antennæ as of articulated organs of motion. They have, for the most part, soft glutinous bodies, a few only being covered with hair, as the aphrodites, or with a calcareous shell, as the sea-hedgehog. Many amphitrites construct an artificial shell of grains of sand, &c; whilst many other animals of this class, viz. the testacea and certain polypes, inhabit a solid house resembling porcelain or stone, congenital, and serving the purposes of residence and defence; in some cases it is carried about by the animal, in others is firmly attached to one spot. No animal of this class has wings, for the springing of the cuttle-fish out of the water is not to be called flying; neither has it any true legs for the support of the body, or for motion. Earth-worms, sea-hedgehogs, sea-anemones, &c. have, however, particular organs, which in some degree answer similar purposes. In many instances too, the deficiency of external organs of motion in worms, is supplied by the power which they possess of alternately elongating and shortening themselves. Instead of *antennæ*, many worms have *tentacula*, soft, fleshy cords or fibres, attached to the head, flexible, *not articulated*, in some cases of considerable length, and serving a variety of purposes; sometimes for touching, at others for taking their prey, and so forth. Of the senses of these animals and the organs devoted to them, still less that is positive can be said than of those of insects. Some have undoubtedly true eyes, as the sepiæ, &c. and others, without having eyes, possess a most acute feeling of sight. In their internal structure, most worms differ as much from insects as these do from red-blooded animals.

"This class also differs from insects in this, that no animal belonging to it undergoes a true metamorphosis, which is so generally the case amongst them. The abode of these animals is generally in water; and by far the greater part of them in the ocean. Some live under ground; others exclusively in the living bodies of other animals, as the intestinal worms, seminal animalcules, &c. Their remarkable powers of reproduction serve to insure the preservation of many animals of this class, and some, as the animalcula of paste, the wheel-animal, &c., possess a kind of revivescence, which appears to

destitute of feet, trail themselves along upon the ground, and find themselves a retreat under the earth, or in the water. As these, like serpents, have a creeping motion, so both, in general, go under the common appellation of reptiles: a lothesome, noxious, malignant tribe, to which man by nature, as well as by religion, has the strongest antipathy. But though worms, as well as serpents, are mostly without feet, and have been doomed to creep along the earth on their bellies, yet their motions are very different. The serpent, as has been said before, having a back-bone, which it is incapable of contracting, bends its body into the form of a bow, and then shoots forward from the tail; but it is very different with the worm, which has a power of contracting or lengthening itself at will. There is a spiral muscle, that runs round its whole body, from the head to the tail, somewhat resembling a wire wound round a walking-cane, which when slipped off, and one end extended and held fast, will bring the other nearer to it; in this manner the earth-worm, having shot out, or extended its body, takes hold by the slime of the forepart of its body, and so contracts and brings forward the hinder part; in this manner it moves onward, not without great efforts; but the occasions for its progressive motions are few.

As it is designed for living under the earth, and leading a life of obscurity, so it seems tolerably adapted to its situation. Its body is armed with small stiff sharp burrs or prickles, which it can erect or depress at pleasure; under the skin there lies a slimy juice, to be ejected as occasion requires, at certain perforations, between the rings of the muscles, to lubricate its body, and facilitate its passage into the earth. Like most other insects it has breathing holes along the back, adjoining each ring; but is without bones, without eyes, without ears, and properly without feet. It has a mouth, and also an alimentary canal, which runs along to the very point of the tail. In some worms, however, particularly such as are found in the bodies of animals, this canal opens towards the middle of the belly, at some distance from the tail. The intestines of the earth worm are always found filled with a very fine earth, which seems to be the only nourishment these animals are capable of receiving.

The animal is entirely without a brain, but near the head is placed the heart, which is seen to beat with a very distinct motion, and round it are the spermatic vessels, forming a number of little globules, containing a milky fluid, which have an opening into the belly, not far from the head; they are also often found to contain a number of eggs, which are laid in the earth, and are hatched in twelve or fourteen days into life, by the genial warmth of their situation; like snails, all these animals unite in themselves both sexes at once; the rep-

---

render them, in some degree, indestructible. The generality of the intestinal worms of animals, and, the sepiæ excepted, by far the greater number of worms, are true hermaphrodites, of which each individual is capable of propagating the species. The mode of copulation in many animals of this class is also very peculiar, as in the common garden and tree snails, which at that time are provided with a remarkable little dart, composed of calcareous matter, and having the shape of a four-edged lance. This dart is fixed loosely in an opening in the neck, and when the two snails meet, each presses its dart into the breast of the other, this mutual excitement being precursory to actual copulation.

"The vast numbers of marine animals in this class, particularly the testacea and corals, are of extreme importance to the general economy of nature, inasmuch as they in the ocean, in the same manner with insects upon the earth, incessantly destroy, consume, and, as it were, metamorphose an infinite variety of noxious or superfluous substances. To man, they are in so far serviceable, that many, particularly of the mollusca and testacea, are eatable; some, as for instance, the venus *mercenaria*, and mytilus *bidens*, serving as a principal article of diet to many navigators and inhabitants of sea coasts. The *purple dye* was procured from certain shell-fish, more formerly than at present. Ink and Indian ink are procured from the peculiar fluid of the cuttle-fish. The beard of certain species of pinna affords a kind of brown silk, which may be manufactured. Many kinds of shells contain pearls. Red coral is an important article of trade, particularly in the East Indies. Several kinds of shells, either entire or divided, pass current as money among some remote nations. From portions of similar shells, the Iroquois and other North American people, made their *wampum*, which serves the purpose of records.

Many savage people use muscle and snail shells for drinking vessels, spoons, &c. The South sea islanders make from them ingenious hooks and a variety of other fishing-tackle. The North-western Americans point their harpoons with angular pieces of muscle shells. In regard to works of art: mother of pearl and many muscle and snail shells are cut like onyx into camoes. The cuttle-fish bone is employed by artists and workmen. Sponge serves a variety of domestic purposes. Madrepore is employed for paving and building on the coasts of the Red sea. Numerous testacea (the shells) and corals are burnt for lime. Some large thin shells are used as glass in the south of China, and in India. The shells of testacea are among the most common ornaments of savage nations. In the great collection of objects from the South seas presented to the academical Museum of Gottingen, is, among other articles, a necklace of neat shells, carefully polished, bored, and ingeniously twisted together with tendons, all the work of a race of men commonly considered as the most wretched outcasts of the human species, viz. the natives of the Sierra del Fuego. Lastly, the leech is of great importance in the treatment of certain diseases. (See an account of the leech in the present volume, page 467.)

"Among the noxious animals of this class, are, in particular, the worms of the human body, which either live in the intestines, as the ascurides fæniæ, &c., or as the Guinea-worm, immediately under the skin. Others of a similar character, are the flukes found in sheep, the hyditids of swine, and the worms found in many quadrupeds and fishes, producing disease. Earth-worms and snails are injurious to plants. Certain species of the genera teredo and pholas perforate ships and dams."—*Blumenbach.*

tile that impregnates, being impregnated in turn: few that walk out, but must have observed them, with their heads laid against each other, and so strongly attached, that they suffer themselves to be trode upon.

When the eggs are laid in the earth, which, in about fourteen days, as has been said, are hatched into maturity, the young ones come forth very small, but perfectly formed, and suffer no change during their existence; how long their life continues is not well known, but it certainly holds for more than two or three seasons. During the winter, they bury themselves deeper in the earth, and seem in some measure to share the general torpidity of the insect tribe. In spring, they revive with the rest of nature, and on those occasions, a moist or dewy evening brings them forth from their retreats, for the universal purpose of continuing their kind. They chiefly live in a light, rich, and fertile soil, moistened by dews or accidental showers, but avoid those places where the water is apt to lie on the surface of the earth, or where the clay is too stiff for their easy progression under ground.

Helpless as they are formed, yet they seem very vigilant in avoiding those animals that chiefly make them their prey; in particular, the mole, who feeds entirely upon them beneath the surface, and who seldom ventures, from the dimness of its sight, into the open air; him they avoid, by darting up from the earth the instant they feel the ground move; and fishermen, who are well acquainted with this, take them in what numbers they choose, by stirring the earth where they expect to find them. They are also driven from their retreats under ground, by pouring bitter or acrid water thereon, such as that water in which green walnuts have been steeped, or a ley made of pot-ashes.

Such is the general outline of the history of these reptiles, which, as it should seem, degrades them no way beneath the rank of other animals of the insect creation: but now we come to a part of their history which proves the imperfection of their organs, from the easiness with which these little machines may be damaged and repaired again. It is well known in mechanics, that the finest and most complicated instruments are the most easily put out of order, and the most difficultly set right; the same also obtains in the animal machine. Man, the most complicated machine of all others, whose nerves are more numerous, and powers of action more various, is most easily destroyed; he is seen to die under wounds which a quadruped or a bird could easily survive; and as we descend gradually to the lower ranks, the ruder the composition, the more difficult it is to disarrange it. Some animals live without their limbs, and often are seen to reproduce them; some are seen to live without their brain for many weeks together; caterpillars continue to increase and grow large, though all their nobler organs are entirely destroyed within; some animals continue to exist, though cut in two, their nobler parts preserving life, while the others perish that were cut away; but the earth-worm, and all the zoophyte tribe, continue to live in separate parts, and one animal, by the means of cutting, is divided into two distinct existences, sometimes into a thousand!

There is no phenomenon in all natural history more astonishing than this, that man at pleasure should have a kind of creative power, and out of one life make two, each completely formed, with all its apparatus and functions; each with its perceptions, and powers of motion and self-preservation; each as complete in all respects as that from which it derived its existence, and equally enjoying the humble gratifications of its nature.

When Des Cartes first started the opinion, that brutes were machines, the discovery of this surprising propagation was unknown, which might, in some measure, have strengthened his fanciful theory. What is life in brutes? he might have said, or where does it reside? In some we find it so diffused, that every part seems to maintain a vivacious principle, and the same animal appears possessed of a thousand distinct irrational souls at the same time. But let us not, he would say, give so noble a name to such contemptible powers, but rank the vivifying principle in these with the sap that rises in vegetables, or the moisture that contracts a cord, or the heat that puts water into motion! Nothing, in fact, deserves the name of soul, but that which reasons, that which understands, and by knowing God, receives the mark of its currency, and is minted with the impression of its great Creator.

Such might have been the speculations of this philosopher: however, to leave theory, it will be sufficient to say, that we owe the first discovery of this power of reproduction in animals to Mr Trembley, who first observed it in the Polypus, and after him, Spalanzani and others found it taking place in the earth-worm, the sea-worm, and several other ill-formed animals of a like kind, which were susceptible of this new mode of propagation. This last philosopher has tried several experiments upon the earth-worm, many of which succeeded according to his expectation: every earth-worm, however, did not retain the vivacious principle with the same obstinacy; some, when cut in two, were entirely destroyed; others survived only in the nobler part; and while the head was living, the tail entirely perished, and a new one was seen to bourgeon

from the extremity. But what was most surprising of all, in some, particularly in the small red-headed earth-worm, both extremities survived the operation; the head produced a tail, with the anus, the intestines, the annular muscle, and the prickly beards; the tail part, on the other hand, was seen to shoot forth the nobler organs, and in less than the space of three months sent forth a head, a heart, with all the apparatus and instruments of generation. This part, as may easily be supposed, was produced much more slowly than the former, a new head taking above three or four months for its completion; a new tail being shot forth in less than as many weeks. Thus two animals, by dissection, were made out of one, each with their separate appetites, each endued with life and motion, and seemingly as perfect as that single animal from whence they derived their origin.

What was performed upon the earth-worm was found to obtain also in many of the vermicular species. The sea-worm, the white water-worm, and many of those little worms with feelers, found at the bottom of dirty ditches; in all these the nobler organs are of such little use, that if taken away, the animal does not seem to feel the want of them; it lives in all its parts, and in every part; and by a strange paradox in nature, the most useless and contemptible life is of all others the most difficult to destroy.

CHAP. III.

OF THE STAR-FISH.

The next order of zoophytes, is that of the star-fish, a numerous tribe, shapeless and deformed, assuming at different times different appearances. The same animal that now appears round like a ball, shortly after flattens as thin as a plate. All of this kind are formed of a semi-transparent gelatinous substance, covered with a thin membrane, and to an inattentive spectator often appear like a lump of inanimate jelly, floating at random upon the surface of the sea, or thrown by chance on shore at the departure of the tide. But upon a more minute inspection, they will be found possessed of life and motion; they will be found to shoot forth their arms in every direction, in order to seize upon such insects as are near, and to devour them with great rapacity. Worms, the spawn of fish, and even muscles themselves, with their hard resisting shell, have been found in the stomachs of these voracious animals; and what is very extraordinary, though the substance of their own bodies be almost as soft as water, yet they are no way injured by swallowing these shells, which are almost of a stony hardness. They increase in size as all other animals do. In summer, when the water of the sea is warmed by the heat of the sun, they float upon the surface, and in the dark they send forth a kind of shining light resembling that of phosphorus. Some have given these animals the name of sea-nettles, because they burn the hands of those that touch them, as nettles are found to do. They are often seen fastened to the rocks, and to the largest sea-shells, as if to derive their nourishment from them. If they be taken and put into spirits of wine, they will continue for many years entire: but if they be left to the influence of the air, they are, in less than four and twenty hours, melted down into limpid and offensive water.

In all of this species, none are found to possess a vent for their excrements; but the same passage by which they devour their food, serves for the ejection of their fæces. These animals, as was said, take such a variety of figures, that it is impossible to describe them under one determinate shape; but in general their bodies resemble a truncated cone, whose base is applied to the rock to which they are found usually attached. Though generally transparent, yet they are found of different colours, some inclining to green, some to red, some to white, and some to brown. In some, their colours appear diffused over the whole surface, in some they are often streaked, and in others often spotted. They are possessed of a very slow progressive motion, and in fine weather they are continually seen, stretching out and fishing for their prey. Many of them are possessed of a number of long slender filaments, in which they entangle any small animals they happen to approach, and thus draw them into their enormous stomachs, which fill the whole cavity of their bodies. The harder shells continue for some weeks undigested, but at length they undergo a kind of maceration in the stomach, and become a part of the substance of the animal itself. The indigestible parts are returned by the same aperture by which they were swallowed, and then the star-fish begins to fish for more. These also may be cut in pieces, and every part will survive the operation; each becoming a perfect animal, endued with its natural rapacity. Of this tribe, the number is various, and the description of each would be tedious and uninstructing; the manners and nature of all are nearly as described; but I will just make mention of one creature, which, though not properly belonging to this class, yet is so nearly related, that the passing it in silence would be an unpardonable omission.

Of all other animals, the cuttle-fish, though in some respects superior to this tribe, posses-

ses qualities the most extraordinary. It is about two feet long, covered with a very thin skin, and its flesh composed of a gelatinous substance, which, however, within-side, is strengthened by a strong bone, of which such great use is made by the goldsmith. It is possessed of eight arms, which it extends, and which are probably of service to it in fishing for its prey: while in life, it is capable of lengthening or contracting these at pleasure; but when dead, they contract, and lose their rigidity. They feed upon small fish, which they seize with their arms; and they are bred from eggs, which are laid upon the weeds along the sea-shore.

The cuttle-fish is found along many of the coasts of Europe, but are not easily caught, from a contrivance with which they are furnished by nature; this is a black substance, of the colour of ink, which is contained in a bladder generally on the left side of the belly, and which is ejected in the manner of an excrement from the anus. Whenever, therefore, this fish is pursued, and when it finds a difficulty of escaping, it spurts forth a great quantity of this black liquor, by which the waters are totally darkened, and then it escapes by lying close at the bottom. In this manner the creature finds its safety; and men find ample cause for admiration, from the great variety of stratagems with which creatures are endued for their peculiar preservation.

CHAP. IV.

OF THE POLYPUS.[1]

Those animals which we have described in the last chapter are variously denominated. They have been called the Star-fish, Sea-nettles, and Sea-polypi. This last name has been peculiarly ascribed to them by the ancients, because of the number of feelers or feet of

[1] Dr George Johnston, in his elegant work on British Zoophytes, recently published, (Edinburgh, 1838, 8vo), has adopted a new and seemingly excellent classification of the zoophyte division of the animal kingdom. Where a plant-like aquatic production, such as the *Sponge*, cannot be discovered to be the work of, or connected with, a polype, he excludes it from the zoophyte class, limiting that term to polypes and their polypidoms. This arrangement clearly defines the class. Of the zoophytes thus distinguished, he forms two sub-classes, radiated zoophytes, and molluscan zoophytes. The characters of these sub-classes are thus described: The radiated zoophytes have a body contractile in every part, and symmetrical; one aperture for receiving food, and expelling its refuse; and are propagated both by globules and by eggs. The molluscan zoophytes have a body non-contractile and non-symmetrical; separate apertures for the reception of food, and expulsion of refuse; and are propagated both by globules and eggs. The radiated zoophytes are so named from the star-like disposition of the calcareous matter of their polypidoms, while the molluscan zoophytes are so entitled, because their polypidoms, unlike those of the preceding class, are living portions of the polypes they contain, as is the case with the shelled molluscous animals, of which the lobster is an example. The radiated zoophytes, again, are divided into three orders, the hydroida, (so called from some affinity in their character to those of the *many-headed* hydra, a fabulous serpent), the asteroida, (from the *star-like* marks which distinguish them), and the helianthoida, (a word which expresses their likeness to certain flowers, as the anemone and marygold.) The molluscan class of zoophytes has but one order, termed the ascidoida, of which the chief distinctive characteristic is the vitality of their enclosing crusts or cases. Of all these orders, there are a number of families and species. Most of the polypi form compound animals, attached to one another by lateral appendages, or by their posterior extremity, participating in a common life, while at the same time they enjoy their individual and independent existence. Many of this tribe are supposed to be gemmiferous, or to extend the race by buds in the same manner as plants, while others propagate their species by means of eggs. In the lowest races of polypi, the distinctive characters of animal life are so slightly developed, that there is much difficulty in distinguishing them from the cryptogamic families of the vegetable kingdom. The resemblance of these animals to plants consists in this, that from the egg is formed a bulb, which shoots up into a stem, and sends off branches; there is also a root, which, however, is merely the organ of attachment, affording no nourishment to the animals. Being thus immovably fixed to a particular spot, they have no other means of providing themselves with food, but by their long tentacula, which act as arms to convey the food to the mouth; these members only are capable of voluntary motion. The vegetable structure of this class, long obtained for them the name of animal plants. Some of them, however, float about in the ocean, as the *pennatula*, or sea pens.

About the year 1699, Imperati and Gesner had remarked the animal structure of polypi or corals; and Peysonnell, in 1727, was the first who ascertained the living inhabitants of those stony and horny structures, and his discoveries have been confirmed by Trembley's treatise upon the hydræ, published in 1740; and subsequently by Reaumur, Jussieu, Donati, Ellis, Boccone, Degeer, Baster, Cavolini, Pallas, Linnæus, and Cuvier. All the animals of this class were placed by Linnæus as an order of his class *Vermes*, under the distinctive appellation of lithophytæ. The sagacity of that great naturalist enabled him to form a superstructure, upon which has been built the more improved, because better known classifications of Pallas, Bruguière, and Lamarck; whose arrangement we mean to follow, as being more comprehensive than that of Cuvier, who divides his class polypi into two orders; the first of which embraces those that are naked, and the second, such as live in polypiferous masses, formed by the united labours of the community. These he subdivides into many families.

Minute as the beings are which construct and inhabit those stony masses called corals, they form one of the largest, and undoubtedly the most singular of the whole classes of animated being. Such is the enormous accumulation of the stony envelopes formed by them in tropical seas, that islands are produced, coasts extended, and harbours blocked up by them. It was the opinion of Lamarck, that it was these minute beings who originally formed the calcareous strata of the globe.

In contemplating the structure of the polypi, the hydra, for example, we find their nutritive organs the simplest of all possible forms; consisting of a mere stomach adapted to receive and digest food, without any other

which they are all possessed, and with which they have a slow progressive motion ; but the moderns have given the name of Polypus to a reptile that lives in fresh water, by no means so large or observable. These are found at the bottom of wet ditches, or attached to the under surface of the broad-leafed plants that grow and swim on the waters. The same difference

apparent organ, being destitute of brain, nerves, or organs of sense ; nor is there the slightest appearance of any thing corresponding to lungs, heart, or even vessels of any kind. We have given a magnified representation of the hydra, laid open by a longitudinal section, pl. 30, f. 79, exhibiting the cavity into which the food is received and digested. The walls of this cavity must be adapted not only to prepare and pour out the fluids by which the food is digested, but also to permit of the transudation through its substance,—probably by means of invisible pores,—of the nutritious particles thus extracted from the food for the purpose of its being incorporated and identified with the gelatinous pulp, of which the body appears wholly to consist. The researches of Trembley have brought to light the extraordinary fact, that not only the internal surface of the polypus is endowed with the power of digesting food, but that the same property belongs also to the external surface, or what we might call the skin of the animal. He found that by a dexterous manipulation, the hydra may be completely turned inside out, like the finger of a glove, and that the animal, after having undergone this singular operation, will very soon resume all its ordinary functions, just as if nothing had happened. It accommodates itself in the course of a day or two to the transformation, and resumes all its natural habits, eagerly seizing animalcules with its tentacula, and introducing them into its newly formed stomach, which has for its interior surface what before was the exterior skin, and which digests them with perfect ease. The truth of this wonderful discovery was subsequently confirmed by Bonnet and Spallanzani.

Still more complicated are the forms and economy of the aggregated polypi, which prolific nature has spread in countless multitudes, over the rocky shores of the whole globe. These grow in the form of plants, and are supported on one common stem, with widely extended flowering branches. These many-headed monsters present myriads of open mouths, each surrounded by single or numerous rows of tentacula, which are extended to catch their prey; these are provided with a multitude of cilia, which, by their incessant vibrations, determine currents of water to flow towards their mouths, carrying with them the floating animalcules on which the entire mass of polypi subsists.

Each mouth leads into a separate stomach, whence the food, after its digestion, passes into several channels, generally five in number, which proceed in different directions from the cavity of each stomach, dividing into many branches, and being distributed over all the surrounding portions of the flesh. These branches communicate with similar channels, proceeding from the neighbouring stomachs, so that the food which has been taken in by one of the mouths, contributes to the general nourishment of the whole mass of aggregated polypi.

The polypi appear in general not to be provided with any distinct channels for conveying aerated water into the interior of their bodies, so that it may act in succession on the nutritive juices, and, after performing this office, may be expelled, and exchanged for a fresh supply. It has accordingly been conjectured, on the presumption that this function is equally necessary to them as it is to all other animals, that the vivifying influence of the surrounding element, is exerted through the medium of the surface of the body. Thus it is very possible that in polypi, while the interior surface of the sac digests the food, its external surface may perform the office of respiration ; and no other mode of accomplishing this function has been distinctly traced in the animals of the order acalepha.

The form of the shelly covering which invests most of the polypi, admits of almost infinite variety. In some it encloses the flesh in a general sheath, leaving only an opening at the end, sufficient for the expansion of each set of tentacula, surrounding the various mouths of the respective animals. In some species these tubes are placed parallel to each other, in the manner of the pipes of an organ, with transverse partitions at regular intervals for their support ; as exemplified in the *Tubipora Musica*, pl. 30, f. 34 and 66. This last figure represents a portion of the tubes highly magnified, and laid open to show the polypi in their interior. Sometimes the tubes are united together endwise, like the branches of a tree, leaving lateral apertures for the animals to extend their tentacula through as exemplified in the *sertularia frutescens*, pl. 30, f. 4 and 10. In some species the horny base is formed into a number of cells, each of which answers the purpose of protecting its respective polype. These are usually situated at the extremity of the branches, and have all the appearance of flowers, as may be seen in the *tabularia ramosa*, pl. 30, f. 59, 60. The different species of the genus *Flustra*,—as will be seen in the species *carbacea*, pl. 30, f. 61, and F. *foliacea*, f. 12,—have the cells excessively minute. These are extended over a flat membraneous substance, having all the appearance of the leaves of plants. These cells are formed in very regular rows, as in the magnified representation of F. *foliacea*, f. 1, and are arranged with as much regularity as the cells of a honeycomb. Nearly the whole of the animals which constitute the other polipiferous masses have an internal inorganic base of support, constituting a kind of skeleton or axis ; the mouths of the polypi being developed at intervals over the surface of the fleshy layer by which this skeleton is covered. This is especially the case with the genera *Gorgonia*, *Antipathes*, and *Corallium*, as they bear the strongest similitude to the branched forms of the stems of vegetables. The flesh contains grains of calcareous matter, which, in the dried specimens, adhere to the surface of the stems. Plate 30, f. 6, is a branch of *Coralium rubrum*, exhibiting the appearance presented by the polypi in their expanded and contracted conditions. F. 7 is the polype of the same, greatly magnified. In many instances the polypi are located in cup-like depressions, situate in the surface of the calcareous axis, which protects them considerably. In the genus *Madrepora*, these depressions are intersected by radiating *plates*, adapted to the number and construction of the tentacula ; and in the *Millepora* the cells are closer and more minute, and do not exhibit any of the star-like radiations. In some species the plates have more of a parallel arrangement ; and in others they form a reticulated appearance.

The materials of which the axis is composed are invariably arranged in concentric layers, thus indicating that their deposition has been successive, and the surface is always marked by longitudinal lines corresponding to the figure of the animal covering the flesh. In some genera the stem consists of horny and calcareous parts alternately disposed, composing a jointed structure. This has been by some naturalists considered an approximation to an articulated skeleton ; as it is susceptible of considerable flection, and yields readily to the currents or waves, without being broken. An example of this structure is seen in the *Isis Hippuris*, pl. 30, f. 21.

Almost the entire class of polypi are attached, by the root of the stem or base, to submarine rocks or other extraneous bodies. The roots are possessed of a very strong adhesive quality.

holds between these and the sea-water polypus, as between all the productions of the sea, and of the land and the ocean. The marine vegetables and animals grow to a monstrous size. The eel, the pike, or the bream, of fresh-waters is but small; but in the sea they grow to an enormous magnitude. The herbs of the field are at most but a few feet high;

The reproduction of all the adhesive polypi depends upon the detachment of gemmules,* or imperfectly formed portions of their soft substance. These gemmules are possessed of active powers of locomotion, apparently for the sole purpose of seeking a place whereon to raise its future habitation at a distance from its parents. This situation once chosen, it is immovably fixed to that spot during its natural life. In the earlier state these gemmules appear on the surface of the parent animal, in the form of small specks, which are visible to the naked eye. In the course of a few months they enlarge in size, and each becomes pyriform, and are observed to protrude from the sides of the internal canals of the parent, adhering by their narrow ends. This form in particular applies to the young of sponges. Shortly after, they are freed, the one after the other, and are borne along by the currents of fluid, which are quickly passing out of the larger openings. Pl. 30, f. 75, represents one of these detached gemmules. Were these devoid of life, they would naturally sink to the bottom by their own gravity, but on the contrary they spontaneously swim about for two or three days, with their broad end forwards. These gemmules, upon microscopic examination, are found to be about two-thirds covered with short cilia, which are in constant and rapid motion: they are extremely minute and transparent, broadest at the base, and tapering to almost invisible points. The strokes of these cilia are made without any regular order, but conspiring to propel the gemmule with the broad end forwards, but without seeming to have an apparent object in view, by a slow gliding motion, quite unlike the zigzag course of animals in search of prey. They appear, however, to have a consciousness of impressions made on them; for if they come in collision with each other, or if they strike against any object, the motion of their cilia is for a short time suspended; they wheel round the spot for some seconds, then renew their vibratory motion, and proceed in their former course.

It is by the narrow extremity that these gemmules become adherent, which soon begins to expand itself laterally, so as to form a broad base of attachment. While this is proceeding, the cilia continue to move rapidly, but their motions soon become languid, and in a very few hours cease entirely to move, and finally disappear, being no longer of use. The same mode of proceeding is common to the gemmules of all the class polypi, except that there is a variety in the head of the gemmules which swims first. The time of their remaining in a free condition varies with the species, from a few hours to three days.

The tentacula of polypi are exquisitely sensible, and are frequently seen, either singly or collectively, curving their extremities towards the mouth, when any minute floating body comes in contact with them. During the time a polype is expanded, a constant current of water is directed towards the mouth: the currents are never produced by the motions of the tentacula themselves, but are always the effects of rapid vibrations of the cilia placed on the tentacula. The polypi of the *Flustra carbasea*, for example, f. 62, pl. 30, have each tentacula, provided with a single row of cilia, extending along both the lateral margins, from their base to their termination: as we have represented at f. 63, in a portion of one of their tentacula, highly magnified. Every polype is furnished with twenty-two tentacula, and there are about fifty cilia on each side of a tentaculum, so that every individual polype has no less than two thousand two hundred cilia. Every square inch contains about one thousand eight hundred cells; the branches of an ordinary specimen present about ten square inches of surface, so that an ordinary specimen of this species presents a congregation of not less than eighteen thousand polypi; with three hundred and ninety-six tentacula, and thirty-nine millions six hundred thousand cilia; while other species undoubtedly contain more than ten times these numbers. Dr Grant has estimated that there are about *four hundred millions* of cilia on a single *Flustra foliacea!* the species which we have represented, f. 12. We have given a representation of a gemmule of the *Flustra carbasea*, pl. 30, f. 64.

It is still an unsettled point whether the aggregated mass is to be considered as one individual, endowed with a common principle of life and growth, or whether each mouth is to be regarded as the organ of a separate animal. Dr Grant is of opinion that the detached polypi called *pennatula*, or sea pens, f. 14, pl. 30, do not possess a voluntary power of locomotion, but that they are carried along by the currents of the ocean. Indeed, none of all this extensive tribe of beings which are invested in a stony covering, or which have a horny or calcareous axis, have the power of locomotion; and it is not until we descend to animals divested of these, that we can trace animals having this power. The fresh-water polypi, called *hydra*, are locomotive. These animals present us with the simplest kind of structure which has yet been ascertained. The hydra consists simply of a fleshy tube, open at both extremities, and the aperture of the tube serving as a mouth, which is situate in the more dilated end, and this mouth is provided at its margin with a single row of tentacula. Looking to this animal, we may suppose that nature has formed it, to prove that animal life may be carried on without the aid of the complicated machinery which she has given to the higher orders of creation. The hydra can change place at will. F. 69, pl. 30, represents the *hydra viridis*. This animal has the power of fixing itself in an erect position by the foot, and if it wishes to change place, it slowly bends till its head touches the plane on which it is moving, and adheres to it by the mouth, or by one or two of its tentacula; the foot is then detached, and by a curve of the body placed close to the head, where it is again fixed, preparatory to a new step, which it performs by a repetition of the same movements.

Sponges, in their general aspect, have much the appearance of plants, and they were by many regarded as such; but it has been satisfactorily ascertained that they are composed of soft flesh, intermixed with a tissue of fibres, some of which are solid, others tubular, and the whole being curiously interwoven into a kind of network. It will be perceived, on examining f. 70, pl. 30, that every part of a living sponge presents to the eye two kinds of orifices, the larger being somewhat round in its shape, with the margins raised, forming projecting papillæ; the smaller being much more numerous, exceedingly minute, and are usually termed the pores of the sponge.

For many ages, indeed, so far back as the time of Aristotle, who died 322 years before the birth of Christ, sponges were supposed to be so sensitive, that they shrunk from the touch; and later naturalists asserted that, if punctured by sharp instruments, they would exhibit visible tremulous motions. But Dr Grant has most effectually refuted this error, by subjecting sponges to the most severe experiments, such as lacerating, puncturing, burning, or otherwise wounding their texture, by

* The word *Gemmule* is taken from the Latin word *gemma*, a bud; and its meaning, as applied to polypi, is that of a young animal, not contained within an envelope or egg.

those of the sea often shoot forth a stalk of a hundred. It is so between the polypi of both elements. Those of the sea are found from two feet in length to three or four, and Pliny has even described one, the arms of which were no less than thirty feet long. Those in fresh waters, however, are comparatively minute; at their utmost size seldom above three

---

the application of corrosive chemical agents. He has discovered the true nature of the currents of fluid issuing at different points, which he thus graphically describes: "I put a small branch of the *spongia coalita*, with some sea-water, into a watch-glass, under the microscope, and, on reflecting the light of a candle through the fluid, I soon perceived that there was some intestine motion in the opaque particles floating through the water. On moving the watch-glass, so as to bring one of the apertures on the side of the sponge fully into view, I beheld, for the first time, the splendid spectacle of this living fountain, vomiting forth, from a circular cavity, an impetuous torrent of liquid matter, and hurling along, in rapid succession, opaque masses, which it strewed every where around. The beauty and novelty of such a scene in the animal kingdom, long arrested my attention, but after twenty-five minutes of constant observation, I was obliged to withdraw my eye from fatigue, without having seen the torrent for one instant change its direction, or diminish, in the slightest degree, the rapidity of its course." It thus appears that the large orifices on the surface of a living sponge, are destined for the discharge of a constant stream of water from the interior of the body. We have attempted to represent the particles thrown out by these currents in f. 70. These currents, issuing from the larger orifices, are best seen by placing the living animal in a shallow vessel of sea-water, and strewing a little powdered chalk over the surface, the motions of which render the current very sensible to the naked eye. It is by the myriads of minute pores, which exist in every part of the surface, that this water enters, conveying with it the materials necessary for the subsistence of the animal. These pores conduct the fluid into the interior, where, after percolating through the numerous channels of communication which pervade the substance of the body, it is collected into wider passages, terminating in the focal orifices above described, and is finally discharged. The mechanism by which these currents are produced, is involved in much obscurity.

The genus *vorticella* is constituted of a small tribe of animals which differ from the polypi in one particular, namely, that of being destitute of tentacula, and having cilia only, surrounding the margin of a bell-shaped body, which is mounted upon a long, slender peduncle. The animals of this genus are always attached to some extraneous body by this footstalk, as represented in *vorticella polypina*, pl. 30, f. 75, but have the power of moving about in all directions, to the extent of the range of the footstalk. Currents are, as usual, excited by the vibrations of the cilia, and these are the efficient instruments of progressive motion. The ordinary position of the peduncle of the vorticella is spiral, but it can extend it quite in a straight line when in search of food; but it suddenly retreats from danger, by resuming the spiral folds of its peduncle.

Lamarck arranges the polypi under five orders, with the following characters:—

I. Polypi Natantes.—Polypi provided with tentacula, united in a common fleshy mass, placed on an axis, free, and floating in the water.

II. Polypi Tubiferi.—Tentaculated polypi united in a common fleshy body, without any solid axis, and covered with tubiform cylinders.

III. Polypi Vaginati.—Polypi with tentacula, always fixed in an inorganic covering, and forming in general compound animals.

IV. Polypi Denudati.—Tentaculated polypi not forming a common envelop, fixed either constantly or spontaneously.

V. Polypi Ciliati.—Polypi without any tentacula; but instead of them, vibratile ciliæ, at or near the mouth.

ORDER I.—POLYPI NATANTES.

Polypi united in a common fleshy body, or congregated mass, free, elongated, enveloping an inorganic axis, cartilaginous, osseous, or stony; each polypus provided with tentacula placed around the mouth, and radiating. The animals of this order are congregated on a common body, in which they all participate, while each appears to enjoy a separate existence, and distinct powers of volition. The common body has the appearance of a naked fleshy mass, with the polypi protruding from its surface, and in the centre is placed an inorganic axis resulting from some deposition of the animals, in the same manner as the outer covering in the other orders. Some of these compound animals float freely in the water, and others remain at the bottom in the mud or sand. Many of them diffuse a vivid phosphorescent light. *Umbellularia Greenlandica*, pl. 30, f. 13. Body free, consisting of a long simple stem, with a bony inarticulated axis, enveloped by a fleshy membrane. Inhabits the Northern ocean. *Virgularia;* body free, filiform or linear, greatly elongated. Inhabits the Northern ocean. *Renilla;* body free, depressed, kidney-shaped, polypi provided with six rays each. *Pennatula phosphorea*, pl. 30, f. 14. Body free, fleshy, penniform, polypi with radiated tentacula. Fig. 65 represents some of the polypes greatly magnified. Inhabits the British seas. *Funiculina;* body free, filiform, very simple, long, fleshy, and provided with warts. Inhabits the American ocean. *Veretillum;* body free, fleshy, simple, cylindrical, polypiferous above, and with the base naked.

ORDER II.—POLYPI TUBIFERI.

Polypi united in a common fleshy body, either simple, lobed, or ramified, and constantly fixed at its base, destitute of any solid internal axis; surface entirely or in part covered with tubiform cylinders, rarely retractile; mouth terminal, provided with eight pectinated tentacula. The tubiferous polypi always exist in the form of a fleshy subgelatinous body, invariably fixed by their base. They are more or less simple, convex, lobed, or slightly ramified. The upper part of the surface of their body is covered with a vast number of small tubiform movable cylinders; having at their summit a roundish sub-octagonal mouth surrounded by eight pectinated tentacula. *Lobularia digitata*, pl. 30, f. 15. Common body of a fleshy consistence, elevated upon the base. Inhabits the coast of Europe. Fig. 16 is a magnified view of a portion of this species. *Cliona;* of a fleshy, irritable substance, provided with siliceous spicula, generally embedded in the cavities of shells. Inhabits empty oyster shells on the British coasts. *Ammothea;* with the common body divided into many short and branched stems. Inhabits the coasts of the Red sea. *Xenia;* the common body provided with thick, somewhat short, naked stems, emanating from the base, and divided at their summit. *Anthelia;* common body spread out in a thin plate, or depressed over marine substances. Inhabits the shores of the Red sea.

ORDER III.—POLYPI VAGINATI.

Each individual polype tentaculated, constantly fixed in an inorganic body, or sheath, which completely envelops them, and forming in general compound animals. This is the most extensive class of polypi, and is divided into seven sections. The animals are very delicate, transparent, and extremely contractile, usually fixed in an inorganic body of their own formation. This calcareous mass is increased in size with every successive generation; and these, in the course of time, accumulate to such a size, that they raise islands in the midst of the ocean. The cells are short, long, or tubular, the orifice

parts of an inch long, and when gathered up into their usual form, not above a third even of those dimensions.

It was upon these minute animals that the power of dissection was first tried in multiplying their numbers. They had been long considered as little worthy the attention of observers, and were consigned to that neglect in

---

sometimes irregular, and at others regular: the interior walls, being simple, longitudinally striated, or lamellated, and stelliform.

SECTION I.

The polypiferous masses composed of two distinct parts; the *first* consisting of numerous horny fibres, either in fasciculi, radiated, interlaced, crossed, or fitted together; the *second* is composed of a fleshy or gelatinous pulp; covering, enveloping, or attaching the fibres, containing the polypi, and assuming in drying a consistence more or less firm. *Alcyonium gorgonoides*, pl. 30, f. 9. The polypiferous masses polymorphous, soft, or fleshy, when recent, but somewhat coriaceous and firm when dried. *Geodia;* the polypiferous mass free, fleshy, tuberous, hollow interiorly. *Tethia;* with a knotty subglobular polypiferous mass, the interior with numerous, fasciculated fibres *Spongia tubulosa*, pl. 30, f. 5. Polypiferous mass soft, gelatinous, very flexible, and fixed; the cartilaginous matter supported by calcareous or siliceous spicula; pores excessively numerous and irregular. The spicula are represented at figs. 71 and 72. It will be seen by the *Spongia coalita*, f. 70, that there are two kinds of orifices; the larger having a rounded shape, provided generally with raised margins, which form projecting papillæ, the smaller being much more numerous, exceedingly minute, and constituting what are termed the pores of the sponge. *Flabellaria pavonia*, pl. 30, f. 17. The polypiferous mass caulescent, fan-shaped, incrusted, and frequently divided. Inhabits the seas of America. *Fincrassata*, pl. 30, f. 2. *Penicillus capitatus*, pl. 30, f. 18. Polypiferous mass, supported on a simple, exteriorly incrusted stalk, filled interiorly with many horny fasciculated fibres, and divided at its summit into a cluster of filiform, dichotomous, articulated branches. Fig. 19 shows the articulations magnified.

SECTION II.

The polypiferous masses branched like plants, and composed of two kinds of substance, namely, a central solid axis, and a fleshy incrustation, which invests and contains the polypi; axis inorganic, corneous, or stony; when dried the polypiferous crust is porous, cellular, and friable. *Corallina corniculata*, pl. 30, f. 11. Polypiferous mass adherent, greatly branched. Inhabit the American and European seas. Fig. 4 is a magnified view of some branches. *Gorgonia verriculata*, pl. 30, f. 8. Polypiferous mass branched and adherent. Indian seas. *Antipathes spiralis*, pl. 30, f. 20. Polypiferous mass adherent and branched. Indian ocean. *Isis hippuris*, pl. 30, f. 21. Polypiferous mass arborescent, and fixed. Indian ocean. *Melitæa;* adherent, tree-shaped, having a jointed knotty axis. *Corallium rubrum*, pl. 30, f. 6. Adherent, branched, stiff, and devoid of articulation. Fig. 7 represents one of the polypi greatly magnified. Indian ocean.

SECTION III.

With stony polypiferous masses, having star-shaped, or waved laminar furrows.

1. With Lateral Stars, or spread over the surface.

Oculina prolifera, pl. 30, f. 22. Polypiferous mass of a stony consistence. Northern ocean. *Seriatopora subulata*, pl. 30, f. 23. Adherent, stony, with slender, subcylindrical branches. *Madrepora fungites*, pl. 30, f. 24. Adherent, subdendroidal, branching. West Indian seas. *Pocillopora;* adherent, branched, lobed, and stony. *Porites clavaria*, pl. 30, f. 25. Adherent, stony, branched, or lobed and obtuse, with a stelliferous surface. American and Indian ocean. Fig. 26, this species greatly magnified. *Astrea radiata*, pl. 30, f. 27. Adherent, incrusting marine substances, or forming a hemispherical or globular mass. American seas. *Asteria denticulata*, pl. 30, f. 26. *Explanaria mesenterina*, pl. 30, f. 28. Adherent, stony, exhibiting a free, foliaceous membrane. Indian ocean. *Echinoptera;* adherent, stony, depressed, and extended into a free membrane. *Monticularia;* adherent, stony, incrusting marine substances. *Meandrina labyrinthica*, pl. 30, f. 29. Adherent, stony, forming a simple, convex, or hemispherical mass. American ocean. *Agaricia ampliata*, pl. 30. f. 30. Adherent, stony, with depressed foliaceous expansions. Indian ocean. *Pavonia agaricites*, pl. 30, f. 31. Adherent, stony, frondescent, with depressed subfoliaceous lobes. American seas.

2. Stars terminal.

Fungia agariciformis; free, stony, simple, orbicular, or oblong, convex and lamellar above. Indian seas. *Cyclolites;* free, stony, elliptical or orbicular, convex and lamellar above, with a hollow centre, depressed below. *Turbinolia;* free, simple, turbinated, or wedge-shaped, and acute at the base. *Caryophyllia cyathus*, pl. 30, f. 33. Mass free, stony, simple, or branched. Mediterranean. Fig. 67, *C.* Smithii. Fig. 68, animal fully expanded. *Sarcinula;* free, stony, consisting of a simple, polypiferous, and thick mass. *Stylina;* mass stony, simple, exteriorly rough; tubes numerous.

SECTION IV.

With a stony polypiferous, solid, and interiorly compact mass: cells perforated, or tubular, and destitute of laminæ. *Tubipora musica*, pl. 30, f. 34. Stony, composed of cylindrical tubes, which are straight, and individually separate. Indian seas. Fig. 66 is a magnified portion of the tubes. *Catenipora;* stony, composed of parallel tubes, inserted in the thickness of vertical plates, anastomosed like net-work. *Favosites;* stony, simple, variable in form, composed of parallel prismatic tubes. *Millepora calcarea*, pl. 30, f. 35. Stony, interiorly solid, polymorphous, branched, or frondescent. European seas. *Distichopora;* adherent, solid, stony, with slightly compressed branches. *Orbulites;* free, stony, orbicular, depressed, or slightly concave. *Lunulites;* free, stony, orbicular, depressed. *Ovulites;* free, stony, egg-shaped, or cylindrical; known only in a fossil state.

SECTION V.

Polypiferous masses of a substony consistence, with frondescent or crustaceous expansions; cells small, short, sometimes in a regular series, at other times irregular, and usually disposed at the surface of the expansions of marine substances. *Dactylopora;* free, stony, cylindrical, obtuse at one extremity, contracted and perforate at the other. *Ocellaria;* stony, depressed as a membrane, variously twisted, somewhat funnel-shaped. *Alveolites;* stony, either forming incrustations, or a free mass disposed in numerous concentric layers, covering one another. *Retepora cellulosa*, pl. 30, f. 36. Stony, interiorly porous, with thin depressed expansions. *Adeona;* nearly stony, caulescent, or fan-shaped. *Eschara foliacea*, pl. 30, f. 37. Nearly stony, but not flexible. *Cellepora pumicosa*, pl. 30, f. 38. Nearly stony, interiorly porous, spreading in a raised, foliaceous crust. Fig. 39 is a magnified view of this mass of polypi. European seas. *Discopora;* suberustaceous, depressed, extended in an undulated, discoid, stony plate, with the upper surface cellular. *Tubulipora transversa*, pl. 30, f. 40. Consisting of a parasitical or incrusting mass, with submembranous cells disposed in clusters or series, and mostly free. Fig. 41, one of the warts magnified. Fig. 42 represents one of the particles of which the crust is composed. Mediterranean. *Flustra foliacea*, pl. 30, f. 12. Flexible, submembranous, stony and frondescent, or consisting of a thin crust, formed of contiguous cells. Fig. 1 is a magnified view of the cells. European seas. *Flustra carbasea*, pl. 30, f. 61, is the

which thousands of minute species of insects remain to this very day. It is true, indeed, that Reaumur observed, classed, and named them. By contemplating their motions, he was enabled distinctly to pronounce on their being of the animal and not of the vegetable kingdom; and he called them polypi, from their great resemblance to those larger ones that were found in the ocean. Still, however, their properties were neglected, and their history unknown.

Mr Trembley was the person to whom we owe the first discovery of the amazing properties and powers of this little vivacious creature. He divided this class of animals into four different kinds: into those inclining to green, those of a brownish cast, those of a flesh colour, and those which he calls the *polype de panache*. The differences of structure in these, as also of colour, are observable enough; but the manner of their subsisting, of seizing their prey, and of their propagation, is pretty nearly the same in all.

Whoever has looked with care into the bottom of a wet ditch when the water is stagnant, and the sun has been powerful, may remember to have seen many little transparent lumps of jelly, about the size of a pea, and flatted on each side; such also as have examined the under side of the broad-leafed weeds that grow on the surface of the water, must have observed them studded with a number of these little jelly-like substances, which were probably then disregarded, because their nature and history were unknown. These little substances, however, were no other than living polypi, gathered up into a quiescent state, and seemingly inanimate, because either undisturbed, or not excited by the calls of appetite to action. When they are seen exerting themselves, they put on a very different appearance from that when at rest: to conceive a just

---

polypiferous mass. Fig. 62 represents the tentacula in the polypes of this species. Fig. 63 is a portion of one of these tentacula highly magnified. Fig. 64 is a delineation of one of the gemmules, greatly magnified. Fig. 78 is a part of *F. verticiliata* greatly magnified.

SECTION VI.

Polypiferous masses consisting of one substance only, slender, fistulous, membranous, or horny stems, flexible and branched, containing polypi in their interior. *Polyphysa;* polypiferous mass fungoid, with a calcareous crust. *Acetabulum;* fungoid, with a calcareous crust. *Tibiana;* adherent, tubular, membranaceous, or horny. *Dichotomaria fruticulosa*, pl. 30, f. 43. Polypiferous mass with tubular, subarticulate, dichotomous stems, and a calcareous incrustation. American seas. Fig. 44 represents the *D. obtusata*, an inhabitant of the coasts of the Bahama islands. *Anguinaria spatulata*, pl. 30, f. 45. Adherent, and extending itself in the form of a plant. Fig. 46 is a magnified portion. *Cellaria thuia*, pl. 30, f. 47. Adherent, with the stems tubular and branched. Fig. 48, a portion of a stem magnified. European seas. *Liriozoa Caribæa*, pl. 30, f. 49. Adherent, branched, calcareous; with tubular stems, jointed, creeping. Fig. 50, a portion of a stem magnified. West Indian seas. *Serialaria lendigera*, pl. 30, f. 51. Adherent, branched, horny, stems, slender. Fig. 52, a portion of a stem magnified. European seas. *Plumularia myriophillum*, pl. 30, f. 53. Adherent, branched, horny, stalks slender. Fig. 54, a portion of a stem magnified. European seas. *Antennularia ramosa*, pl. 30, f. 55. Adherent, horny, with the stems fistulous, simple, or branched. Fig. 56, a portion of a stem magnified. European seas. *Sertularia frutescens*, pl. 30, f. 10. Adherent, horny, stems slender and fistulous. Fig. 4, a portion of a stem magnified. European seas. *S. abietina*, pl. 30, f. 73 and 77. *Campanullaria verticillata*, pl. 30, f. 57. Adherent, stems fistulous, filiform, horny, simple, or branched. Fig. 58, a magnified portion of a branch. *Cornularia;* adherent, horny, with simple, funnel-shaped stems. *Tubularia ramosa*, pl. 30, f. 59. Adherent, slender, tubular, simple, or branched, horny. Fig. 60, a magnified portion of a branch. British seas. Fig. 74, *T. magnifica.* Tropical seas. *Plumatella;* adherent, slender, tubular, branching, submembranous, extremities of stems and branches terminated each by a polypus.

SECTION VII.

Polypiferous masses either free, isolated, and floating in the water, or adherent, and agglomerated in cellular masses, composed of one substance on aquatic bodies; polypi provided with numerous tentacula, which do not complete the circle round the mouth. The animals of this section chiefly inhabit fresh water. *Alcyonella;* incrusting, thick, convex, and irregular, consisting of an aggregation of vertical subpentangular tubes, open at their summit. *Spongilla;* adherent polymorphous, cellular, irregular, composed of subpiliferous laminæ. *Cristatella;* free, globular, gelatinous, covered by short, thick, polypiferous tubercles, each of which encloses a polypus. *Difflugia;* body small, gelatinous, contractile, enclosed in a testaceous tube, projecting.

ORDER IV.—POLYPI DENUDATI.

Polypi provided with tentacula, and not forming a polypiferous mass; greatly diversified in form, in the number and situation of their tentacula, and fixed either constantly or spontaneously. *Pedicellaria;* adherent, formed of a stiff peduncle. *Coryne;* fleshy, seated on a peduncle. *Hydra viridis*, pl. 30, f. 76. Oblong, linear, in the form of a reversed cone, narrowed below, gelatinous, transparent, and fixed spontaneously by the base. *a.* exhibits the body extended, and *b.* the body in a contracted state. Fig. 69, body expanded. Inhabits fresh waters.

ORDER V.—POLYPI CILIATI.

Mouth provided with ciliated and gyratory organs which agitate the water, but do not seize the food.

SECTION I.—ROTIFERI.

With one or many organs in a circular form, ciliated, and rotatory at the opening of the mouth. *Tubicolaria;* body contractile, oblong, contained in a tube fixed on aquatic bodies. *Vorticella polypina*, pl. 30, f. 75. Body naked, pedunculated, fixed spontaneously, or constantly by its base. Inhabits stagnant waters. *Urceolaria;* body free, contractile, urceolate, sometimes elongated, without tail or peduncle. *Furcularia;* body free, contractile, oblong, provided with a short or elongated tail. *Brachionus;* body free, contractile, nearly oval, covered, at least partly, by a transparent sheath. *Folliculina;* body contractile, oblong, inclosed in a transparent sheath.

SECTION II.—VIBRATILES.

Ciliæ placed near the mouth, moving in interrupted vibrations. *Vaginicola;* body minute, oval, or oblong, anteriorly ciliated, and provided with a tail; enclosed in a transverse sheath, but not attached. *Trichocerca;* body minute, oval, or oblong, anteriorly truncated. *Rattulus;* body minute, oblong, truncated, or anteriorly obtuse.

idea of their figure, we may suppose the finger of a glove cut off at the bottom; we may suppose also several threads or horns planted round the edge like a fringe. The hollow of this finger will give us an idea of the stomach of the animal; the threads issuing forth from the edges may be considered as the arms or feelers with which it hunts for its prey. The animal, at its greatest extent, is seldom seen above an inch and a half long, but it is much shorter when it is contracted and at rest; it is furnished neither with muscles nor rings, and its manner of lengthening or contracting itself more resembles that of the snail, than worms, or any other insect. The polypus contracts itself more or less, in proportion as it is touched, or as the water is agitated in which they are seen. Warmth animates them, and cold benumbs them; but it requires a degree of cold approaching congelation before they are reduced to perfect inactivity; those of an inch have generally their arms double, often thrice as long as their bodies. The arms, where the animal is not disturbed, and the season not unfavourable, are thrown about in various directions, in order to seize and entangle its little prey; sometimes three or four of the arms are thus employed, while the rest are contracted like the horns of a snail, within the animal's body. It seems capable of giving what length it pleases to these arms; it contracts and extends them at pleasure, and stretches them only in proportion to the remoteness of the object it would seize.

These animals have a progressive motion, which is performed by that power they have of lengthening and contracting themselves at pleasure; they go from one part of the bottom to another; they mount along the margin of the water, and climb up the side of aquatic plants. They often are seen to come to the surface of the water, where they suspend themselves by their lower end. As they advance but very slowly, they employ a great deal of time in every action, and bind themselves very strongly to whatever body they chance to move upon as they proceed; their adhesion is voluntary, and is probably performed in the manner of a cupping-glass applied to the body.

All animals of this kind have a remarkable attachment to turn towards the light; and this naturally might induce an inquirer to look for their eyes; but however carefully this search has been pursued, and however excellent the microscope with which every part was examined, yet nothing of the appearance of this organ was found over the whole body; and it is most probable that, like several other insects which hunt their prey by their feeling, these creatures are unfurnished with advantages which would be totally useless for their support.

In the centre of the arms, as was said before, the mouth is placed, which the animal can open and shut at pleasure, and this serves at once as a passage for food, and an opening for it after digestion. The inward part of the animal's body seems to be one great stomach, which is open at both ends; but the purposes which the opening at the bottom serves are hitherto unknown, but certainly not for excluding their excrements, for those are ejected at the aperture by which they are taken in. If the surface of the body of this little creature be examined with a microscope, it will be found studded with a number of warts, as also the arms, especially when they are contracted; and these tubercles, as we shall presently see, answer a very important purpose.

If we examine their way of living, we shall find these insects chiefly subsisting upon others, much less than themselves, particularly a kind of millepedes that live in the water, and a very small red worm, which they seize with great avidity. In short, no insect whatsoever, less than themselves, seems to come amiss to them; their arms, as was said before, serve them as a net would a fisherman, or perhaps, more exactly speaking, as a lime-twig does a fowler.

Wherever their prey is perceived, which the animal effects by its feeling, it is sufficient to touch the object it would seize upon, and it is fastened without a power of escaping. The instant one of this insect's long arms is laid upon a millepede, the little insect sticks without a possibility of retreating. The greater the distance at which it is touched, the greater is the ease with which the polypus brings the prey to its mouth. If the little object be near, though irretrievably caught, it is not without great difficulty that it can be brought to the mouth to be swallowed. When the polypus is unsupplied with prey, it testifies its hunger by opening its mouth; the aperture, however, is so small that it cannot be easily perceived; but when, with any of its long arms, it has seized upon its prey, it then opens the mouth distinctly enough, and this opening is always in proportion to the size of the animal which it would swallow: the lips dilate insensibly by small degrees, and adjust themselves precisely to the figure of their prey. Mr Trembley, who took a pleasure in feeding this useless brood, found that they could devour aliments of every kind, fish and flesh, as well as insects; but he owns they did not thrive so well upon beef and veal, as upon the little worms of their own providing. When he gave one of these famished reptiles any substance which was improper to serve for aliment, at first it seized the prey with avidity, but after keeping it sometime entangled near the mouth, it dropped it again with distinguishing nicety.

When several polypi happen to fall upon the same worm, they dispute their common prey with each other. Two of them are often seen seizing the same worm at different ends, and dragging it at opposite directions with great force. It often happens, that while one is swallowing its respective end, the other is also employed in the same manner, and thus they continue, swallowing each his part, until their mouths meet together; they then rest, each for some time in this situation, till the worm breaks between them, and each goes off with his share; but it often happens that a seemingly more dangerous combat ensues, when the mouths of both are thus joined upon one common prey together; the largest polypus then gapes and swallows his antagonist; but what is very wonderful, the animal thus swallowed seems to be rather a gainer by the misfortune. After it has lain in the conqueror's body for about an hour, it issues unhurt, and often in possession of the prey which had been the original cause of contention. How happy would it be for men if they had as little to fear from each other!

These reptiles continue eating the whole year, except when the cold approaches to congelation; and then, like most others of the insect tribe, they feel the general torpor of nature, and all their faculties are for two or three months suspended: but if they abstain at one time, they are equally voracious at another, and, like snakes, ants, and other animals, that are torpid in winter, the meal of one day suffices them for several months together. In general, however, they devour more largely in proportion to their size, and their growth is quick exactly as they are fed; such as are best supplied, soonest acquire their largest size, but they diminish also in their growth with the same facility if their food be taken away.

Such are the more obvious properties of these little animals, but the most wonderful still remain behind: their manner of propagation, or rather multiplication, has for some years been the astonishment of all the learned of Europe. They are produced in as great a variety of manner as every species of vegetable. Some polypi are propagated from eggs, as plants are from their seed: some are produced by buds issuing from their bodies, as plants are produced by inoculation; while all may be multiplied by cuttings, and this to a degree of minuteness that exceeds even philosophical perseverance.

With respect to such of this kind as are hatched from the egg, little curious can be added, as it is a method of propagation so common to all the tribes of insect nature; but with regard to such as are produced like buds from their parent stem, or like cuttings from an original root, their history requires a more detailed explanation. If a polypus be carefully observed in summer, when these animals are chiefly active, and more particularly prepared for propagation, it will be found to bourgeon forth from different parts of its body several tubercles or little knobs, which grow larger and larger every day; after two or three days' inspection, what at first appeared but a small excrescence takes the figure of a small animal, entirely resembling its parent, furnished with feelers, a mouth, and all the apparatus for seizing and digesting its prey. This little creature every day becomes larger, like the parent to which it continues attached; it spreads its arms to seize upon whatever insect is proper for aliment, and devours it for its own particular benefit: thus it is possessed of two sources of nourishment, that which it receives from the parent by the tail, and that which it receives from its own industry by the mouth. The food which these animals receive often tinctures the whole body, and upon this occasion the parent is often seen communicating a part of its own fluids to that of its progeny that grows upon it; while, on the contrary, it never receives any tincture from any substance that is caught and swallowed by its young. If the parent swallows a red worm, which gives a tincture to all its fluids, the young one partakes of the parental colour; but if the latter should seize upon the same prey, the parent polypus is no way benefited by the capture, but all the advantage remains with the young one.

But we are not to suppose that the parent is capable of producing only one at a time; several young ones are thus seen at once, of different sizes, growing from its body, some just budding forth, others acquiring their perfect form, and others come to sufficient maturity, and just ready to drop from the original stem to which they had been attached for several days. But what is more extraordinary still, those young ones themselves that continue attached to their parent, are seen to bourgeon, and propagate their own young ones also, each holding the same dependence upon its respective parent, and possessed of the same advantages that have been already described in the first connection. Thus we see a surprising chain of existence continued, and numbers of animals naturally produced without any union of the sexes, or other previous disposition of nature.

This seems to be the most natural way by which these insects are multiplied; their production from the egg being not so common; and though some of this kind are found with a little bladder attached to their bodies, which is supposed to be filled with eggs, which afterwards come to maturity, yet the artificial method of propagating these animals is much more expeditious, and equally certain. It is

indifferent whether one of them be cut into ten, or ten hundred parts, each becomes as perfect an animal as that which was originally divided; but it must be observed, that the smaller the part which is thus separated from the rest, the longer it will be in coming to maturity, or in assuming its perfect form. It would be endless to recount the many experiments that have been tried upon this philosophical prodigy: the animal has been twisted and turned into all manner of shapes; it has been turned inside out, it has been cut in every division, yet still it continued to move; its parts adapted themselves again to each other, and in a short time it became as voracious and industrious as before.

Besides these kinds mentioned by Mr Trembley, there are various others which have been lately discovered by the vigilance of succeeding observers, and some of these so strongly resemble a flowering vegetable in their forms, that they have been mistaken by many naturalists for such. Mr Hughes, the author of the natural history of Barbadoes, has described a species of this animal, but has mistaken its nature, and called it a sensitive flowering plant; he observed it to take refuge in the holes of rocks, and, when undisturbed, to spread forth a number of ramifications, each terminated by a flowery petal, which shrunk at the approach of the hand, and withdrew into the hole from whence before it had been seen to issue. This plant, however, was no other than an animal of the polypus kind, which is not only to be found in Barbadoes, but also on many parts of the coast of Cornwall, and along the shores of the continent.

CHAP. V.

OF THE LITHOPHYTES AND SPONGES.[1]

It is very probable that the animals we see and are acquainted with, bear no manner of proportion to those that are concealed from us. Although every leaf and vegetable swarms with animals upon land, yet at sea they are still more abundant; for the greatest part of what would seem vegetables growing there, are in fact nothing but the artificial formation of insects, palaces which they have built for their own habitation.

If we examine the bottom of the sea along some shores, and particularly at the mouths of several rivers, we shall find it has the appearance of a forest of trees under water, millions of plants growing in various directions, with their branches entangled in each other, and sometimes standing so thick as to obstruct navigation. The shores of the Persian Gulf, the whole extent of the Red sea, and the western coasts of America, are so choked up in many places with these coraline substances, that though ships force a passage through them, boats and swimmers find it impossible to make their way. These aquatic groves are formed of different substances, and assume various appearances. The coral plants, as they are called, sometimes shoot out like trees without leaves in winter; they often spread out a broad surface like a fan, and not uncommonly a large bundling head like a faggot; sometimes they are found to resemble a plant with leaves and flowers; and often the antlers of a stag, with great exactness and regularity. In other parts of the sea are seen sponges of various magnitude, and extraordinary appearances, assuming a variety of fantastic forms, like large mushrooms, mitres, fonts, and flowerpots. To an attentive spectator, these various productions seem entirely of the vegetable kind; they seem to have their leaves and their flowers, and have been experimentally known to shoot out branches in the compass of a year. Philosophers, therefore, till of late, thought themselves pretty secure in ascribing these productions to the vegetable kingdom; and Count Marsigli, who has written very laboriously and learnedly upon the subject of corals and sponges, has not hesitated to declare his opinion, that they were plants of the aquatic kind, furnished with flowers and seeds, and

[1] See the preceding note. There are about fifty different species of sponges, of which nine or ten belong to this country. They are found in the Mediterranean and those seas in warm and temperate latitudes, diminishing in number and becoming of inferior quality on the approach to cold regions. They adhere to rocks in places the least exposed to the action of currents and waves, which the ebbing tide does not leave uncovered. The best sponges known to us are those which come from the Archipelago, where they abound near many of the islands, whose inhabitants may be said to subsist by the sponge-fishery, if we may so call it. At the Cyclades, for instance, sponge-diving forms the chief employment of the population. The sea is at all times extremely clear, and the experienced divers are capable of distinguishing from the surface the points to which the sponge is attached below, when an unpractised eye could but dimly discern the bottom. Each boat is furnished with a large stone attached to a rope, and this the diver seizes in his hand on plunging head foremost from the stern. He does this in order to increase the velocity of his descent; thus economizing his stock of breath, as well as to facilitate his ascent when exhausted at the bottom, being then quickly hauled up by his companions. Few men can remain longer than about two minutes below; and, as the process of detaching the sponge is very tedious, three, and sometimes four divers descend successively to secure a particularly fine specimen.

The best sponge is that which is the palest and lightest, has small holes, and is soft to the touch. By the old physicians, sponge was regarded as a cure for a long list of maladies; this list is now much abridged, though burned sponge, in which form only it is used, still has a place in the materia medica.

endued with a vegetation entirely resembling that which is found upon land. This opinion, however, some time after, began to be shaken by Rumphius and Jussieu, and at last by the ingenious Mr Ellis, who, by a more sagacious and diligent inquiry into nature, put it past doubt, that corals and sponges were entirely the works of animals, and that, like the honeycomb which was formed by the bee, the coral was the work of an infinite number of reptiles of the polypus kind, whose united labours were thus capable of filling whole tracts of the ocean with those embarrassing tokens of their industry.[1]

[1] *Coral.*—The method in which the polypus secretes the coral, which, when taken from the sea, is in stalks about a foot high and half an inch thick, is understood to be as follows: An egg or new animal, when ejected, falls upon some body, to which, from its gelatinous nature, it adheres. On this foundation it spreads and moulds itself, till at length from the middle of it a sort of excrescence rises upwards, containing the germ of a new animal, which attains its growth by degrees, and sends up a similar extension. These deposite calcareous or chalky matter in the middle, and by the constant generation of new polypi, and the secretion of additional matter, the coral, at the end of ten years, which is the period necessary for its perfect growth, has attained the height and thickness mentioned. It is of various colours—red, vermilion, and white, the latter being most common, and consequently least valuable. When taken out of the sea, it is covered with moss and marine vegetable matter, and is generally somewhat softer and duller in hue than it ultimately becomes.

The coral fisheries form a very considerable trade in several parts of the Mediterranean. From the hollows and caverns of the rocks, where it takes root, the coral is brought up with nets; it also grows, but in less quantities, on the sides of the ocean crags. The greatest height to which it attains is never above a foot, and its usual thickness is about that of the little finger, though often much less. The most extensive fisheries are those carried on in the straits of Messina, off the Sicilian coast, and about three miles distant generally from the land. The fishermen have divided the whole tract, about six miles in length, into ten parts. Every year they fish only in one of these parts, and do not interfere with it again till ten years have elapsed, for the purpose of bringing away only such coral as has attained its full growth.

The appearance of the coral as it is observed in the sea, is said to resemble a miniature forest, from its great quantity and branching character. The greatest portion is procured from a depth of from sixty to a hundred and twenty-five feet; but some fisheries are carried on to the depth of nine hundred feet. Those of the coasts of Marseilles, Barbary, and Trapani, are the principal rivals to the Sicilian fisheries in the European market, but none of them produce the coral in equal quantities, or of equal quality, with the latter. From Messina 3000 pounds are said to be exported annually; the price of which is so much affected by the colour and quality, that, while some of it is valued at ten guineas a pound, other portions are considered not worth ten pence. The vermilion-coloured coral, being the rarest, is the most expensive. The common red, however, brings a high price also, when the quality is good. Chemical analysis has proved that the coral consists of carbonate of lime, a species of chalk, for it dissolves completely in aquafortis, or nitric acid.

Though we may regard with some degree of wonder

If, in our researches after the nature of these plants, we should be induced to break off a branch of the coraline substance, and observe it carefully, we shall perceive its

the production of stalks of coral by a small oyster-like polypus, our astonishment cannot fail to be increased when we consider, that, by an animal of the same size and species as the coraliferous polypus, whole reefs of great extent, and even islands, have been founded and originated. The animal or polypus that accomplishes this is called the Madrepore, and has long been erroneously considered as identical with the coral polypus; hence the masses of land alluded to have received the appellation of coral reefs and islands. These have never yet been found in any extent excepting in the Pacific and Asiatic seas, but in these immense waters the coral rocks and reefs are abundant.

The principal groups of islands of coral formation are, from the New Hebrides, eastward, the Friendly islands, Navigation islands, and the Society islands; and, to the northward of the latter group, the Marquesas. These groups are separated from each other by channels or seas, wider than those which separate the individual islands which form the respective groups; but all these waters abound with shoals and minor islets, which indicate the existence of a common base, and show that the processes by which they will hereafter be united above the level of the sea, are in constant operation.

The structure and progress of these islands towards a state of fitness for the habitation of man, has been thus described. At a vast but unknown depth, below the surface of the sea, the insects attach themselves to the upper points and ridges of rocks, which form the bottom of the ocean, and many of which, in the Pacific ocean, are supposed to be of volcanic origin. Upon these foundations, the little architects labour, building up by means of the secretion before described, pile upon pile of their rocky habitations, until at length the work rises above the sea, and is continued to such a height, as to leave it almost dry at low water, when the insect leaves off building upon that part. A solid rocky base being thus formed, sea-shells, fragments of coral, and sea-sand, thrown up by each returning tide, and broken and mixed together, by the action of the waves, become in time converted into a sort of stone, and thus raise up the surface higher and higher. The heat of the sun so penetrates this mass of stone, that it brakes off into flakes, and these flakes are again raised one upon another by the waves, at high water. The ever active surf continues to throw up the shells of marine animals, and other materials, which fill up the crevices between the stones, and the sand upon the surface being now undisturbed, offers to the seeds of trees and plants cast upon it by the waves, a soil upon which they rapidly grow, and over-shadow the dazzling whiteness of the new formed lands. Trunks of trees, washed into the sea by the rivers from other countries and islands, find here a resting place, and with these come some small animals, chiefly of the lizard and insect tribes. Even before the trees form a wood, the sea-birds nestle among them, and soon the stray land-bird takes refuge in the bushes. At a latter period, man appears, builds his hut upon the fruitful soil formed by the corruption of the vegetation, and calls himself lord and proprietor of this new creation.

These islands vary in extent, as well as in the degree of *finish* to which they have arrived. Of thirty-two examined by captain Beechey, the largest was thirty miles in diameter, and the smallest somewhat less than a mile. They were of various shapes, and all formed of living coral, except one, called Henderson's island, which was partially surrounded by it; and they all appeared to be increasing in size by the active operations of the zoophytes, which are gradually extending, and building up

whole surface, which is very rugged and irregular, covered with a mucous fluid, and almost in every part studded with little jelly-like drops, which, when closely examined, will be found to be no other than reptiles of the polypus kind. These have their motions, their arms, their appetites, exactly resembling those described in the last chapter; but they soon expire when taken out of the sea, and our curiosity is at once stopped in its career, by the animals ceasing to give any mark of their industry: recourse, therefore, has been had to other expedients, in order to determine the nature of the inhabitant, as well as the habitation.

If a coraline plant be strictly observed, while still growing in the sea, and the animals upon its surface be not disturbed, either by the agitation of the waters, or the touch of the observer, the little polypi will then be seen in infinite numbers, each issuing from its cell, and in some kinds the head covered with a little shell, resembling an umbrella, the arms spread abroad, in order to seize its prey, while the hinder part still remains attached to its habitation, from whence it never wholly removes. By this time it is perceived, that the number of inhabitants is infinitely greater than was at first suspected; and that they are all assiduously employed in the same pursuits, and that they issue from their respective cells, and retire into them at pleasure. Still, however, there are no proofs that those large branches which they inhabit, are entirely the construction of such feeble and minute animals. But chemistry will be found to lend a clue to extricate us from our doubts in this particular. Like the shells which are formed by snails, mussels, and oysters, these coraline substances effervesce with acids: and may therefore well be supposed to partake of the same animal nature. But Mr Ellis went still farther, and examined their operations, just as they were beginning. Observing an oyster-bed which had been for some time neglected, he there perceived the first rudiments of a coraline plantation, and tufts of various kinds shooting from different parts of this favourable soil.

above the level of the sea those parts which are at present below the water. Twenty-nine of the number had *lagoons*, (or morasses) in the centres, within which, it has been observed, the smaller species of coral seek a quiet abode, and labour silently and slowly, in throwing up banks, which, in process of time, unite with islets that surround them, and at length fill up the *lagoon*, so that what was at first a ring of little islands, becomes one connected mass of land. All these islands are situated within the action of the trade wind, except one (Oeno,) which is on the verge of it, and follow one general rule in having their *windward side* higher, and more protected than the other, and not unfrequently, well wooded, while the other is only a half drowned reef, or wholly under water. At Gambier and Matilda islands this inequality is very conspicuous; the weather-side of both being wooded, and, of the former, inhabited, while the other sides were twenty or thirty feet under water, where they might be perceived equally narrow and well defined. One of these islands (Malden island,) presented the singular appearance of perpendicular coral cliffs, elevated eighty feet above the level of the sea; these were of dead coral, but the outside of the island was surrounded with a belt of living coral, sloping from the cliffs, to from three to twenty-five fathoms under water, after which it descends abruptly to a depth where a 200-fathom line does not reach the bottom. The surface of this island is flat; and it is not easy to account for its present elevation, unless by an earthquake or sub-marine volcanic explosion.

Gambier Group consists of five large islands and several smaller ones, the whole (as well as the five separate islands,) being enclosed in a reef of coral, forming an irregular diamond-shaped space. The older islands are volcanic, and the largest rises in two peaks, 1248 feet above the level of the sea. The outer belt of coral descends abruptly outside to an unfathomable depth, but slopes inward by a decreasing declination, to about 120 or 150 fathoms below the surface; and within this enclosure, a number of low islands are already formed, and others are in progress, rendering it almost certain that, in process of time, the whole space will become one island, each of the original islands being also inclosed with its own reef. These are inhabited by a race of men with fine Asiatic countenances, wearing mustachios and beards, and they appeared to be more civilized than those of many other islands. Specimens of spars, crystals, alumine, jasper, and chalcedony, have been procured on these islands by the naturalists who accompanied captain Beechey. They are covered with a deep soil, and well wooded with trees and evergreens of different kinds.

It is a fact worthy of remark, that on all these islands, a plentiful supply of fresh and sweet water may be obtained, by digging three or four feet into the coral; and that even within one yard of high water mark, such a supply is to be found. This is an important consideration to the navigators of those seas, where such a resource is so valuable, on account of the extreme heat to which they are exposed; and it shows also the powerful properties of the coral, in divesting the sea-water of its saline particles. These properties, which are probably *chemical*, and not merely the effect of filtration, have never been examined or experimented upon, but they furnish a subject of consideration for the naturalist, and the man of science.

Of the rapidity with which the coral grows, we are not in possession of sufficient information, on which to form a correct judgment. Matilda, or Osnaburg island, is supposed to have been only a reef of rocks, when the Matilda was wrecked there, in 1792; it is now an island, fourteen miles in length, and covered on one side with tall trees, and the lagoon in the centre is dotted with columns. The coral, therefore, has probably made a rapid growth since 1792, although Captain Beechey found two anchors of a ton weight each, and a kedge anchor, which he supposes belonged to the Matilda, thrown upon the sunken reef of live coral, and around these anchors, the coral had made no progress in growing, while some large shell-fish, adhering to the same rock, were so overgrown with coral, as to have only space enough left to open about an inch. It is probable, however, that the oxide proceeding from the anchors may have been prejudicial, as far as its effects extended, to the coral insect, and thus have prevented its growth. All navigators, who have visited these seas, state that no charts or maps are of any service after a few years, owing to the number of fresh rocks and reefs which are continually rising to the surface; and it is perfectly accordant with the instincts of animals, to continue working without intermission, until their labours are consummated or their lives are extinct.

It was upon these he tried his principal experiment. He took out the oysters which were thus furnished with coralines, and placed them in a large wooden vessel, covering them with sea-water. In about an hour, he perceived the animals, which before had been contracted by handling, and had shown no signs of life, expanding themselves in every direction, and appearing employed in their own natural manner. Perceiving them, therefore, in this state, his next aim was to preserve them thus expanded, so as to be permanent objects of curiosity. For this purpose, he poured, by slow degrees, an equal quantity of boiling water into the vessel of sea-water in which they were immersed. He then separated each polypus with pincers from its shell, and plunged each separately into small crystal vases, filled with spirit of wine mixed with water. By this means the animal was preserved entire, without having time to contract itself, and he thus perceived a variety of kinds, almost equal to that variety of productions which these little animals are seen to form. He has been thus able to perceive and describe fifty different kinds, each of which is seen to possess its own peculiar mode of construction, and to form a coraline that none of the rest can imitate. It is true, indeed, that on every coraline substance there are a number of polypi found, no way resembling those which are the erecters of the building: these may be called a vagabond race of reptiles, that are only intruders upon the labours of others, and that take possession of habitations which they have neither art nor power to build for themselves. But, in general, the same difference that subsists between the honeycomb of the bee, and the paper-like cells of the wasp, subsists between the different habitations of the coral-making polypi.

With regard to the various forms of these substances, they have obtained different names from the nature of the animal that produced them, or the likeness they bear to some well-known object, such as corallines, fungi-madrepores, sponges, astroites, and keratophytes. Though these differ extremely in their outward appearances, yet they are all formed in the same manner by reptiles of various kinds and nature. When examined chemically, they all discover the marks of animal formation; the corals, as was said, dissolve in acids, the sponges burn with an odour strongly resembling that of burnt horn. We are left somewhat at a loss with regard to the precise manner in which this multitude of cells, which at last assume the appearance of a plant or flower, are formed.

If we may be led in this subject by analogy, it is most probable, that the substance of coral is produced in the same manner that the shell of the snail grows round it: these little reptiles are each possessed of a slimy matter, which covers its body, and this hardening, as in the snail, becomes a habitation exactly fitted to the body of the animal that is to reside in it; several of these habitations being joined together, form at length a considerable mass; and as most animals are productive in proportion to their minuteness, so these multiplying in a surprising degree, at length form those extensive forests that cover the bottom of the deep.

Thus all nature seems replete with life; almost every plant on land has its surface covered with millions of these minute creatures, of whose existence we are certain, but of whose uses we are entirely ignorant; while numbers of what seem plants at sea, are not only the receptacles of insects, but also entirely of insect formation. This might have led some late philosophers into an opinion, that all nature was animated; that every, even the most inert, mass of matter was endued with life and sensation, but wanted organs to make those sensations perceptible to the observer: those opinions, taken up at random, are difficultly maintained, and as difficultly refuted; like combatants that meet in the dark, each party may deal a thousand blows without ever reaching the adversary. Those, perhaps, are wiser who view nature as she offers; who, without searching too deeply into the recesses into which she ultimately hides, are contented to take her as she presents herself; and storing their minds with effects rather than with causes, instead of the embarrassments of systems, about which few agree, are contented with the history of appearances, concerning which all mankind have but one opinion.

SUPPLEMENT

ON

CRUSTACEA AND MOLLUSCA.

NATURALISTS have experienced much difficulty in finding an appropriate place for *Crustacea*. In the present volume, they will be found described along with *Mollusca*, in book IV. of Goldsmith's history of Fishes, p. 326, *et seq.* To Goldsmith's description we have added most copious notes; and little more will be required here than to give the scientific arrangement of the animals, as figured in the illustrative plates.

The crustacea (which include crabs, lobsters, prawns, shrimps, &c.) rank among those animals which are destitute of a back bone; and are comprehended in the division termed *Artici lata*, or animals whose members or limbs consist of segments or rings, articulated into each other, to the inside of which their muscles are attached. Chemists have found the shells of crustaceous animals to consist of phosphate of lime in combination with animal matter, while those of the testaceous mollusca are composed of lime along with the gelatinous substance. But a still more obvious distinction exists between these animals; the shells of oysters and other testaceous animals generally consist of one or two pieces, enveloping the whole animal, (except in the Cirripedes, see note on Conchology, p. 350-358) and adheres permanently during life: while the coverings of the crustacea are cast and renewed periodically, and invest the animals as it were in a coat of mail.

Linnæus placed crustacea between the fishes and mollusca, united them to his class *Insecta*. In the earlier writings of Cuvier and Latreille, they adopted the views of Linnæus, while Lamarck followed the ideas of Brisson, who formed them into a separate class, as well as spiders; giving the former the name *Crustacea* and the latter *Arachnoides*. This improvement has been generally acknowledged, and followed by subsequent writers on Natural History.

Crustaceous animals present remarkable physiological distinctions. They respire by means of branchiæ, or by branchial plates, usually attached to their feet or to their jaws; they have from five to seven pairs of feet; their head is frequently not distinct from the trunk, provided with from two to four jointed setaceous antennæ; and two compound movable eyes seated on peduncles, which are sometimes movable, and at others fixed; they have a distinct heart, and a regular circulating system: their organs of reproduction are placed either in the feet or tail.

In those genera where the head is not separated from the trunk, the shield or covering envelopes the whole thorax. In other genera the head is distinct from the body, which is divided into seven segments, to the lower sides of which the feet are attached; these for the most part have a tail, consisting of many segments. The limbs vary from ten to fourteen, each having six articulations. The two anterior limbs, and sometimes even three on each side, are provided with forceps; at other times they are terminated by simple hooks, and in many instances by appendages which fit them for swimming.

The branchiæ in crustaceous animals, unlike those of fishes, are external, although frequently concealed, and placed at the sides of the feet, limbs, or under the tail; they are, however, more frequently at the sides of the feet; and consist either of filamentary tufts, or pyramidal laminæ.

The mouth has usually two mandibles, a *labium*, or lip below, and from three to five pairs of jaws. The first, or first three pairs of these, have been termed *feet-jaws*. These small leg-shaped appendages are not fitted

for locomotion, but, being situated near the mouth, assist in the operation of feeding.

The nervous system consists of a ganglion or brain situated above and before the intestinal canal, with a continuous elongated double chord, having ganglions placed on the lower surface of the body, extending, in some instances, its whole length ; while in others, it consists of a central medullary circle, with radiated elongations.

Many of the crustaceous animals have an acute faculty of sight; a number of them also possess the senses of smell and taste; but from their shelly envelope their sense of feeling must be very blunt: while their touch must be very sensible, from the number of tentacula possessed by many of them.

Lamarck divides the Crustacea into *five* orders.

ORDER I.—DECAPODA.

The head is not distinct from the trunk; branchiæ formed like leaflets, close to the base of the four feet-jaws, and hidden under the sides of the shell.

SECTION I.—BRACHYURA.

Branchiæ, seven on each side, moving on a common axis; post-abdomen, bent underneath; generally received into a cavity beneath the præ abdomen; without a fin at the termination.

Family I.—Quadrilatera.

Thorax nearly square, frequently heart-shaped; anterior angles expanded; posterior extremity transversely truncated; front protruded, more or less inclined; none of the feet terminated by a fin. The genera of this family are Octypoda, Gelasimus, Myctris, Pinnotherel, Gecarcinus, Plagusia, Grapsus, Gonoplax, Thesphusa, and Eriphia. *Thelphusa fluviatilis*, pl. 23, fig. 1.

Family II.—Arcuata.

The shell anteriorly arched, to nearly the centre of the sides; posteriorly narrowed and truncated. The genera are, Pilumnus, Cancer, Pirimela, Atelecyclus, Podophthalmus, Lupa, Portunus, Thia, and *Portunus corrugatus*, pl. 23. f. 2.

Family III.—Orbiculata.

Orbicular, narrowed before, usually with two furrows; exterior feet-jaws with their third joint triangular. The genera are, Matuta, Orithyia, Corystes, Leucosia, and Hepatus. *Leucosia Urania*, pl. 23, f. 3.

Family IV.—Cryptopoda.

Nearly triangular; vaulted, and dilated at the posterior angles, for the feet in repose: with large, crested, and compressed forceps. The genera are, Œthra and *Calappa tuberculata*, pl. 23, f. 4.

Family V.—Trigona.

Subovoid or triangular; anterior extremity compressed and pointed; claws in the males frequently longer than in the females. The genera are, Parthenope, Eurynome, Pisa, Maia, Stenopus, Hyas, Inachus, Macropodia, Leptopodia, Pactolus, and Lithodes. *Pisa tetraodon*, pl. 23, f. 5.

Family VI.—Notopoda.

Having two or four posterior feet, inserted on the back, or somewhat above the line of the rest. The genera are, Homola, Ranina, Dromia, and *Dorippe nodulosa*, pl. 23, f. 6.

SECTION II.—MACROURA.

Bodies longer than in former section; post-abdomen carinated above; antennæ terminated by filaments.

Family I.—Hippides.

Last abdominal segment lengthened, and foliaceous; two anterior feet, tapering; frequently with a monodactylous hand; sometimes with a claw; the other six feet with their last joint fin-shaped. The genera are, Albunea, Hippa, and *Remipes testudinarius*, pl. 23, f. 7.

Family II.—Pagurii.

Shell but slightly crustaceous; two anterior feet didactyle; next four pairs with long acute tarsi; last four pairs smaller, terminating with a forceps; sometimes with a pointed hook. The genera are, Birgus, and *Pagurus laticauda*, pl. 23, f. 8.

Family III.—Palinurini.

Terminated by a fan-shaped post-abdomen, produced by the lateral appendages of the last and preceding segments. There is but one genus: *Polinurus locusta*, pl. 23, f. 9.

Family IV.—Syllarides.

Having the peduncle formed like a depressed crest. The genera are, Thenus and Scyllarus.

Family V.—Galathinæ.

Feet all alike, but the two anterior, which are didactyle. The genera are, Eryon, Magalopa, Galathea. *Porcellana platycheles*, pl. 23, f. 10.

Family VI.—Astacinæ.

Four or six of the anterior feet didactyle; terminating abdominal exterior leaflets, entire in some, and in others divided by a suture. The genera are, Thalassina, Gebia, Axius, Callianassa, Nephrops, and *Astacus Marinus*, pl. 23, f. 11.

Family VII.—Carides.

Intermediate antennæ placed above the lateral ones, protruding with two or three filamentary terminations, The genera are, Penæus, Stenopus, Alpheus, Hippolyte. Autonomea, Gnathophyllum, Hymenocera, Nika, Athanas, Atya, Egeon, Crangon, Pandalus, Pasiphæa, and *Palæmon Serratus*, pl. 23, f. 12.

Family VIII.—Schizopoda.

Feet slender, filiform, fitted for swimming only; one of them hand-shaped, but having either a long, lateral appendage, or deeply cleft, or multifid at their extremity. The genera are, Mysis, Zoea, and *Nebalia Herbstii*. pl. 23, f. 13.

ORDER II.—STOMAPODA.

The branchiæ suspended, in the form of tufts, on the lower appendages of the post-abdomen; head, distinct from the trunk, large, and separated into two parts; shell, membranaceous; intermediate antennæ with two or three filaments at their terminations; six posterior feet filiform; body terminated by a foliaceous fin.

Family I.—Unipeltata.

With an elongated and narrow body; eyes and intermediate antennæ placed on an anterior elongation of the thorax; exterior feet-jaws, and four anterior limbs, terminated by a monodactyle forceps; the other six limbs fitted for swimming, with the last joint brush-shaped; lateral antennæ having a scale at the base; intermediate ones trifilamentary. The genera are, Squilla, Erichthus, and *Alima Hyalina*, pl. 23, f. 14.

FAMILY II.—BIPELTATA.

Body depressed, membranous, and thin; thorax with twin shields; anterior, very large, oval; posterior one supporting the feet-jaws, and five pairs of transverse and angular feet; intermediate antennæ with two filaments. It has but one genus, Phyllosoma.

ORDER III.—LÆMODIPODA.

Head not distinct from the trunk; the second and third segments, having four vesicular bodies under them; antennæ four, multi-articulate; mandibles destitute of palpi; post-abdomen short.

FAMILY I.—OVALIA.

An oval body with transverse segments; limbs strong, of medium length; those of the second and third segments imperfect, with a long, cylindrical, blunt termination, each provided with an elongated vesicle at the base. It has but one genus. *Cyamus ceti*, pl. 23, f. 15.

FAMILY II.—FILIFORMIA.

With an elongated, linear body, and narrow longitudinal segments; limbs long and slender; last portion of the upper antennæ jointed. The genera are, Caprella, Proto, and Leptomera.

ORDER IV.—AMPHIPODA.

Head separate from the segment, to which the anterior feet-jaws are attached; post-abdomen provided with branchial and swimming appendages beneath. They are narrow, lengthened, and multi-articulate, transversely striated, or branched; mandibles provided with palpi; some of the feet having vesicles.

FAMILY I.—GAMMARINÆ.

Body posteriorly furnished with cylindrical or conical styliform appendages, or with none in some genera. The genera are Cerapus, Melita, Amphithoe, Dexamine, Gammarus, Pherusa, Orchestia, Talirus, Atylus, Corophium, Podocerus, Jassa, Phronima, and *Leucothoe articulosa*, pl. 23, f. 16.

FAMILY II.—UROPTERA.

Lateral appendages at the posterior extremity of the body, in the form of leaflets, and acting as fins. The genera are Hyperia and Phrosine.

FAMILY III.—DECEMPEDES.

Animals provided with ten feet only. The genera are Typhis, Anceus, and Praniza.

FAMILY IV.—HETEROPA.

With fourteen feet, in most instances all fitted for swimming on the four last only. The genera are, Ione, and *Apseude talpas*, pl. 23, f. 17.

ORDER V.—ISOPODA.

Having a distinct head; mandibles devoid of palpi; three pairs of jaws, the lower ones appearing like two small feet united at their base, or a lip having two palpi; body somewhat depressed, divided into from three to seven segments; feet ten or fourteen; tail varying from one to nine segments, with branchials; destitute of shell; eyes granulated; antennæ generally four.

SECTION I.—AQUATICA.

Antennæ four, anterior with three or four joints; sometimes without antennæ; lower appendages of post-abdomen usually vesicular, having no openings for the entrance of air.

FAMILY I.—EPICARIDES.

Body much depressed above, and concave below, having neither eyes, antennæ, mandibles, nor caudal fin. But one genus, Bopyrus.

FAMILY II.—CYMOTHOADES.

Eyes and antennæ four, sometimes indistinct; mandibles horny; feet fitted for walking and prehension; posterior extremity with a fin on each side: post abdomen with four or six segments. The genera are, Cymothoe, Cirolana, Eurydice, Nelocira, Limnoria, Serolis, and *Ægа Marginata*, pl. 23, f. 18.

FAMILY III.—SPHÆROMIDES.

Post-abdomen with three segments, the last with two leaflets. The genera are, Zuzara, Sphœroma, Campecopea, Næsa, Dynamene, Cymodocea, and *Anthura gracilis*, pl. 23, f. 19.

FAMILY IV.—ASELLOTA.

Last abdominal segment devoid of swimming appendages. The genera are, Asellus, Janira, and Jæra.

FAMILY V.—IDOTEIDES.

Branchial appendages situated under the post-abdomen, covered by the valves of the last segment; four antennæ in a transverse line, lateral ones with a filamentous termination: post-abdomen of three segments. The genera are, Idotea, and *Stenosoma lineare*, pl. 23, f. 20.

SECTION II.—TERRESTRIA.

The two intermediate antennæ hardly visible, one or two jointed; post-abdomen of six segments; posterior margin of the last with two or four cleft styles.

FAMILY VI.—ONISCIDES.

Consisting of the true Oniscæ. The genera are, Ligia, Philoscia, Oniscus, Porcellio, and *Armadillo Vulgaris*, pl. 23, f. 21.

ORDER VI.—LOPHYROPODA.

Head not distinct from the trunk; eye, or eyes, compound and sessile; shell sometimes of two pieces, usually large; no palpi on the mandibles; jaws destitute of branchiæ; feet variable in number, fitted for swimming, simple, or branched, or formed of hairy laminæ, organs of respiration supposed to be situated in them.

FAMILY I.—UNIVALVIA.

Shell in one piece, the most part of the body being uncovered. *Cyclops quadricornis*, pl. 23. f. 22.

FAMILY II.—OSTRACODA.

Shell either folded in two, or in the form of two valves united by a hinge, and enveloping the body. The genera are Polyphemus, Daphnia, Lynceus, Ceytherina, and *Cypris ornata*, pl. 23, f. 23.

ORDER VII.—PHYLLOPODA.

Head not distinct from the trunk; eyes sessile, smooth, and approximate; antennæ very short; shield crustaceous, free behind; mandibles two; destitute of palpi; the first pair of feet oar-shaped, the other sixty set in pairs, and fitted for swimming.

FAMILY I.—ASPIDIPHORA.

Eyes not placed on peduncles. The genera are, Limnadia and Apus.

FAMILY II.—CERATOPHTHALMA.

Having no shell, and the eyes seated on peduncles. The genera are, Artemia and *Branchipus stagnalis*, pl. 23, f. 24.

ORDER VIII.—XYPHOSURA.

Body in two parts; without a siphon; base of the feet, except the last, spinous, which serve as jaws; with a hard twin shell covering the whole body, having longitudinal furrows above; termination of the body sabre-shaped. This order consists of but one species, Limulus Polyphemus.

ORDER IX.—SIPHONOSTOMA.

Family I.—Caligides.

Body somewhat oval, with a distinct shell. The genera are *Argulus*, Caligus, Cecrops, and *Anthosoma Smithii*, pl. 23, f. 25.

Family II.—Lernæiformes.

Destitute of shell; body nearly cylindrical, jointed, and worm-shaped. This family consists but of one species, Dichelesthium Sturionis. Many fossil species have been found, which naturalists refer to existing genera.

Anatomy of a Plagusia.—Order I. Family I. Pl. 30, f. 31, head; *a*, *a*, eyes; f. 32, an eye seated on its pedicle; f. 35, tail; f. 29 and 34, teeth; f. 38 and 30, antennæ; f. 27, post abdomen; f. 26, internal structure of thorax; f. 33, internal structure of abdomen.

MOLLUSCOUS ANIMALS.

Molluscous Animals, like crustacea, are comprehended in the second great division of the animal kingdom—animals without a backbone. They are destitute of an articulated skeleton or vertebral column. The nervous system is not developed in the form of a spinal cord, but simply into a certain number of medulary masses situated in different points of the body, the principal of which is called the brain, and is placed transversely on the œsophagus, and envelopes it with a nervous collar. The organs of sensation and motion have not the same uniformity in point of number and position as in the vertebrate animals, and a greater aberration is observable in the position of the heart and organs of respiration, as well as in the structure of the latter. Some species are formed for breathing elastic air, and others fresh or salt water. Their organs of locomotion, and others, which are external, are generally symmetrically arranged on the two sides of an axis.

The mollusca have a double circulation, their pulmonary system invariably describing a distinct circle. The function of breathing is always assisted by, at least, one ventrical, situated between the pulmonary veins and the arteries of the body and not, as in fishes, between the veins of the body and pulmonary arteries. It is then an aortic ventrical. It is only the cephalopoda[1] that are provided with a pulmonary ventrical, which is subdivided. The aortic ventrical is likewise divided in some genera, as in the arca[2] and lingula.[3] In some other bivalves, the auricle only is divided. When more than one ventrical exists, they do not consist of a single mass, as in warm-blooded animals, but are remote from each other.

The blood in molluscous animals is white, or bluish-white, and seems to contain a smaller proportion of fibrin than that of vertebrate animals. Cuvier supposes that the veins perform the functions of absorbent vessels.

The muscles in this class are attached to their skin by various points, forming, in those places, tissues which possess more or less density. Their motions consist of different contractions, varying in their direction, producing inflections and prolongations, together with relaxations of their several parts, by means of which they creep, swim, and seize upon such objects as the formation of these parts are adapted to. They are, however, incapable of rapid progress, their limbs not being supported by articulated and solid levers.

Most of the mollusca are possessed of great irritability, frequently continuing after they are cut asunder. Their skin is naked, extremely sensible, and usually covered with a mucous substance, which is secreted from its pores. No organ of smell has yet been detected in them, although they appear to possess that sense. Cuvier thinks it probable that the whole skin may be susceptible of distinguishing odours. All the *cephala*, *brachiopoda*, *cirripeda*, and part of the *gasteropoda*, and *pteropoda* are destitute of eyes, while the *cephalopoda* enjoy them in as complicated a degree as the warm-blooded animals. The eyes are situated sometimes at the base, sometimes at the middle, and frequently at the extremity of the tentacula. The cephalopoda are the only ones in which have been discovered the organ of hearing, and where the brain is enveloped in a kind of case, of a cartilaginous consistence.

Almost all molluscous animals have a peculiar development of the skin, which covers their body, like a *mantle*, and has received that appellation. This process, however, is sometimes narrowed into a simple disk, or is tubiform, or hollowed into a sac, and in some cases it is divided and extended in the shape of fins. There are two distinct kinds of molluscous animals, namely, cephalous, or such as are provided with a head, and acephalous, or destitute of a head. These are again distinguished by such as are *naked* mollusca and *testaceous* mollusca, or with a shelly envelop. The naked mollusca have a membranous or fleshy mantle; which, however, has frequently one or more hard laminæ in its texture. These are increased in dimensions and thickness, by a deposit of earthy and animal matter combined; the new layers overlapping the old ones. When this substance remains concealed

[1] See note on Conchology, in the present volume, Class I., Order II., p. 354.
[2] Ib. Class II., Order II., p. 355.
[3] Ib. Order I., p. 355.

within the tissue of the mantle, the animals are called naked mollusca. The common field-snail, (*Limax agrestis*, pl. 24, f. 5.) and the black-snail, (*L. ater*, pl. 27, f. 25.) are examples of animals of this kind. More frequently however, this shelly matter becomes so greatly developed that the animal, in a state of repose, can contract itself within it; it is then termed a *shell*, or a *testaceous* animal, which is exemplified by the common garden snail-shell. (*Helix aspersa*, pl. 24, f. 15.) The epidermis which covers these animals, is very thin and sometimes dessicated, or of a woolly texture.

The variety of forms, surface, colour, brilliancy, and substance is almost infinite. They are nearly all calcareous, although some are simply of a horny consistence; but in both cases they consist of matter deposited in layers, or exuded from the skin under the epidermis, in the same manner as the hardened mucous covering, nails, hairs, horns, scales, and even teeth. The shelly tissue differs according as its transudation is deposited, either in parallel laminæ, or in close set vertical filaments.

Every mode of mastication and deglutition is illustrated in the mollusca; for we find their stomachs simple, complicated, and frequently provided with a peculiar armature; the alimentary canal is variously prolonged. Most species have salivary glands, and always a liver, but neither pancreas nor mesentery. Several have peculiar secretions.

Several of the mollusca are bisexual. Some produce their young alive, while others are oviparous. The eggs in some are covered by a shelly envelop, and others only by a simple viscosity.

The turbinated mollusca appear to be animals in a slight state of development; they possess but little industry, and are only preserved by their great fecundity, and extreme tenacity of life. They are all oviparous; their reproduction consequently depending on sexual impregnation.

Some genera of mollusca inhabit the sea and fresh waters, while others are entirely terrestrial: and a few species are amphibious, as may be exemplified in the *succinea, amphibia*, pl. 31, f. 75.

They feed on all substances, both animal and vegetable; some will eat these even in a putrid state, while others will only consume them fresh.

The uses of this numerous class are extremely varied. Many of them are taken as food by man, and others supply nutritious prey for birds and fishes. Their shelly coverings are converted into many useful articles of commerce; and from the veins of certain species of shells called *purpura*, is extracted the beautiful dye of the ancients called Tyrian purple. The *P. lapillus*, which is common on the British shores, adhering to stones, yields this dye; it is represented in pl. 24, f. 79. For a description and figures of the different parts of testaceous mollusca, see the note on Conchology, in this volume, p. 350—358.

CLASS I.

CEPHALOUS MOLLUSCA, OR SOFT ANIMALS WITH A HEAD.

Lamarck divides the turbinated testaceous mollusca into five orders, depending upon the complication of their internal organization. These are first:—

ORDER I.—HETEROPODA.

Destitute of arms arranged around the head; unprovided with a foot under the belly or throat for locomotion, but furnished with one or more irregularly set fins.

The animals of this order are distinguished from all the other mollusca by the form of their foot, which, in place of a horizontal disk, is compressed into a circular lamina, and is used as a fin, and on the edge of which, in several species, is a dilatation forming a hollow cone, representing the disk of the other orders. Their branchiæ are situated on the posterior part of the back, and composed of plumiform lobes, directed forward; immediately behind these are the heart, a small liver, with part of the viscera and internal organs of generation. Their bodies are of a gelatinous, transparent substance, lined with a muscular layer, elongated, and terminated by a compressed tail, in most species. There is a muscular mass belonging to the mouth, and the tongue is provided with little hooks; the œsophagus is very long; the stomach thin; on the right side of the visceral mass are two prominent tubes affording a passage for the fæces, ova, &c. They generally swim on their back, with the foot upwards. They possess the property of distending their body by filling it with water, in a way which is not yet properly understood. *Carnaria Cymbium*, pl. 31, f. 1.

ORDER II.—CEPHALOPODA.

Lower part of the body enveloped in a bag-shaped mantle, with the head issuing from the sac, and having inarticulated arms, to which are attached cups, surrounding the mouth of the animal, which is furnished with two horny mandibles. The mantle unites under the body; in several species the sides are extended into fleshy fins: head projecting from the sac, is provided with two large eyes, and crowned with longer or shorter fleshy arms or feet, capable of motion in all directions, their surface provided with cup-shaped suckers, by means of which they can adhere firmly to other bodies; these feet are used for prehension, natation, and walking. They swim with the head behind, and crawl in all directions, with the head under the body. At the opening of the sac in front of the neck, is placed a fleshy funnel as a passage to the excretions. See the note on Conchology, p. 350—358.

Division I.—Cephalopoda Sepiaria.

Loligo vulgaris. Medium cuttle-fish, pl. 27, f. 6.

Division II.—Cephalopoda Monothalama.

Shell unilocular, entirely external, and enveloping the animal. *Argonauta Argo.* Paper Nautilus, pl. 31, f. 2. and pl. 24, f. 1.

Division III.—Cephalopoda Polythalama.

FAMILY I.—AMMONACEA.

Septa sinuous, lobed and cut at the margin, meeting together upon the inner wall of the shell, and articulated by jagged sutures. Shell multilocular, partly or

entirely internal, and inserted in the posterior part of the body.

All the species of this division are fossil. See the note on Organic Remains, vol. i. p. 22.

FAMILY II.—NAUTILACEA.

Shell discoform, with a central spine, and short cells, which do not extend from the centre of the circumference.

Nautilus Pompilius, pl. 31, f. 3, and pl. 24, f. 63. The other genera are fossil. See the note on Organic Remains.

FAMILY III.—RADIOLACEA.

All the genera are fossil. See the Note on Organic Remains, vol. i. p. 22—27.

FAMILY IV.—SPHERULACEA.

Fossil, except one species found near Corsica, which is so minute that the animal has not been ascertained. See as above.

FAMILY V.—CRISTACEA.

All the species are fossil. See as above.

FAMILY VI.—LITUOLACEA.

Shell partially spiral; the last volution continued in a straight line. *Spirula Peronii*, pl. 31, f. 4. Animal a cephalopode, pl. 24, f. 2. The body or that part which inhabits the shell, *a*.

FAMILY VII.—ORTHOCERATA.

Animals of the genera unknown. See the Note on Conchology, p. 350—358.

ORDER III.—TRACHELIPODA.

Body usually spirally convoluted, and separated from the foot, which is free, flat, and attached to the neck at its base for the purpose of locomotion; the body always enveloped by a spiral shell.

SECTION I.—ZOOPHAGOUS TRACHELIPODA.

FAMILY I.—INVOLUTA.

Shell destitute of a canal, but with the base of its aperture notched or effuse, and its volutions broad, compressed, and rolled up in such a manner, that the last nearly covers all the others. *Conus generalis*, pl. 24. f. 3. *Cypræa Europea*, pl. 24. f. 8. *Buccinum undatum*, pl. 24, f. 19, 20. The extracted animal; *a a*, the foot; *b*, the head; *c*, a kind of platform raised above the thoracic cavity, on which the point of the boring trunk rests. This organ is represented at f. 31, 32, and 33. *d, d, d*, the cavity of the thorax; *e*, the mantle; *f*, the rectum; *g*, the stomach; *h*, the heart, thrown below, and to the right side of its natural situation, to allow the opening of the tube to be seen; *i*, the respiratory trunk; *k*, the organs of the muscles of the boring trunk; *l*, the course of the tube by which the foot is supplied with water; *m*, its termination; f. 34, magnified representation of the stomach and alimentary tubes; *a*, the throat; *b*, the outer coating; *c*, the alimentary canal; *d*, the opening from the stomach.

FAMILY II.—COLUMELLARIA.

No canal at the base of the aperture, but a subdorsal notch more or less apparent, and a fold upon the columella. *Voluta scapha*, pl. 31, f. 14. The animal has a large thick and fleshy foot, and the head is provided with a vail, from the sides of which issue the tentacula: the proboscis is rather long, and there is an appendage on each side of the base of the siphon. When the proboscis is extended, it can bend in all directions, by means of the retractor muscles, acting with opposing forces. This interesting mechanism is illustrated by f. 32, wherein the proboscis is represented retracted about a half; the external cylinder, *a*, is seen enveloping a portion of the inner one, *b*, the point of which *c* is the termination of the proboscis; the muscles which draw it within the body, *d d*, are in a state of contraction, and at *e* is represented the great annular muscle, which pushes forward the inner cylinder, and consequently lengthens the organ.

FAMILY III.—PURPURIFERA.

Shell with a short canal ascending posteriorly, or with an oblique notch at the base of its aperture, directed backwards. They are all operculate. *Purpura lapillus*, pl. 24, f. 79.

FAMILY IV.—ALATA.

Shell with a greater or less canal at the base of the aperture, of which the right lip changes its form as the animal advances in age, and has a sinus at the lower part. *Strombus Succinctus.*

FAMILY V.—CANALIFERA.

Shell with a canal more or less long at the base of the aperture, and of which the right margin does not change its form as the animal advances in age. *Murex acanthopterus*, pl. 31, f. 32.

SECTION II.—PHYTIPHAGA.

Destitute of projecting siphon, and respiring generally by an orifice, furnished with jaws, and feeding on vegetables, shell with the aperture entire, and without any notch or canal. Many of the species live upon land, and respire air, while others inhabit fresh water, either stagnant or running. Many are marine. Some families are furnished with an operculum attached to the foot of the animal.

FAMILY I.—TURBINACEA.

Shell turreted or conoid, having an oblong or rounded aperture, not widened, and the margin disunited. *Turbo smaragdus*, pl. 31, f. 45. *Turbo littoreus*, pl. 24, f. 13.

FAMILY II.—SCALARIDES.

Shell devoid of plicæ or folds on the columella; the margins of the aperture are united in circular forms. *Scalaria coronata*, pl. 31, f. 51.

FAMILY III.—PLICACEA.

Shell with the aperture not widened, and folds on the columella. *Tornatella flammid*, pl. 31, f. 54.

FAMILY IV.—MACROSTOMA.

Shell auriform, with the aperture very wide, and the margins disunited; destitute of columella and operculum. *Haliotis tuberculata*, pl. 31, f. 55, and pl. 24, f. 12. *Sigaretus Haliotoideus*, pl. 24, f. 42. Shell concealed in the mantle; *m*, the membranous shield under which the shell is concealed; *n*, a sinus through which an arm is sometimes protruded; *o*, the tentacula, at the base of which the eyes are placed.

FAMILY V.—IANTHENIA.

Shell gibbous, conoidal, thin, transparent, aperture triangular, columella straight, surpassing the base of the right margin; destitute of an operculum. *Ianthena exigua*, pl. 31, f. 59.

FAMILY VI.—NERITACEA.

Shells semiglobular or oval, destitute of a columella, and the left margin edged and transverse, provided with an operculum; inhabit fresh waters and the sea.

Natica monilifera, pl. 24, f. 35. A front view, with tentacular head and mantle reflected; *c*, the head; f. 37, a view of the head from beneath; f. 38, one of the cartilaginous jaws. *Neritina fluviatilis*, pl. 24, f. 18.

FAMILY VII.—PERISTOMIDA.

Shell conoid or sub-conoid with an operculum, and the margins of the aperture united. All the species

are fluviatile, the animals respiring in water. *Paludina impura*, pl. 24, f. 11. *Valvata piscinalis*, pl. 24. f. 61.

FAMILY VIII.—MELANIDES.

The margins of the aperture disunited, and the right one edged; animal provided with two tentacula. *Pirena Madagascarensis*, pl. 31, f. 67.

FAMILY IX.—LYMNÆCEA.

With an oblong acutely tapering spire, generally smooth on the external surface, and having the outer margin of the aperture always acutely edged, and not reflected. Animal amphibious, generally destitute of an operculum, and the tentacula flattened. *Lymnæa stagnalis*, pl. 24, f. 4.

FAMILY X.—COLIMACEA.

Shells acutely spiral, with no projecting parts on their exterior, except the markings of their periodical additions; the right margin of the aperture frequently reflected outwards; the tentacula are cylindrical, and usually four in number, but two in others, and destitute of operculum. They are terrestrial animals. *Cyclostoma elegans*, pl. 24, f. 10. *Succinea amphibia*, pl. 24, f. 58. *Pupa sexdentatus*, pl. 24, f. 57. *Helix aspersa*, pl. 24. f. 15; f. 92, apparatus of vision in *Helix Pomatea;* f. 65, toothed cartilage of do.

ORDER IV.—GASTEROPODA.

Body never spiral, destitute of any shell, provided with a muscular foot attached its whole length under the belly, for the purpose of locomotion. Some of the animals of this division are naked and destitute of any calcareous covering, others are provided with a dorsal plate, and a third series have a shell which is more or less concealed in their mantle. The animals of this order are limited by Lamarck to those whose bodies are straight, and never spirally convoluted, and which are provided with a muscular disk or foot, united to the body nearly its whole length. F. 66, pl. 24, exhibits the nervous system of the *Aplysia;* f. 67,* *Clio Borealis;* f. 67, the same in the act of swimming.

SECTION I.—PNEUMOBRANCHIÆ.

Branchiæ in the form of a vascular net on the wall of a particular cavity, opening by a hole, which the animal contracts and dilates at pleasure.

FAMILY I.—LIMACINÆ.

Branchiæ in the form of a vascular net on the partition of a particular cavity, the aperture of which the animal can contract or dilate at pleasure. The body of the animals is elongated, and they crawl by means of a ventral disk bordered on the sides by a very narrow mantle. *Vitrina beryllina*, pl. 24, f. 7. *Testacella Scutulum*, pl. 24, f. 6. *Limax ater*, pl. 27, f. 25. *Onhidium Typha*, pl. 27, f. 7.

SECTION II.—HYDROBRANCHIÆ.

FAMILY III.—LAPHYSIACEA.

The branchiæ are situated in a particular cavity towards the posterior part of the back, and covered by an opercular scutellum; they are provided with tentacula. The animals of this family resemble large snails, but have a thicker body, and are broader towards the posterior part, and have a larger margin to their mantle; the head projects, and is provided with four tentacula, two of which are placed near the mouth, and the other two more behind. The branchial scutellum is corneous or cretaceous. *Dolabella callosa*, pl. 31, f. 88. *Laphysia deplians*, pl. 27, f. 8, pl. 24. f. 17.

FAMILY III.—BULLACEA.

Head very distinct: the branchiæ are situate in a particular cavity, towards the posterior region of the back, and covered by a mantle; they are destitute of tentacula, and branchial operculum. Some species are unprovided with either exterior or interior shell, and in others the shell is completely concealed in the mantle, and there are several which have an external shell attached by a muscle. *Bulla hydatis*, pl. 24, f. 86. This figure exhibits the back of the shell, with the lateral fin-like membranes protruded *a*. F. 87. The gizzard magnified. *a, a, a*, the tips of the plates covered by a thin membrane, and surrounding a muscular integument, thickened at the upper part *b;* the part attached to the mouth *c*, with the œsophagus communicating with the gizzard; *d*, the intestinal canal. F. 88. The gizzard laid open at its anterior end, showing the three corrugated corneous plates *e, e, e*, with their connecting ligaments *f*, magnified. *Bulla aperta*, pl. 24, f. 83 and 68. Lateral lobes of the foot thickened and reflected upwards; head indistinct; destitute of tentacula; branchiæ dorsal; shell concealed in the mantle, *a*. F. 84, the gizzard composed of three testaceous plates, showing the smaller plate *b*, with the connecting ligament *c*. F. 85, another view of the gizzard, showing the two larger plates *d d*, with their connecting ligaments; *e*, the gullet, *f*, the alimentary canal.

FAMILY IV.—CALYPTRACEA.

The branchiæ are situate in a cavity on the back near the neck, and projecting beyond or included in the cavity; shell always placed exteriorly *Ancylus fluviatilis*, pl. 24, f. 9.

FAMILY V.—SEMIPHYLLIDIACEA.

The branchiæ are situated under the margin of the mantle, and disposed in a longitudinal series on the right side of the body; respiring in water. *Pleurobranchus plumula*, pl. 24, f. 14, f. 22. Alimentary canal; *a* the first stomach; *c* the second stomach; *d* the third stomach; *e* the fourth stomach. The œsophagus dilates into a membranous crop *a;* at the lower part of which, *b*, the bile is poured in. It communicates by a narrow cardia with the second stomach *c*, which is a gizzard with thin but muscular parietes. The third stomach *d*, is membranous, and precisely resembles the plicated stomach of ruminants, in being disposed in large but delicate folds, by means of which the alimentary matter contained in it is moulded into long whitish cords. The fourth stomach *e*, is membranous, like the crop, but smaller. It is remarkable that the gizzard contains a narrow groove, running through its whole length, leading from the first to the fourth stomach, and probably subservient to a species of rumination. F. 44. Another view of the animal; *g*, its protracted foramen; *h h*, the lower lamina, or border of the sustentaculum; *i*, the upper lamina, under the middle of which the shell is concealed; *k*, a plumose feeler; *l*, the tentacula, at the base of which the eyes are placed.

FAMILY VI.—PHYLLIDIACEA.

The branchiæ are situate under the margin of the mantle, and disposed in a longitudinal series around the body. The animals all respire in water. *Patella vulgata*, pl. 24, f. 21. F. 23. The alimentary canal. *a*, the mouth; *b*, the buccal mass; *c*, the tongue; *d*, the stomach; *e e*, the intestine. F. 24, represents the tongue of the patella of its natural size; f. 25, is a portion magnified; f. 26, 27, and 28, are the cartilaginous jaws. *Chiton cinereus*, pl. 24, f. 78. F. 93. The animal extracted. *a a*, the ventre; *c c c*, the intestinal canal; *e*, the anal opening; *d d d d*, the liver; *f*, the ovarium.

FAMILY VII.—TRITONIACEA.

The branchiæ are placed exteriorly, and situated above the mantle on the sides or on the back. The animals respire in water. The animals of this family are distinguished from those of the other Gasteropoda, by the situation of their branchiæ, which are all exterior; in several genera these appear to be a degeneration of the mantle, or to be formed by portions of it having become branchial; the body is always destitute of a shelly covering, and neither have they one internally. All the animals inhabit the sea. *Doris argus*, pl. 27, f. 9. *Tethys leporina*, pl. 24, f. 30. The alimentary canal. *a*, the proboscis; *b*, the œsophagus; *c*, the stomach; *d*, the intestine; *e*, the hepatic duct; *f*, the liver; *g*, the hepatic artery; *h h*, salivary glands—the parts are laid open; f. 29. the horny jaws of a *Tritonia*.

ORDER V.—PTEROPODA.

Destitute of any shell, foot or arms, either for locomotion or seizing their prey; but provided with two opposite and similar fins, fitted for swimming. The animals of this order are provided with two opposite fins; they are mostly of a small size, and either destitute of appendages, or having very short ones, situate at the head; some species are provided with a thin cartilaginous or horny shell. *Hyalæa tridentata*, pl. 24, f. 36.

CLASS II.

ACEPHALOUS MOLLUSCA, OR SOFT ANIMALS DESTITUTE OF A HEAD.

The second great division of testaceous Mollusca, consists of animals which are destitute of any apparent head, and have been denominated by Lamarck, Conchifera. Their mouth is concealed in the bottom, or between the folds of their mantle, which is usually doubled and incloses the body, in the same manner as a book is clasped over by its cover; but it often happens, that, in consequence of the two lobes uniting before, it forms a tube; sometimes it is closed at one end, and then it represents a sac. The mantle is generally covered by a calcareous, testaceous bivalve shell united by a hinge or ligament, and in some instances the shell is multivalve; in two genera, however, it is only of a cartilaginous or membranaceous nature. The animal is always attached to this shelly covering by strong muscles, by means of which it can open or close the sides of its covering at pleasure. The brain is situated over the mouth, where one or two other ganglia are observable. The branchiæ or gills, generally consist of large lamellæ covered with vascular meshes, under or between which passes the water; and are more simple in those genera which are destitute of a shell. The leaflets of which the branchiæ are composed are generally crescent-shaped, placed on each side of the cloak, covering the abdomen of the animal upon the sides of which they are attached in pairs; they are formed of a tissue of small vessels arranged close together, like the pipes of an organ. From these branchiæ the blood proceeds to the heart, which is placed towards the back, is very small, but provided with venous and arterial vessels. The liver is extensive, and embraces the stomach and the greater proportion of the alimentary canal. The mouth is always devoid of teeth, and is capable of only receiving the molecules, conducted to it by the water; at each side of the mouth are four thin triangular leaflets, which are the extremities of the lips. Some species are provided with two stomachs. The whole animals of this division fecundate themselves, and in many of the species, the young ones are extremely numerous, and pass some time in the thickness of the branchiæ before quitting the parent. The whole acephala are aquatic animals. The foot of the animal when it exists is a mere fleshy mass, the motions of which are effected by a mechanism analogous to that which acts on the tongue of the mammalia.

The Conchifera of Lamarck are separated into two orders as follows:—

ORDER I.—MONOMYARIA.

With but one internal muscle of attachment, and the shell marked interiorly with one subcentral muscular impression.

SECTION I.

Ligament none, or at least unknown, or replaced by a tendinous cord, which supports the shell.

Family I.—Brachiopoda.

With two opposite ciliated arms, placed near the mouth, rolled up in a spiral form when the animal is in a state of repose; mantle provided with two separate lobes before, which envelope the body. Shell bivalve, adhering directly, or by means of a tendinous cord, to marine substances. *Lingula anatina*, pl. 32, f. 1.

Family II.—Rudista.

Nothing is known of the animal, nor of the ligament and hinge of the shell; the valves are very unequal; and no distinct hooks are visible. *Crania personata*, pl. 24, f. 75.

SECTION II.

Ligament not marginal, but inclosed in a hollow space under the beak, always perceptible, and never forming a tendinous cord under the shell.

Family I.—Ostracea.

Ligament interior, or at least partly so; shell irregular, foliaceous, and sometimes papyraceous. The animal has neither foot, arm, nor projecting siphon. *Anomia ephippium*, pl. 24, f. 41. *Ostrea Edulis*, the Edible oyster, pl. 24, f. 73. f. 98, muscle of the oyster.

Family II.—Pectenides.

Ligament either interior, or partly so, being discoverable in some through an opening in the joint; shell in general regular, compact, and not foliaceous. Some genera fix themselves to marine bodies, by a byssus, while in others the lower valve is immovably attached; and many of the pectens are at liberty. *Spondylus gæderopus*, pl. 24, f. 52. *d e*, the branchiæ; *b*, the mouth; *g h i*, the abdomen; *k*, the great adductor muscle. *Pecten Jacobæus*, pl. 24, f. 77. *a b c d*, the two lobes of the mouth; *e e*, the byssus; *f f*, the abdomen; *z*, the intestinal canal; *g*, the mouth, ornamented with a fringe; *h*, the great adductor muscle. The animals of this genus possess considerable powers of locomotion, which was well known at the time Aristotle wrote. They have the power of removing themselves from one place to another, on dry land, by successive leaps. This has been fully established by recent experiments. A basket filled with the *Pecten opercularis*, or common edible scallop, has been placed on the sea shore, near the edge of the water, when all the individuals have speedily found their way to the sea. *Lima squamosa*, pl. 24, f. 72.

SECTION III.

Ligament marginal and elongated.

Family I.—Malleacea.

Ligament marginal, sublinear, and either simple or interrupted by crenulations; shell foliaceous or more or less inequivalve. *Avicula Tarentina*, pl. 24, f. 90. *a b c d*, the mantle, the duplicate of which contains the

ovarium, *f f g g*; the byssus, *h i*; the abdomen, *k*; *s*, the anal opening.

FAMILY II.—MYTILACEA.

Hinge with a sub-interior ligament, which is marginal, linear, and very entire, occupying a great part of the anterior border; shell but seldom foliaceous. Nearly the whole of this family attach themselves to marine bodies by a byssus. They have a tongue-shaped foot, by the aid of which they attach their byssus to extraneous substances. *Pinna nobilis*, pl. 24, f. 91. *a, b, c, d*, lobes of the mantle: *g g, h h*, adductor muscles; *x f*, part of the abdomen. *Mytilis edulis*, pl. 24, f. 71. f. 76, the animal.

FAMILY III.—TRIDACNITES.

The shell is transversely equivalve, with the muscular impressions situated under the middle of the upper margin, and prolonged on each side; the mantle is close and perforated by three holes, through one of which passes the foot; the second furnishes an entrance and exit for the water requisite for respiration; and the third is a passage for the excretions; the two latter not being prolonged into tubes as in the Mytilacea. *Tridacna gigas*, pl. 24, f. 64. The tendinous byssus by which these gigantic shells—sometimes weighing 300 pounds—attach themselves to rocks, is so thick and strong that an axe is required to sever it. Nearly allied to this species is *Tridacna squamosa*, pl. 32, f. 27.

ORDER II.—DIMYAIRA.

Shell having two distinct and lateral muscular impressions, which are deep and widely separated, being placed near the lateral extremities of the valves.

SECTION I.

Shell always inequivalve and irregular.

FAMILY I.—CHAMACEA.

Shell inequivalve, irregular, and adherent; with two separate muscular impressions; ligament placed externally; the animal provided with short, separate siphons, *Chama gryphoides*, pl. 24, f. 54. *Chama antiquata*, pl. 24. f. 55. *a b*, the lobes of the mantle; *c*, the abdomen; *d d*, the foot.

SECTION II.—LAMELLIPEDES.

FAMILY I.—NAYADES.

This family consists of fresh water shells; the hinge sometimes provided with an irregular, simple, or cleft tooth, and a longitudinal prolonged one; sometimes destitute of any; or is furnished in its whole length with irregular granular tubercles; the posterior muscular impression compound; and the umbones often decorticated; the muscular impressions are lateral and distant, that of the posterior side being composed of two or three distinct, unequal impressions; the animal is destitute of any projecting tube or siphon; the foot is elongated, transverse, and rounded, which it protrudes between the valves, and uses to change its position. *Anadonta cygnea*, pl. 24, f. 43. *a*, the mouth, into which a bristle has been introduced; *b*, the stomach, under which the intestine makes five turns in the foot amidst the ovary, and then as it returns, runs posteriorly along the back of the animal beneath the hinge, and above the respiratory organs, passing through the midst of the heart, *c*, and opening at *d* above the posterior muscle closing the shells, beneath the small tube of the cloak. This description applies generally to most trivalves, but in the oyster the rectum does not pass through the heart. *Unio pictorum*, pl. 24, f. 49.

FAMILY II.—TRIGONACEA.

Primary teeth of the shell lamelliform, and striated transversely; ligament exterior. *Castalia ambigua*, pl. 32, f. 35.

FAMILY III.—ARCACEA.

Primary teeth of the shell small, numerous, and disposed in a line on each valve of the shell, either in a straight or interrupted series. The valves do not close perfectly in the centre, in consequence of having a horny plate or fillet placed before the abdomen of the animal, that serves as a foot, and by which it adheres to submerged bodies. *Arca Noæ*, pl. 24, f. 59. *Arca barbata*, pl. 24, f. 70. *a*, the foot. *Pectunculus Pilosus*, pl. 24, f. 56. f. 74, animal of do.

FAMILY IV.—CARDIACEA.

Primary teeth of the shell irregular, both in their form and situation, and having generally one or two lateral teeth. In the animal, the mantle is open before, and there are besides, two separate apertures, one for respiration and the other for the fæces, which are prolonged in tubes, sometimes distinct, and at others united in one single mass. There is always a transverse muscle at each extremity, and a foot generally used for locomotion. Those which are provided with long tubes always live in ooze or sand. *Isocardia cor*, pl. 24, f. 98. *Cardium rusticum*, pl. 24, f. 60. *a e*, the tracheæ; *a*, part of the abdomen; *b b*, the branchiæ; *c*, the adductor muscle.

FAMILY V.—CONCHACEA.

Shell with three primary teeth, at least in one valve, and the other with a similar number, or less in some species; sometimes provided with lateral teeth. The animal has generally two tubes or siphons projecting from its mantle, one of which answers the purpose of a passage for the water to the branchiæ, and the other for dejected matters; the foot is lamelliform. All the animals of this family inhabit sand or mud.

Subdivision I. Generally destitute of lateral teeth; inhabiting the ocean; siphons of the animal elongated and unequal; the foot broad and projecting. *Venus Verrucosa*, pl. 24, f. 39. *Cytherea Chione*, pl. 24, f. 48. *Artemis orbiculata*, pl. 24, f. 53.

Subdivision II. Fresh water shells covered with a spurious epidermis, and having lateral teeth. *Cyclas cornea*, pl. 24, f. 50. *Piscidium obliquum*, pl. 24. f. 51.

SECTION III.—TENUIPEDES.

FAMILY I.—NYMPHACEA.

Shell never having more than two primary teeth in each valve; frequently gaping at its lateral extremities; ligament exterior. The foot of the animal is small, and often compressed; the species all inhabit the shores of the sea. *Donax trunculus*, pl. 24, f. 46. The animal has two long slender tubes, which are received into a sinus of the mantle; and provided with a broad foot. F. 47. The right valve removed. *a a*, the adductor muscles; A the foot; *s s*, the right lip; *m n*, the two lobes of the branchiæ; *b d, c e*, the two tracheæ; the left vein is at *i*. *Tellina planata*, pl. 24, f. 97.

FAMILY II.—LITHOPHAGI.

The shells gape more or less at their anterior side; ligament exterior; they bore into rocks and clay, without the aid of accessory shells, but by what means naturalists have not yet discovered. *Venerupis irus*, pl. 24 f. 69.

FAMILY III.—CORBULACEA.

Shell inequivalve, with the ligament placed interiorly. *Pandora rostrata*, pl. 32, f. 72.

FAMILY IV.—MACTRACEA.

Shell equivalve, frequently gaping at the lateral extremities; ligament placed interiorly, or partly exteriorly; animal with the foot small and compressed; the tubes are united and short. *Mactra Neapolitana*, pl. 24, f. 40. *b c*, the trachæa; *d*, the foot.

SECTION IV.—CRASSIPEDES.

The mantle, either entirely or in part united before the foot, thick, placed posteriorly; the shell gaping when shut.

FAMILY I.—MYARIA.

Shell with a broad spoon-shaped tooth in each valve, or in one only, and gaping at both lateral extremities, or at one only; ligament placed interiorly. Live sunk in ooze or sand. *Mya arenaria*, pl. 24, f. 45.

FAMILY II.—SOLENIDES.

Shell transversely elongated, without accessory pieces, and gaping at the lateral extremities only; ligament placed exteriorly; the foot issues from the anterior extremity or from that side in which the teeth are nearest. *Solen Vagina*, pl. 24, f. 96. The foot of the animal is conical, which enables it to burrow with great facility in the sand. *e*, the trachiæ; *k*, the cloak; *n n*, the adductor muscles; the foot, *b c*.

FAMILY III.—PHOLADARIA.

Shell bivalve, with accessory pieces to the valves; they generally gape much anteriorly. The whole family are borers. *Pholas dactylus*, pl. 24, f. 95. f. 89, muscle of do.

FAMILY IV.—TUBICOLA.

Shell contained in a testaceous sheath, distinct from its valves, incrusted entirely or in part in the wall of this tube, or projecting outwards. *Teredo navalis*, pl. 24, f. 16. These acephala, while quite young, penetrate and establish their habitations in submerged pieces of wood, such as piles and the bottoms of ships; completely destroying them in a very short space of time. *a*, the œsophagus, which is very short, and lies on the left side of the neck; the canal swells out, and becomes a stomach, *b*, which, in its external appearance, is a large bag, extending the whole length of the cavity of the abdomen, but, when laid open, it is found to have a septum, *c*, dividing it longitudinally into two equal cavities, except at the lowest part, where they communicate at *d*, the septum being wanting. The intestine has its origin close to the termination of the œsophagus, is extremely small, dilates into a cavity containing a hard, white spherical body, the size of a pin's head, and then makes a turn upon itself. The course it follows is shown by the letters *e e*.

CLASS CIRRIPEDA.

The Cirripeda form an intermediate group between the Mollusca and Articulata. The bodies are enveloped in a mantle, and testaceous plates or valves, which are nearly allied to those of the Acephala. The mouths of the animals are provided with lateral jaws, and the abdomen with filamentary jointed processes, named *cirri*, arranged in pairs, composed of numerous little ciliated articulations, and corresponding to feet or fins, similar to those which exist under the tail of crustaceous animals. Their heart is situated in the back, and the branchiæ emanate from the sides; the nervous system forms a series of ganglions, on the lower part of the abdomen. These cirri, however, may be considered as analogous to the articulated appendages of some species of Terredo, while the ganglions are in some measure repetitions of the posterior ganglion of the bivalve Mollusca. The position of these animals in the shell is such, that the mouth is at the bottom, and the cirri near the orifice. Between the last two cirri is a long fleshy tube, that has sometimes, but erroneously, been taken for their proboscis, and at the base of which, near the back, is the anal opening. Internally, a stomach is found inflated by a multitude of small cavities in its parietes, which appear to fulfil the functions of a liver, a simple intestine, a double ovary, and a double serpentine oviduct, whose walls produce the prolific fluid, and which, prolonged in the fleshy tube, open at its extremity. The animals of this class are incapable of locomotion, being always fixed. This class was all ranked under a single genus by Linnæus, by the title of Lepas. Brugieres divided them into two, and Lamarck has subdivided them still further, at the suggestion of Dr Leach, and they now form a class of themselves. The animals of this class are always protected by a multivalve shelly covering, which is composed of a number of separate pieces; these are connected by a membrane in the *pedunculata*, and those of the *sessilia*—six in number—are articulated at their sides, and kept together from their base, being attached to a calcareous plate, which is firmly attached to some extraneous substance. These last form a conical covering, open at the top, which is protected by an operculum or lid, composed of four pieces. The first order of cirripeda have but five valves, and these are placed on the summit of a tubular, membraneous peduncle, varying in length in different species. In one genus, besides the five principal valves, other smaller ones are found, which are termed accessory valves. All the animals are hermaphrodite and marine. The characters of the class are, soft animals, destitute of head and eyes, covered with a plurality of shells, and always fixed to a certain spot; the bodies are inarticulated, provided with a mantle, tentacula, and cirri; arms issuing from above, and many-jointed.

ORDER I.—PEDUNCULATA.

The body compressed, and supported on a tubular peduncle. *Otion Cuvieri*, pl. 33, f. 26. *Cineras vittata*, pl. 33, f. 27. *Pollicipes mitella*, pl. 33, f. 28. *Anatifa vitrea*, pl. 33, f. 30.

ORDER II.—SESSILIA.

Body destitute of a peduncle, and inclosed in a shell of various parts, fixed immovably by its base, with a testaceous lamina to extraneous marine bodies; the mouth at the upper and anterior part of the body. In the interior of the opening is placed an operculum formed of two or four movable pieces, which the animal opens in the centre while projecting its tentacular arms. *Pyrgoma crenata*, pl. 33, f. 31. *Balanus communis*, pl. 24, f. 94. *aa*, the ventre; *vv*, the liver; *xx*, the ovarium; *h*, the spermatic ducts; AB, the œsophagus.

CLASS ANNELIDES.

This class is the first of the great division Articulata, consisting of animals which have their bodies or members composed of articulated rings. The characters of the Annelides, are, the body soft, more or less elongated, and either naked or enclosed in a tube, and divided into a number of segments ; and are the only animals devoid of a backbone, which have red blood circulating in a double system of complicated vessels. Their nervous system consists in a double knotted cord, like that of insects. Some species have a head, and others are devoid of one ; when it exists it is merely a slight anterior thickening, distinct from the first segment of the body, and upon which the eyes and antennæ are placed. The antennæ consist of articulated filaments, sometimes short and thick, and never exceed five. They have either two or four eyes, situate behind the antennæ. The tentacula are either situated on the head or fore part of the body, they consist of articulated filaments, or papillæ more or less elongated. They are provided with a fleshy contractile proboscis, of either one or two rings, inclosing horny or calcareous jaws. The body of the Annelides in many species is naked, and free from hairs ; some are furnished with contractile bristles. The whole class respire by branchiæ, and inhabit the waters, sand, mud, or moist earth. The branchiæ are extremely variable in form and situation ; as are also the tubes or sheaths, which are either membranous or horny, incrusted exteriorly with minute fragments of shells or grains of sand ; in others they are solid testaceous tubes. They are all carnivorous, sucking the blood of other animals ; and are hermaphrodite.

ORDER I.—SEDENTARIÆ.

The animals inhabit a testaceous tube, which they never leave; they are destitute of eyes; the branchiæ are situated at one end of the body. The animal is elongated, worm-shaped, having the sides of the body provided with subulate short bristles; and also with hooked bristles to enable it to move in its tube.

Family I.—Serpulacea.

Branchiæ separate, or covered by an operculum; tube, solid and testaceous; destitute of tentacula, eyes, or jaws; body furnished on the sides with setaceous papillæ, and hooked retractile bristles. *Serpula vermicularis*, pl. 24, f. 82.

Family II.—Amphitritæa.

Branchiæ neither separated nor covered by an operculum, and disposed towards the anterior part of the body; with a horny or membranous tube, more or less arenaceous; the branchiæ are placed at or near the anterior extremity, they are sometimes large, projecting above the mouth, and sometimes they are short. Many of the animals have tentacula, but all of them are destitute of eyes, proboscis, or jaws. *Amphitrite magnifica*, pl. 24, f. 81.

Family III.—Maldaniæ.

The branchiæ are indeterminate; and the tube is open at both ends. *Dentalium entalis*,

Family IV.—Dorsaliæ.

The branchiæ are dorsal, or disposed longitudinally along the body. *Siliquaria anguina*, pl. 33, f. 51.

ORDER II.—ANTENNATÆ.

The head is antenniform, provided with two eyes, and a projectile proboscis, frequently armed with jaws, and setiferous retractile pediform papillæ; branchiæ disposed longitudinally.

SECTION I.

Branchiæ in the form of complicated leaves or tufts, or very ramose, always large and apparent; destitute of spines.

Family I.—Amphinomæ.

Branchiæ and cirri placed superiorly at all the pairs of pediform papillæ, and having no jaws.

SECTION II.

Branchiæ in the form of small crests or laminæ, or filamentous and pectinated on one side; sometimes not distinct.

Family II.—Eunicæ.

While the branchiæ are distinct, all the pediform papillæ are placed without interruption; jaws numerous, and always more than two, but fewer on the right than on the left side; destitute of the first pair of feet.

Family III.—Nereides.

When the branchiæ are distinct, there are superior cirri on all the pairs of pediform papillæ; two jaws or none. *Spio quadricornis*, pl. 27, f. 14.

Family IV.—Aphroditæ.

The upper branchiæ and cirri alternating in their position to the twenty-third or twenty-fifth pair of pediform papillæ; having four jaws. *Halithea aculeata*, pl. 27 f. 4.

ORDER III.—APODES.

Animals destitute of feet, or setiferous and retractile papillæ; when provided with branchiæ, they are disposed interiorly along the body; but they have no antenniferous head. Although the animals of this order have red blood, and a true circulation, they are otherwise the most imperfect in their form. They are destitute of head, tentacula, and pediform papillæ; their branchiæ are situated internally, either in or under the skin. They are usually naked, and have no retractile spines.

Family I.—Echioreæ.

Body with bristles projecting, but not retractile. *Lumbricus terrestris*, pl. 27, f. 39. The earth worm.

Family II.—Hirudineæ.

Body without projecting bristles. *Hirudo geometra*, pl. 27, f. 13. Leech. See it described in the present volume, at p. 467.

SUPPLEMENT

ON

MICROSCOPIC DISCOVERY.

INTRODUCTION.

The invention of the microscope is justly considered one of the most important achievements of human science and art, claiming at least equal eminence with the discovery of the telescope. The latter instrument brings us into comparative intimacy with other worlds, or what we infer to be such from the analogies discoverable between them and our terrestrial globe; the former instrument carries us to the opposite bounds of creation, and reveals the atomic miracles with which we are immediately surrounded. The results of astronomical research usually strike us with more awe than those of microscopical inquiry; yet perhaps we regard the latter with deepest interest, and for this reason,—the telescope communicates a few particulars concerning things on which we can bring but *few* analogies to bear, and consequently imparts a vague and indefinite knowledge to the mind; the microscope, on the contrary, refers us to objects wonderfully minute, yet usually so analogous to larger existences, that the information derived concerning them is satisfactory and complete.

To estimate duly the value of the microscope, as a means of enlarging the boundaries of human knowledge, we must refer to the utter ignorance concerning some things, and the gross misconceptions regarding others, that prevailed prior to its introduction. Before the invention of this instrument, the mite was considered the least of animal beings, and the existence of living atoms, with which compared, the mite may rank as an elephant, had never been conjectured. The wondrous beauty and contrivance in the formations and appendages of the insect tribes had never been beheld. The miracles of creative power, folded up in every plant and blossom, had not been fully displayed. Vague and indefinite opinions were held regarding the vital fluid in animals; and the manner of its circulation through the body was very imperfectly understood. The strange fallacy of equivocal generation was universally maintained, and fetid corruption was deemed the parent of animal and vegetable life. It would occupy much space to name all the instances of ignorance and misconception that characterized the times in which the microscope was unknown: let those to which we have alluded suffice to show how limited was the sphere of human knowledge concerning many things that daily met the eye, and how totally unconscious were the philosophers of those ages of the wonderful creations that science and art were preparing to unveil. "Who," says Baker, "would have imagined it possible to distinguish myriads of living creatures in a single drop of water! Or, that the purple tide of life, and even the globules of the blood, should be seen distinctly rolling through veins and arteries smaller than the finest hair? That millions of millions of animalcules should be discovered in the *semen masculinum* of all creatures? That not only the exterior form, but even the internal structure of the bowels, and the motion of the fluids in a gnat or louse should be rendered objects of sight? Or, that numberless species of creatures should be made visible, though so minute, that a million of them are less than a grain of sand? These," he continues, "are noble discoveries, whereon a new philosophy has been raised, that enlarges the capacity of the human soul, and furnishes a more just and sublime idea than mankind had before, of the grandeur and magnificence of nature, and the

infinite power, wisdom, and goodness of nature's Almighty Parent."[1]

At the period when Goldsmith wrote, the microscope had certainly been long in use, and allusion is made in his Natural History to some of the interesting facts it had then made known. When, however, we consider the inefficient construction of the instrument, the consequent unsatisfactory results of many observations, and the prevailing tendency to exaggerate the discoveries of that day, we are at no loss to comprehend the reason why our author lays comparatively little stress on microscopic inquiry. Subsequent editions of the Natural History have, it is true, supplied in a good measure this deficiency in the original work, and presented to the popular view a large amount of discoveries in the minute world; this information, however, has usually been conveyed in a desultory form, ill calculated to impress upon the mind the vast accessions of knowledge progressively derived from microscopic investigation. The attention which has, in late years, been given to the construction of the microscope and the improvement of its elements, has given a new impulse to inquiry, and led to the elucidation of facts so astonishing, and to the discovery of formations and phenomena so replete with interest to the natural historian, that a new edition of Goldsmith's work could scarcely be deemed complete if it did not include a connected view of the most remarkable discoveries that have been made in the various kingdoms of nature by the aid of optical science. This digest we propose to give in three consecutive chapters, dividing the subject as follows:—

Chap. I. The results of microscopical inquiry concerning the minute formations and phenomena of the natural world.

Chap. II. Infusorial Animalcules.

Chap. III. Spermatic Animalcules.

CHAP. I.

THE RESULTS OF MICROSCOPICAL INQUIRY CONCERNING THE MINUTE FORMATIONS AND PHENOMENA OF THE NATURAL WORLD.

Microscopic investigation has been carried to a greater or less extent through all the kingdoms of nature. We shall, for the sake of orderly arrangement, commence with the *Mineral Kingdom*, the discoveries in which, though less diversified, are equally interesting with those in the animal and vegetable worlds. In this division of the subject our attention is more particularly called to the remarkable phenomena connected with congelation and crystallization, to the formation of minute mineral bodies, and to fossil remains of insects, animalcules, and vegetables. We shall first advert to the singular appearances presented in the congelation of water and snow crystals; for though these cannot be included amongst mineral bodies, they can be more conveniently reviewed in this place than in any other department of our essay.

If water be exposed to a freezing atmosphere in a capacious vessel, thin laminæ, or plates, of ice will shortly be observed on its surface. These cross and intersect each other in a most surprising manner, and present the appearance of a fancifully tesselated device. If one of these plates be separated from the rest with a knife and brought under the microscope, a moderate power will develope its conformation, which much resembles that of a herring bone: a large stem runs through the centre, and from each side of this diverge a number of parallel spines, inclined to the central stem in an angle of about sixty degrees. In the Micrographia of Dr Hooke notice is taken of a peculiarity in the congelation of water thinly spread on smooth marble, which is said to exhibit a variety of figures resembling feathers; these forms are however nearly allied to the plates before mentioned, and the points of difference between them are not particularly remarkable. Urine when slightly frozen discovers a number of very beautiful six-branched figures; but as the same formations, or others very closely resembling them, may be observed in a congelation of common salt and water, we prefer directing our remarks to the latter. These star-like figures commence at the centre, which elevates itself, and ultimately forms the apex of a solid angle; from the centre six branches jut out, each two inclosing an angle of sixty degrees; from these main branches proceed a number of smaller shoots, all on the same side of the branch being parallel to each other, and forming with it an angle of sixty degrees; from these shoots issue forth smaller branchings in like manner, and from these latter others still more minute, till at length the figure becomes too complicate to be analysed, and presents merely the appearance of an even mass of ice. It is however to be observed, that the beauty of these stars is greatly enhanced by accidental circumstances, which disturb the regular process of congelation, and cause the branches at times to throw out a number of circular plates curiously overlapping each other. It may be necessary to add that these figures differ materially from those observed in the ordinary crystallization of common salt by evaporation.

[1] See article *Microscope*, in the Supplement to *the Popular Encyclopedia*.

The fantastic and picturesque formations so commonly observed on the windows in the winter season, will, if closely examined, be found to consist of a series of branches disposed under the uniform angle of sixty degrees; and all the irregular variety is merely the result of numerous small impediments to the freezing process.

An almost infinite variety of configuration may be observed in the flakes of falling snow, all however thus far resembling each other, that they uniformly consist of six branches radiating from a centre. The side shoots are also disposed according to the general principle, and in all the peculiarities of figure we discover the angle of sixty degrees determining the formation. Plate 35, figs. 50 and 51, are two snow flakes. In fig. 50 we observe the branchings from the centre, and the side shoots disposed according to the general law. The hexagonal figures terminating the main branches are explained thus: the two sides connecting with the branch are lateral shoots from it, the two next are lateral shoots from the former two, and the other two sides are similar shoots from the second two. And it is in this manner by a little consideration of the figure, that we are enabled, in almost every instance, to trace out a uniform principle of conformation. In fig. 51 we see the six branches and the lateral shoots as before, and the leaf-like outline of the figure is nothing more than the natural result of the lateral shoots near to the centre pressing upon each other, and the central ones extending farther out than those more recently put forth.

Congelation and crystallization, though closely resembling each other, are distinct operations. Congelation fixes the whole fluid mass; but the process of crystallization causes the particles of mineral bodies, when suspended in fluid or separated by fusion, to assemble in regular figures, agreeably to ascertained principles of formation.

Notwithstanding the variety of figure observable in crystals, their primitive forms are few, such as the cube, parallelopipedon, &c.; and all eccentric formations arise from a peculiar arrangement of their laminæ on the faces of the primitive crystal. Dr Hooke suggested that crystallization merely exhibited the various regular forms resulting from the combination of small globular particles; and this opinion has been adopted by many writers. There is, however, a difficulty in conceiving how globular particles should with undeviating exactness constantly assume the same primitive figure, in (for instance) the crystallization of common salt. The simple form of these crystals is always a cube; now we cannot comprehend the reason why this should be the case on the supposition that they are merely an accumulation of globular particles; for these particles can unite only by mutual attraction, and might, for ought we perceive to the contrary, assemble in any other primitive form as readily as that of the cube. A more recent theory supposes the particles to have either the figure of the primitive crystal or that of a cube, a solid angle, or a parallelopipedon; and we can pretty well discover in every instance, on this hypothesis, how the primitive form is invariably determined. Much light has been thrown upon this subject by the microscope, which brings immediately under the eye of the observer the whole process of crystallization, from (in several cases) the primitive form, to the most intricate combination which it ultimately develops. A more beautiful sight cannot be conceived than that which is presented when any saline solution is suffering gradual evaporation under the microscope, and the crystals begin to shoot and extend themselves over the field of the instrument. It is not exaggeration to say that it partially draws aside the veil that is cast over the first creation of material forms. Adopting the hypothesis, that primitive chaos was a fluid holding in solution the particles of all solid matter, we may imagine the small drop of water on the stage of the microscope to be that chaos, from which we see glaciers and rocks rising up with a rapidity, precision, and beauty truly astonishing.

In Plate 35 the figs. 44 and 45 exhibit the compound crystals of common salt. These have been selected for illustration in consequence of their showing the process of superposition in the most simple manner. The figures closely resemble each other; but in fig. 44 the various laminæ are not so easily recognized as in fig. 45. The crystal commences with the formation of the nucleus, which in this case is a very minute cube, composed of cubic particles; a layer of four similar cubes immediately begin to form under this nucleus, and raise it up, or propel it forward; a third layer of nine similar cubes then form under the layer of four; and thus the crystal goes on increasing, each successive layer taking an additional cube into the side. Now as the cubic *particles* are small beyond our comprehension, and since the aggregation will frequently be affected by the superposition of laminæ, the thickness of these particles only, it is easy to conceive the reason why, even in microscopic crystals, the sides frequently present to our weak vision, and its limited aids, a perfectly polished surface free from all irregularities. In fig. 44, the laminæ are not perceptible towards the apex of the crystal; whilst in fig. 45 the layers are distinctly recognised: these varieties are the result of mere accidental circumstances, in the

one case facilitating, and in the other retarding the formation of the successive layers. Fig. 48 is an irregular formation, in which, however, the different laminæ exhibit themselves with much distinctness. Figs. 47 and 52 are likewise crystalline structures of common salt; but their integral parts are too minute to be particularly noted; they are drawn exactly as they appear under a superficial magnifying power of 90,000. Fig. 46 shows the crystals of saliva, under the same amplifying power; these, as might naturally be expected, bear strong resemblance to, indeed are nearly identical with, fig. 52.

Our limits will not permit us to enter extensively into the subject of crystallization; but we deem it sufficient to have called attention to the fact that the microscope is an invaluable assistant in detecting the process by which crystalline structures are matured. For the instruction of young experimentalists, we may add, that the salts whose crystals they wish to examine must be dissolved in water; metallic substances, and those which have metallic bases, on being heated, give out crystals as they gradually cool; these latter exhibit beautiful conformations when immersed in solutions that act upon them chemically. We conclude with an extract, relevant to our subject, from Gould's *Companion to the Microscope*, a useful little treatise, by a talented and practical man:

"Another important field of inquiry by the microscope is chemical action. This opens an endless subject of investigation of a very rich order. The mode of pursuing this class of observations is very simple. Prepare a few pieces of thin and perfectly flat glass, of a size suitable to the stage of the microscope; some of these should be the eighth of an inch less every way than the others. A variety of chemical agents should be provided in small glass bottles with stoppers, and a few glass rods about four inches long, with a rounded end, for the purpose of taking up a small drop of liquid. In experimenting, at the outset adapt the focus of the microscope to one of the glass plates. Then, upon one of the larger plates, spread thinly any chemical substance with which you wish to work. Lay the glass upon the stage, and examine leisurely the character and form of the substance. Then, upon one of the smaller glasses, lay, with a glass rod, a small drop of any acid or other fluid with which you wish to act; and, having spread it on the glass, lower it down nearly upon the other glass, so that the edges of the upper glass shall not reach beyond the under one; as the upper glass, when once brought in contact, should never be disturbed. The two substances will thus, by pressure, be reduced to one uniformly thin film; and the action which takes place may be very accurately investigated.

"For instance, let the first glass receive a very minute portion of the carbonate of copper, and the upper glass a drop of nitric acid; on contact, the carbonic acid of the carbonate will be seen coming away in globules, whilst the carbonate of copper breaks down and disappears. The field is gradually occupied with a solution of nitrate of copper; and this is seen to crystallize in minute rhombic crystals. Lift up the upper glass, and add a small drop of ammonia, and slip down the glass again; the crystals of the nitrate disappear; a new combination takes place; and you see the beautiful foliations of the nitrate of ammonia interspersed with groups of the still more beautiful prisms of the deep blue ammoniuret of copper. Or, instead of the ammonia, add muriatic acid; the nitrate is changed into a grass-green solution of the muriate of copper, which crystallizes in bundles of spears shooting in all directions across the field of vision.

"These phenomena may be multiplied to any extent by the use of the numerous chemical agents to be obtained. Iodine presents an endless variety of aspects in combination with different agents. The crystallization of hydriodate of potass is very beautiful, if a drop of the solution is put on a glass. Put on the other glass sulphuric acid. When brought in contact, the acid takes the potass, and forms crystals of the sulphate of potass, and the iodine is developed both in solution, which passes off by evaporation, and in the crystalline structure of the substance itself. Again: combine solution of iodine with solution of sulphate of soda. The alcohol, in the solution of iodine, takes part of the water from the soda, and the rest of the sulphate of soda crystallizes in prisms. The iodine, deprived of the alcohol, is developed in cherry-red drops of liquid and in dark rhombic crystals.

"To these observations may be added, the examination of various crystallizations in polarized light. Between the reflecting mirror and the stage of the microscope insert a plate of tourmaline, so that the condensed light of the mirror be thrown upon the object through the tourmaline. This polarizes the light received. Then above the eye-piece lay another plate of tourmaline, or, what is better, an analysing prism of Iceland spar. This enables the observer to perceive the changes produced by the polarized light. Many crystals so observed, as sulphate of potass, &c. exhibit the most beautiful colouring, according as the upper plate of tourmaline is turned round on its axis. Some crystals, as nitrate of potass, exhibit these colours without the upper, or analysing plate. The laminæ of the crystal itself, as is the case with the mineral called iolite or

dichroite, serve to polarize the light passing through it, and to make it visible.

"A few other similar experiments may be mentioned:

"1. Add sulphuric acid to common salt, or muriate of soda, or to carbonate of ammonia.

"2. Add sulphuric acid to bichromate of potass or muriate of soda. The result is crystals of sulphate of soda, with chloro-chromic acid.

"3. Add acetic acid to the bichromate of potass. The crystallization of the bichromate takes place in very beautiful forms.

"4. Add sulphate of alumina and potass to muriate of cobalt. The crystals of the alum form in great perfection.

"5. Add acetic acid to nitrate of copper. The biperacetate of copper forms slowly and crystallizes in great beauty.

"6. Add terrocyanate of potass to sulphate of iron.

"7. Add nitrate of potass, or aqua potassæ, to sulphuric acid. The sulphate of potass forms in solution. Raise the upper glass with a knife the smallest degree, and let it fall again; the crystallization is instant.

"8. The smallest drop of any liquid containing lead may be examined by the usual tests for lead; and wine may, in the same way, be tested in a drop not bigger than a pin's point.

"9. The ben-iodide of mercury is a beautiful crystal, and open to a variety of experiments.

"10. Investigate the comparative purity of successive crystallizations of nitrate of potass."[1]

In proceeding to consider the formation of minute mineral bodies, our attention is called, in the first place, to what are designated the *active molecules* of matter. With the exception of bodies perfectly soluble in water, metals that cannot be reduced to atoms sufficiently minute, and a few other substances, the whole range of matter exhibits the phenomena of molecular activity. The method of bringing these atoms under microscopic investigation is very simple. On a slip of glass, adapted to the stage of the microscope, place a small drop of water; then with any substance sufficiently hard, rub the mineral body whose atoms you require; touch the water with the rubber, and it will transfer to the fluid the minute particles separated by friction. Apply a deep power, say a one-twentieth inch doublet, and a vast number of apparently small spheres will be seen in rapid and continual motion. This motion of the particles will not cease in any definite time, if care be taken to supply fresh water as the other evaporates. The movement of these atoms very closely resembles that of the infusorial monads and the spermatic animalcules. The writer was led himself to experiment on the nature of these active molecules, and from a variety of phenomena presented by minute particles of camphor floating in spirits of turpentine, he was led to attribute the activity to electric or magnetic agency. Having put a drop of spirits of turpentine on a slip of glass, he added thereto an extremely thin shaving of camphor, which was rapidly decomposed by the spirit, and fell down into minute crystals, spheres, cylinders, circular planes, &c. The activity of these tiny forms was truly wonderful and delightful to witness; and though this is not the great point to which he would now direct attention, he still thinks that a detailed account of the appearances will be interesting to all who have not made similar observations. The crystals were rhomboidal, and frequently revolved with greater or less rapidity on their longest axis; after turning one way for some time, they would then reverse their motion; at other times, the revolving movement would be entirely suspended, and they would direct alternately the two ends (poles?) of their axis to some particular point in the field. The spheres exhibited the same phenomena in revolving, with this peculiarity, that the rapidity of their motion far exceeded that of the crystals; and whenever they ceased to revolve, it was to fly off in a right line to another quarter of the field. It should be remarked that whilst revolving, neither the crystals nor the spheres made any progressive advance, at least speaking generally. The circular planes revolved in like manner on a diametric axis; and these progressed over the field in the direction of the revolution. The small cylindric forms pointed their ends alternately to the same point, frequently revolved on their axes, and occasionally exhibited all the lively motions of the most active vibrio animalcules. When the crystallizing process began, as the turpentine evaporated round the edges of the field, these several forms cleared from the centre and united themselves to the foliations. It was then that a vast number of very minute particles were discovered, moving rapidly in the manner of ordinary molecular atoms; as the star-shaped crystals began to form in the midst of them, they were seen to strike rapidly and repeatedly against the projecting points, till at length they adhered to the mass, and were incorporated with it. The phenomenon was precisely that of an insulated cork ball striking against the conductor of an electrical machine, in which case it becomes electrified itself and is repelled, when quickly losing the electricity it had acquired, it again strikes the conductor. It seems probable then that molecular activity is the mere result of successive attraction and repulsion among a vast number of suspended particles; and it does not appear difficult to conceive that motion will be-

[1] Gould's Companion to the Microscope, p. 62, et seq.

get motion in such a host of atoms, and that their activity may be indefinitely prolonged. We shall again refer to the activity of molecules when we come to speak of infusorial and spermatic animalcules whose movements they greatly resemble.

Ores and minerals should first be examined in very small portions in their native state; as their complex structure cannot be so well understood from an artificial crystallization, which rather developes primitive forms and elementary principles. The crystalline formations and foliations of any mineral may be subjected to microscopic examination, by dissolving a few particles in muriatic or nitric acid. It would answer no purpose to enter into an extended description of the crystalline structures of minerals, as exhibited under the microscope; since these can only be adequately comprehended from actual observation, or from very elaborate illustrative engravings. We shall therefore confine ourselves to the mention of a variety of minute native bodies discovered by various observers.

On the sea-shore, along the banks of rivers, and in many inland places, various species of sand are discovered, widely differing from each other, and all exhibiting a beauty of structure and finish well worthy of observation. "These species differ in colour, figure and size; and as among stones some are called precious for their excellency, so also amongst sands there are some that deserve the same epithet for their beauty. The grains of sea-sand are very large, and afford great variety of all shapes and colours, both opaque and transparent. River sands are smaller grained, of different colours and forms; and the inland, or pit sands, vary also exceedingly, being some white, some brown, some yellow, &c." "These varieties are very agreeable to examine by the microscope, which shows, in some of the shining kinds, grains having all numbers of sides and angles, and so finely polished, that no diamond is more exquisitely beautiful. On others, grotesque figures, or representations of landscapes, buildings, plants and animals at once surprise and please." There are several kinds of black sand brought from the East Indies, and also from Virginia and other parts of America, which exhibit beautifully polished surfaces, and may be attracted by the load-stone. A red-coloured sand is also brought from abroad (we believe from Africa) which presents a delightful picture under the magnifier, resembling a heap of gems carelessly thrown together.

Small, irregularly shaped particles of the precious stones, are very interesting microscopic objects. Leuwenhoeck's method of examining the diamond, and the phenomena it presented, are thus described by Baker. "He broke a small one between two hammers, and placing the pieces before his microscope, in the sun-shine, he saw many sparkling flames issue from them, with a continual corruscation, in some, like faint lightning. Then viewing them in the shade, he observed, among other pleasing appearances, a little flame that seemed to dart from each particle of the diamond: and it was a glorious sight to behold multitudes of sparkling flames, most of a bright fire colour, and others greenish, flashing faintly and like lightning at a distance. In other pieces of the diamond the *lamellæ*, or layers, were very plainly distinguished." This description is somewhat grandiloquent, yet perfectly agrees with later observations: the powerful refractions of this gem and its structure are both very distinctly developed by the microscope. Minute crystalline formations, vulgarly called diamonds, are frequently found in the cavities of flint or rock; these vary considerably in form, and by their action on the rays of light become objects of great interest to the microscopical observer. Sir David Brewster has called attention to the singularly shaped microscopic cavities in gems and other mineral bodies, "containing two fluids unknown to the chemist, groups of crystals, floating balls, and exhibiting actual chemical operations going on in these minute laboratories when exposed to changes of temperature. In some of the precious stones, particularly in diamond, garnet, &c., these cavities are perfect spheres." In his recent Treatise on the microscope, this unwearied observer gives diagrams of "the cavities containing the two new fluids that will not mix, though in the same cavity;" and also of the beautiful spear-shaped cavities formed in topaz.

The examination of the inferior minerals, such as common free-stone, &c., whilst it has gratified the observer with a view of their structure, has also developed serviceable truths relative to the value and capabilities of the materials in the ordinary concerns of life. Their compactness or porosity, their durable or perishable nature, may be determined with much exactness by the aid of the microscope. What is called Kettering stone (from the locality of the quarry whence it is dug) is shown, for example, to be eminently adapted for filters, as it is composed of small globular particles cohering so firmly together as to form a substance harder then free-stone, yet is filled with innumerable interstices arising from the spherical surfaces touching only in certain points.

Before dismissing this portion of our subject, it may be interesting to transcribe the remarks of the old micrographers regarding the minute globules of steel produced by the com-

mon operation of striking fire from flint and steel.

"In the common way of striking fire with a flint and steel, fiery sparks fly out at every blow; which sparks are nothing more than small pieces of the flint or steel, (but usually of the steel) broken off by the violence of the stroke, and either melted instantaneously into steel globules, or made at least red hot, and thereby capable of kindling tinder or touchwood. The heat is likewise so intense as sometimes even to vitrify the broken particles. Dr Hooke struck fire over a sheet of very white paper, and observing diligently where the sparks seemed to vanish, he discovered there certain very small, black, but glittering and movable specks, which when examined with his microscope, appeared to be little round globules; some whereof did, from their surface, yield a very bright and strong reflection on that side next the light, and resembled iron balls. The melting of the particles of steel, instantaneously, upon the collision, is very wonderful, and comes up nearly to the effects of lightning." The combustible nature of iron and steel is evidenced by the simple experiment of letting drop the filings of either through the flame of a candle, when a number of the particles will be found melted into small globules. On burning a red wafer over a piece of glass, and submitting the latter to the microscope, several very regularly formed globules of lead will be discovered.

We must now glance at the minute petrifactions, and fossil remains, of marine animals, insects, animalcules and vegetables; and this division of our subject will bring before us startling discoveries, to which the mind is scarcely disposed to give credence. A little reflection, however, upon the mighty operations which are continually going forward in the microscopic world, will lead us to apprehend so much of these wonders as is necessary to excite our belief in them. We shall of course be understood to refer to the infusorial organic remains discovered by Ehrenberg.

Referring to the remains of marine animals, Mr Pritchard has the following observations, in his *Microscopic Illustrations*, p. 20 :—"Look at the discoveries of Agassiz on the fossil creatures of the deep! By a microscopic investigation of such portions of them as have withstood the destructive power of time, namely, their scaly covering, he has been able so to group and class them, that the characters and habits of the genera belonging to each distinct era are clearly demonstrated. A microscopic examination also of the testaceous remains of sundry Entomostraceans, found in slate-clay formations, now elevated much above the level of the sea, prove them to have been at some time or other imbedded in the waters. And the naturalist may even determine by an inspection of the shell, whether the species were the inhabitants of fresh or salt water, and consequently whether the strata themselves were the indurated beds of the sea, or of some river or lake."

Fossil remains of insects have hitherto rarely been met with; and of those which have been discovered very few are satisfactorily developed by the microscope. Blumenbach divides them into three sections.

I. "The *Determinable;* such for instance as those found in the schist at Oeningen, larvæ of Libellulæ, Notonectæ, &c. II. *Dubious;* to which head belong most of those inclosed in amber, as also most of the petrified crabs. III. *Unknown;* such are the celebrated Dudley-fossils, which are found in various places, but no where finer than at Dudley, in Worcestershire, and frequently retaining their crab-like shell." Plate 4, figs. 39, 40, 41, 42, 43, 50, 95, represent a few of the insects that have been discovered in a fossil state; as these are particularly noticed in the general summary of organic remains, it would be needless repetition to describe them here. Plate 35, fig. 41, exhibits a singular insect, much resembling a mite, discovered in a siliceous formation at Uckfield in Sussex. It is drawn with nearly four times the surface it exhibited under a doublet of one-thirtieth inch focus. Its real size seems to vary from 1-3000th to 1-1500th of an inch in diameter.

The recent discovery of animalcular fossils by Dr Ehrenberg of Berlin, has caused a great sensation in the philosophical world, and promises to aid in no small degree the advancement of geological science. "These remains," says Sir David Brewster, "are the siliceous shells of animalcules belonging to the division *Bacillaria*, and form strata of tripoli, or poli-schiefer (polishing-slate), at Franzenbad, in Bohemia. M. Ehrenberg has still more recently discovered them in the semi-opal found along with the polishing-slate in the tertiary strata of Belin, in the chalk flints, and even in the semi-opal or noble opal, of the porphyritic rocks. The size of a single individual of these animals is about 1-288th of a line, or 1-3456th of an inch. In the polishing slate from Belin, in which there appear to be no vacuities, *a cubic line* contains, in round numbers, 23 millions of these animals, and *a cubic inch* contains 41,000 millions of them. The weight of a cubic inch of the polishing-slate is 270 grains. There are, therefore, 187 millions of these animals in a single grain, or the siliceous covering of one of these animals weighs the 187th millionth part of a grain!"

We anticipate the questions which will arise on a perusal of this brief statement:—

How can animalcules so inconceivably minute be congregated in such masses? What new powers have been added to the microscope by which it is enabled to develope these delicate formations? In reply to the latter question, we simply state the fact, that recently a high degree of defining and penetrating power has been given to the microscope, for want of which, at an earlier period, researches into the minutiæ of nature were frequently inconclusive and deceptive. Deeper magnifiers than any formerly known are now, also, brought into effective use. The first inquiry,—how can these animalcules be collected in such countless myriads of myriads?—will be satisfactorily answered in the following extracts from a most talented article in Chambers' Edinburgh Journal.

"The productions of the kindred zoophytes, in the innumerable coral reefs and islands which bestud the ocean, are truly wonderful; but not less astonishing certainly is it, that the organic remains of these invisible atoms should abound to such an extent, as actually, in the language of Dr Ehrenberg, to swell in no small measure the amount of the solid matter of the crust of the globe. Many of these animalcules are of a beautiful green colour. If water, then, containing some of these, be taken from a pool or marsh, and conveyed into a covered vessel, a layer of fine powder, speedily becoming a green crust, will ere long be found on its surface, and more particularly near the margin of the glass. This crust, at first a bright green, gradually assumes a brown and yellow hue. This constitutes the well known *Priestley matter* of former days, which at one time so much engaged the attention of philosophers. It seems formed of the more solid portions of these animalcules, which, in successive generations, have ceased to live." The fecundity of these small animals is beyond all conception: each individual produces a host; and "generation succeeds to generation with a rapidity which cannot be estimated, and their remains thus accumulate in countless myriads, and to a vast extent." The slimy substance which not unfrequently covers stagnant waters, and is sometimes spread over wet and marshy soils, has been discovered to consist of large masses of animalcules in thin layers. "When we are thus informed of layers of dead infusoria formed on common marshes, or in ditches, we are in some measure prepared to understand how the same substances may have formed great layers or *strata*, taking their place amongst the other rocks which fall under the attention of the geologist. The fact, however it may be received, is so. Vast layers of rock, at or near the surface of the earth, and many feet in thickness, have been discovered in various parts of the world, which the microscope has found to be composed solely of the shields or hard parts of Infusoria; these remains of Infusoria having, of course, been deposited from great bodies of water which formerly overspread the place. Dr Ehrenberg has actually shown, by experiment in the royal deer park at Berlin, how such rocks may be formed by means of the Infusory tribes; and the only difference between the crust formed in experiments like his, and a layer of rock several feet thick, and of large extent, is in the scale on which the phenomenon takes place. In the one case we have a natural operation on a large scale, and in the other an artificial operation on a small one. All the other features of the process must be considered as identical." The writer from whom we have been quoting, dismisses his subject with these apposite remarks:—"No doubt the abundant vegetation of the elder world, to which we are also indebted for our beds of coal, had something to do with the production of these vast quantities of animalcules, which never fail to be found where the least amount of dead vegetable matter has been allowed to rest in still water. Extensive seas of fresh water, commingled with decaying forests, or which had passed over such, would be the birth place of our fossil Infusoria, the remains of which, as generation after generation perished, would sink in an impalpable powder to the bottom, and there in time be accumulated in the form of a layer of rock."

The fossil remains of vegetables present most interesting phenomena to the geologist; these have been already referred to and illustrated in the course of the work, and in this place we have only to notice that the microscope affords considerable aid in the development of this class of objects, particularly the fossil woods, specimens of which can now be procured cut so extremely thin as to admit of their being viewed by transmitted light, by which means all their peculiarities of structure can be readily ascertained. We shall lay before the reader Mr Pritchard's eloquent and philosophical remarks on this subject:—"To the botanist the aid of the microscope is indispensable. In the investigation of our fossil-flora, what does it not exhibit to us! How beautiful and delicate is the structure of the envelope of some of the fossil-fruits; those, for instance of our London clay, when viewed under this instrument! And how important is it, that, by its assistance, we can determine with accuracy the natural orders, genera, and sometimes the very species of the trees and plants of former epochs! How, beyond all question, is now demonstrated the vegetable origin of our coal! Preserved within a bituminous lump of coal, which has been deposited for thousands of years deep in

the bowels of the earth, you may discern not only the woody fibre, its arrangement, and the disposal and form of the medullary rays, but even the most delicate of the vegetable organs, such as the spiral vessels and the beautiful terminations of those vessels! These are distinctly discoverable as in the finest preparations of a recent plant. And what can be more amusing and instructive than the examination of the silicified woods, when formed into sections no thicker than the paper of a bank-note? Thus rendered pervious to light, the organic structure of the wood becomes plainly distinguishable. And emanating from this, what can be a more interesting subject than the inquiry into the mode in which the silicifying process has been carried on—by which the constituent elements of the inmost and minutest portions are changed—whilst their form and situation and colour remain the same? In investigating also that extinct genus of plants, the Lepidodendra, a similar idea is raised in the mind, as to what must have been the particular state of the earth with respect to atmosphere and temperature at the period of their growth, and what the changes which have since taken place, in order to bring it to its present condition."—"In the foregoing remarks on the application of the microscope to botanical purposes, I have given the reader only a general outline; to enter upon any thing like details, would of necessity extend our introductory chapter of this description far beyond its proper bounds. I may, nevertheless, be permitted to make use of one example by way of illustration. But how shall I select one where the materials suited to construct it are so superabundant, and where they all present so many points of interest? It will be readily admitted that this is by no means an easy choice. I will limit my observations, however, to a single microscopic slider, and see what instruction is derivable from it. Suppose this slider to contain some sections of a fossil wood; for instance, three specimens or shavings of such extreme tenuity, that if they were exposed, they would be wafted away on the slightest breeze. Let them be weighed, and they will not exceed a grain. Hand them to the chemist, and he can only prove to you that their primary constituents are oxygen, hydrogen, carbon, &c., and in so doing, he will destroy them. What, then, does an inspection of them under the microscope reveal? It will tell you, in the first place, whether they grew up, like our forest trees, by yearly additions to the outside of their woody centres, or by internal accessions, like most of the productions of the tropics. It will tell you whether their leaves were veined or not—whether their embryos were dicotyledons or monocotyledons—whether the trees from which they were cut had branches or not—and, if they had, whether these were thick and sturdy, like the boughs of the oak; or thin and flexible, like the branches of the fir tribe. It will tell you whether the wood might be easily cleft asunder, like deal; or would sooner break, like beech; whether it was elastic, like the pine—so admirably suited for the masts of ships; or like the stubborn oak, would rather snap than yield to the wind. These are some of the ordinary properties developed by the microscope. Again, in taking a more minute physiological survey, our information will be by no means less complete. For these same specimens will disclose to us, under the microscope, the form and arrangement of their woody fibres, the disposition of their barks, the beautiful structure of the tubular receptacles by which their secretions have been carried on, and their growth promoted. In short, so much will be revealed by them in this manner, that the actual distinction between a wild and a cultivated tree may be, in some cases, clearly traced."[1]

We now proceed to the second branch of our subject, namely, the consideration of the minute formations and phenomena of the *Vegetable Kingdom*. Here opens a rich field of interesting observation, and the more interesting because it embraces an extensive range of objects with which readers in general can claim familiar acquaintance, so far as their features are obvious to the unassisted eye. It would, we venture to say, be difficult to find a person, young or old, who, in his rural walk, has not stopped to look upon the broad and massive foliage of the oak, or rested beneath the shade of its far spreading branches,—who has not gathered the wild flowers that embroidered his sylvan couch, and wondered at their surpassing loveliness,—or has not lingered with pleasing delight amidst the luxuriant display of vegetable beauty in the carefully tended flower-garden. And to those who look with admiration on trees, plants, and flowers, as they exhibit themselves to the unaided sight, and in a passing glance, it cannot be uninteresting to know that under these obvious beauties lie concealed formations so exquisite, and mechanical powers so wonderfully contrived by the great Artificer of nature to produce, sustain, and carry on the vegetable organization, that, wanting a knowledge of these, we can scarcely be said to know anything of the vegetable creation. And here again we call Mr Pritchard to our aid:—"Vegetable organography," he observes, "upon which the modern botanist depends so much for his systematic arrangement, and

[1] *Pritchard's Microscopic Illustrations*, New Edition, pp. 21 and 25.

ch which the student is so greatly interested, and amused, owes almost its very existence to the microscope. This observation will be found to apply in an especial manner both to the cellular and vascular tissues of plants. The membraneous cellules of cellular tissue are sometimes not more than 1-1000th of an inch in diameter; and those of the ordinary size, are about 1-200th or 1-300th. How then is it possible that we could become acquainted with their forms and arrangement but by the aid of the microscope? And so with respect to vascular tissue: it is absolutely indispensable toward acquiring an accurate knowledge of the structure and forms of these membraneous tubes, and of the spiral, or annular, fibre that surrounds them. A knowledge of the fructification, if I may so express myself, of that numerous and curious class of plants, the Acrogens, could not be obtained without it; nor could the existence of many of them, such as the Fungi, Algæ, and some of the Musci, be proved. By its powers, even the ashes of vegetables may be seen to contain the decisive characteristics of organic structure; and the long debated question of the antiquarian whether the "fine linen of Egypt" in the times of the Pharaohs, was of linen or cotton fibre, seeing the latter is now indigenous to that country, is for ever set at rest."

But, not to insist in this place on the aid afforded by the microscope to the professed botanist or the scientific inquirer, let us glance at those simple yet highly interesting and pleasing observations, which appeal so forcibly to every one who has a mind constituted to relish and enjoy the beauties of nature. In an ordinary survey of flowers, we found our admiration on the beautiful shape and texture of the petals, their number, colour and arrangement; and the singular or striking disposition of the stamina and other parts reposing in the cup of the blossom. But when we take a single flower and subject it in detached parts to microscopic examination, what a fund of pleasing knowledge is opened to us! The velvet surface of the petals is resolved into a fabric which no human art can imitate; and the stamens and adjacent parts when examined in detail, exhibit formations which could not have been conceived to exist in so small a space. Every flower has microscopic beauties peculiar to itself; and it would occupy the leisure of an extended life, to make one minutely acquainted with the floral products of the humblest village garden. Then, again, what a variety of shape and character is to be observed in seeds; some with beautiful shining surfaces, others most singularly marked and figured, or strangely peculiar in form, or provided with curiously wrought appendages,—yet all strikingly adapted to further and assist the reproduction of the plants to which they respectively belong. The fibres, veins, peculiarities of surface, &c., of the plant leaves demand careful investigation; and the young wood of the shoots is likewise worthy of being minutely examined. A thin transverse section of the latter discovers under the microscope a structure resembling, but far surpassing, the richest lace work. It is time, however, to leave these desultory remarks, and proceed with our subject in an orderly manner.

We have before alluded to the active molecules of matter in connection with the mineral kingdom, and we are now briefly to notice the same phenomenon of atomic activity in vegetables. Indeed, it was during a course of experimental observations on the latter substances, that this phenomenon was first witnessed by Robert Brown, Esq. F.R.S. Having found that the *pollen* of plants, when suspended in water, exhibits a most remarkable activity, evidently resulting from other causes than the agitation of the fluid or the breath of the observer, he naturally concluded, that the minute particles of inorganic bodies might present similar appearances, if similarly suspended.[1] This conclusion is proved to be correct. So far as the writer has observed, there is no difference between the motions of mineral and vegetable molecules, beyond what may be explained by the different principles on which these two species of atoms are presumed to combine, for the formation of inorganic and organic bodies. Our space will not permit us to speculate on this point of identity between the vegetable and mineral kingdoms; it must, however, strike the reflecting reader as a remarkable circumstance, that the minutest atoms of vegetable and mineral bodies are controlled by one common law; and he may be led to the inference that probably organic and inorganic bodies are produced by one and the same principle, modified by secondary agencies. There is, notwithstanding, this broad and decisive distinction between organic and inorganic structures; the former are mere aggregations of atoms, the latter are laboratories, in which complicated operations are continually going forward to prepare matter, so that it may assimilate with and enter into their constitution.

The circulation of the fluids in plants seems to link them with animal existences; but we find, on close examination, that the motion of vegetable fluids differs widely from that of the blood. Blumenbach observes;—"However varied the reticular and other connections of the vessels may be, no relation can be

[1] This molecular activity is exhibited, not in the vegetable dust, palpable to the naked eye, and usually named the pollen, but in the particles of the true farina hereafter to be noticed.

detected between them, of such a nature as to keep up a circulation of fluids, such as is found in all red-blooded, and so many white-blooded animals." Most probably what is termed the circulation in plants is nothing more than the nutritive juices proceeding through capillary vessels to all parts of the plants, whence they do not return. The reader may, however, choose to hear Mr Pritchard's remarks on this subject, the more particularly as they are the result of careful observation with the finest instruments that can be constructed.—"The circulation in plants, termed *cyclosis*, is a *revolution* of the fluid contained in each cellule, and is distinct from those surrounding it. It can be observed in all plants in which the circulating fluid contains particles of a different refractive power or intensity, and the cellules are of sufficient size and transparency. Hence all lactescent plants, or those having a milky juice, with the other conditions, exhibit this phenomenon. The following aquatic plants are g nerally transparent enough to show the circulation in every part of them :—Nitella Hyalina, Nitella translucens, Chara vulgaris, and Caulinia frigalis. In the Frog-bit (Hydrocharis) it is best seen in the stipulæ of the leaves and the ends of the roots. The magnifying powers suited for the above are between 100 and 250 times linear. In the Spider-wort (Tradescantia virginica) it is seen in the filaments surrounding the stamens of the flowers: power required, 300 to 500 times linear. In the common groundsel (Senecio vulgaris) it is said to be seen in the hairs surrounding the stalks and flowers."

The respiration of plants is another feature in which we trace a similarity between vegetable and animal bodies. The leaves in plants answer the same purpose as the lungs in animals, "for the execution of the phlogistic process, which in the latter, is effected principally by the inspiration of the respirable part of the air on its basis, oxygen; and which, in plants, is performed almost exclusively by the leaves. In plants also, this respirable gas, or its basis, is, as in animals, indispensable to the support of life; particularly as Ingen-Housz's experiments have rendered probable, for the purpose of preparing in their vital laboratory their principal material of nutrition, carbonic acid, the excess of which they subsequently exhale in the form of carbonic acid gas. This important process is carried on in its greatest activity in the dark. During the day-time, on the contrary, and particularly in sun-shine, it is much more languid: hence at such time, plants prepare and consume carbonic acid in smaller quantities; and, on the contrary, evolve oxygen, the respirable part of the atmosphere. from their leaves." By the assistance of the microscope we discover, in the cuticle on the under side of the leaves, a number of small openings, termed *stomata*, which are considered subservient to the respiration of plants, as well as to the exhalation of the fluids which are evaporated from them in considerable quantities. It is worthy of remark with reference to the evaporation of moisture, that this process is as necessary to vegetable, as that of perspiration is to animal life; for if the stomata of the leaf be closed up artificially, or otherwise, the plant, or that immediate part of it, becomes diseased and withers. The alternate exhalation of oxygen and carbonic acid gas from the leaves of plants, must appear a remarkable provision, subservient to the health and comfort of man. During the day, when mankind are in activity and requiring a full supply of respirable air, the plants, in place of taking from, add to its healthy qualities; and when, at night, the human race are wrapt in slumbers, and the functions of the animal body are performed with less activity, and when consequently less oxygen is required to carry them on, the plants, in turn, take in their supply of this gas, evolving it again with the morning light for the benefit of the awakening world.

Let us notice a few of the interesting facts ascertained from a microscopic examination of a flower. We will begin with the petals, or leaves, which surround and protect the reproductive organs of the vegetable, and constitute the largest portion of the flower. The upper and under surface of these are first to be examined, and the disposition of the downy covering, or spines, or other remarkable features, carefully noted. If then we are able to separate the cuticle on the under side, it will discover to us the *stomata;* and the removal of the cuticle exposes the absorbents of the petal, whose use is to absorb the elements of vegetable nutrition from the atmosphere. Strip off the remaining petals from the flower, and leave only the reproductive organs on the receptacle, or base. Take one of the stamens and carefully observe it; it consists of two parts, the *filament*, and the *anther*. The former of these is found to be a capillary tube for the conveyance of nutrition to the anther, a variously shaped body placed on the summit of the stamen. The anther is the principal object of regard. When submitted to microscopic examination, a number of minute particles are seen scattered over its surface, but if it be pressed, and its interior displayed, the particles become innumerable;—these are, what is usually termed, the pollen or fertilizing dust necessary for the impregnation of the pistil, or female organ of the blossom. They exhibit a most wonderful variety of structure in different flowers, and have always been objects

of great interest to the microscopic observer. Plate 34, fig. 28, is the pollen of the marsh-mallow, consisting of small globes thickly studded with prickles. These atoms are not, however, the actual farina; for on examination with deep powers they are found to be delicate little bags, containing an inconceivably fine powder, the true vegetable semen. The pistil is the next object for observation: it consists of three parts, the *germen*, the *style*, and the *stigma*. The style is a hollow tube, forming a communication between the other parts of the pistil; the stigma is usually a small bulbous substance supported by the style; and the germen is the lower extremity of the pistil, reposing within the corolla of the flower. At the time of fecundation the farina falls on the stigma, whence it is presumed to pass through the style to the germen, the seeds in which thus become impregnated and indued with vegetable vitality. The stigma in some flowers is either divided, or has a small opening which contracts and expands at intervals; in others this organ exhibits a porous surface; in either case it is suitably constructed for the office it fulfils. The germen is the most remarkable part of the pistil, answering to the ovaries in animals. If the outer covering be carefully removed, the seeds will be discovered, clustered like grapes, and a considerable difference of formation will be observed in the germen of different flowers. We have here slightly glanced at a few leading facts elicited from a microscopic examination of blossoms; and in connection with them, we would mention the singular means by which the impregnation of the pistil by the farina is frequently effected. Some flowers are hermaphrodite, and contain within themselves both the male and female organs of reproduction; others are either male or female. "The motion which is observed at the time of impregnation in those flowers which unite the sexes is very remarkable: thus, for example, the stamina of the common barberry, when touched on their inner side, (that turned towards the germen) as may happen when an insect settles on the flower, to suck the honey from its basis, suddenly move inwards, and strike their anthers against the stigma, by that means effecting the fecundation." When the organs are in separate flowers, and, as is the case with the hop, hemp, &c., on different plants, the farina will frequently be carried from the stamen of the male flower to the stigma of the female, by the honey bee, which visits the various blossoms to collect their sweetness, and almost invariably bears away on its wings and body a portion of the farina from one flower, and unconsciously deposits it on the stigma of another. There are other means of impregnation in these cases, more obvious; such as the agency of the wind, or the actual deposition by the florist of the farina on the female organ.

When the impregnation of the germen is effected, all the superfluous parts of the plant fall off, and the former increases in size till the seeds contained in it have reached maturity. "The form, as well of the different seeds, as of the coverings in which they are inclosed, is as various as that of the flowers, and adapted in the most admirable manner to the preservation of the species as regards their extended dispersion, their security, &c. The provision, too, is remarkable, by means of which, whatever may be their position in the ground, when they germinate, they invariably shoot their radicle downwards, and the plumula upwards." The principal parts of a seed are the *cotyledons*, or seed-lobes, which after germination become leaves, and the *corculum* or heart, consisting of the radicle and the plumula. Seeds require, in general, to be prepared for microscopic examination, by steeping them in hot water, when the several parts just named separate and discover their respective formations. The exterior of many seeds is, however, so remarkable, that without any preparation they are most interesting objects under every power that will afford light sufficient to develope their structure. To attempt a description of all the varieties, is impossible; we must simply refer to some of their singular appendages, and describe a few whose formation is most striking.

The *pappus*, or down, with which many seeds are provided is a wonderful characteristic, whether we regard the structure of the down itself, or the ends it is intended to serve. Plate 34, fig. 9, exhibits a filament of thistle down, as it appears under a linear magnifying power of 80. This down, with some variety of form, is either placed on the top of seeds in the manner of a crown, or on each side like wings, or it covers the entire surface; in any case the purpose is much the same, namely, to provide the seed with means of transit from the seed-case to the spot of earth on which it is destined to fall and germinate. And to this wonderful contrivance of nature for the propagation of vegetable life, we are to attribute much of the verdure and floral loveliness of those wild, sequestered spots, where the cultivating hand of man has never been employed, and where the human foot has rarely trod. The down is sometimes designed as a protection to the seed; it either repels the moisture which would injure it, or prevents undue pressure from contiguous bodies. And in some cases, it is so disposed, that it not only directs the seed into a proper position for germination, but also, if the seed be placed in the earth with its plumula downwards, will work it up to the surface again, and re-de-

posit it with the plume upwards! The only other appendage to which we shall refer, is the *ala*, or wing, a fine membrane attached either to the back or margin of certain seeds. On a microscopic examination, this does not appear to be intended so much for a means of transit, as for absorbing nutriment to facilitate the germination of the seed. It is, in most instances, a layer or reticulation of capillary tubes, protected by a double membrane.

The conformation of poppy seeds is exceedingly curious. In outline they somewhat resemble a kidney, and their surfaces are divided into angular compartments, by means of reticulated fibres connected by an exceedingly thin and transparent membrane. Plate 34, fig. 29, is the seed of the Calampelus Scaber, in which the ala, or wing, is a characteristic feature; the external tunic, or outer integument of the seed, is also worthy of observation. Fig. 30, represents a seed of the French Marygold; and in this we notice the wing-like disposition of the down before adverted to. Had the object been sufficiently magnified, this down would have exhibited the character of fig. 9. It is barbed, or spinated; and whilst it serves as a vehicle for the transit of the seed, it also controls its position when placed in the earth, as previously stated. Fig. 42, exhibits the *Theca*, or seed vessel of Moss, under a superficial magnifying power of 100. Without the aid of the microscope, the fructification of the mosses could never have been understood. Botanists are now enabled to distinguish the various genera, by observing the character of the fringe round the mouth of the seed-vessel, and the peculiarities of figure in the seed itself. The powder, or seed, of Puff-ball, a species of Fungus, is an object of great interest, under a high magnifying power. Baker describes it in these words:—"The seed of the Puff-ball seems to the naked eye like a smoke or vapour; but when examined by one of the greatest magnifiers (for else it cannot be distinguished) it appears to be infinite numbers of little globules, of an orange colour, somewhat transparent, whose axis is not above the fiftieth part of the diameter of a hair: so that a cube of a hair's-breadth diameter, would be equal to an hundred and twenty-five thousand of them." The same author's remarks on the seed-vessels of ferns, the second order of Cryptogamian plants, agree with recent observations. "The ancients," he says, "imagined the capillary plants and many other kinds to produce no seeds at all, but the microscope has discovered that all the several species of fern are so far from being barren in this respect, that they are amazingly fruitful: that the seed-vessels are on the backs of the leaves, and that the dust which flies off when we meddle with them, is nothing but their minute seeds. These seed-vessels appear to the naked eye like a black or brown scurf on the back side of the leaf; but, when viewed by the microscope, resemble little circular tubes, divided into many cells, containing seeds. When the seed is ripe, the vessels fly open with a spring, and spirt the seeds out on every side, in the form of dust: and if at that season some of the leaves are put in a paper cone, and that be held to the ear, the seed-vessels may be heard to burst with a considerable noise. Some of these minute vessels contain at least one hundred seeds, invisible to the naked eye. Fig. 33, shows the pod and seed of a kind of fern, named polypodium, that vegetates on the bark of the oak. The seeds contained in each pod correspond in number to the divisions on its circumference. The figures exhibit all the details observed under a superficial magnifying power of 40,000."

The plant, or tree leaves, require to be considered distinctly from the petals of the blossom; for though the two have some things in common, the latter affect the flower only, whilst the former are organs on which the health and vitality of the whole vegetable structure principally depends. We have already adverted to the cuticle, stomata, and absorbent vessels, and the important offices they fulfil; the other points of microscopic interest are included in the following observations by Blumenbach. "The leaves are essentially the same in composition with the trunk and branches, inasmuch as it is possible to distinguish in them cuticle, bark, woody substance and medullary cellular structure. The latter occupies the middle of the leaf, between the two reticular layers of woody substance, from which the other parts may be removed by corrosion and similar processes, leaving a skeleton leaf, as it is called. This reticular woody substance is covered on both sides of the leaf with a peculiar membrane, generally called cuticle, but differing materially from the proper cuticle already mentioned, (which is really expanded over the outer surface of the leaves,) and penetrated by numerous absorbing vessels."

We extract some interesting remarks concerning leaves, from an author before quoted;* and the reader will admire the acuteness with which he has anticipated the comparatively recent discovery of the *cyclosis*, or circulation in plants.

"The leaves of trees or plants are full of innumerable veins and ramifications, that convey the perspirable juices to the pores, for their discharge. Whether or no there be any circulation in them is still a matter of doubt; but as their juices, when let out, immediately

* Baker. The Microscope made Easy, p. 246.

break, coagulate, and become a stiff jelly, it seems probable there may be some circulation which prevents the same effects in the vessels. The sudden shrinking, closing, and opening of flowers, the rising and sinking of the heads of poppies, &c., the vermicular motions of the veins of plants when exposed to the air, seem also to imply somewhat like sensation. The microscope may perhaps be of service to discover much more on these subjects than we yet know. Mr Leeuwenhoeck tearing to pieces a leaf of the species of box called *Palma cereris*, that he might examine it the better, computed one side of it to be furnished with one hundred and seventy-two thousand and ninety pores; and as the other side must have as many, (?) the whole number of pores in a single leaf of box will be three hundred and forty-four thousand, one hundred and eighty. The leaves of rue seem full of holes, like a honey-comb; all the kinds of St John's wort appear likewise struck full of pin-holes to the naked eye; but the microscope shows that the places where those holes seem to be, are really covered with an exceeding thin and white membrane. The under side of the herb Mercury, looks as if rough cast with silver, and the ribs full of white round transparent balls, like numberless grapes, fastened by slender foot-stalks. A sage leaf appears like rug or shag, full of knots, tasseled with silver thrums, and embellished with fine round crystal beads or pendants, fastened by little foot-stalks. The under side of a rose leaf, but especially of sweet-briar, looks diapered with silver."

"Every body knows that the leaves of stinging nettles are thick set with sharp prickles, that penetrate the skin when touched, and occasion pain, heat, and swelling: which symptoms were imagined, formerly, to ensue from the prickles being left in the wounds they make. But the microscope discovers something much more wonderful in this common vegetable, and shows that its prickles are formed and act in the same manner as the stings of living animals. For every one of them is found to be a rigid, hollow body, terminating in the most acute point imaginable, with an opening near its end. At the bottom of this cavity lies a minute vessel or bag, containing a limpid liquor, which, upon the least touching of the prickles, is spirted through the little outlet; and, if it enters the skin, produces the mischief before mentioned by the pungency of its salts. Hence it comes to pass, that when the leaves of the nettles are considerably dried by the heat of the sun, they sting but very little; whereas such as are green and juicy, produce violent pain and inflammation. But the quite contrary to this would happen, if the symptoms were only owing to the breaking of the prickles in the flesh: since when dry, they must be more brittle, as well as more rigid, than when they abound with juice." Our author concludes his remarks by suggesting this query:—"Are there any valves in the vessels of vegetables, as in those of animals, to let the juices pass, but hinder their return?" To this inquiry we believe no answer has yet been returned by any subsequent observer; it is scarcely necessary to say that it is deserving of patient investigation.

We must now briefly glance at the general structure of those cryptogamian plants, whose parts are too minute to be distinctly seen by the naked eye. Of these plants there are four Orders:—the Ferns, the Mosses, the Algæ, and the Fungi.

The most remarkable features in the *ferns*, namely, their seed-vessels and seeds, have already been noticed. The seed-vessels are termed *capsules*, and are usually surrounded by an elastic ring; the seeds themselves are named *sporules*. These are objects that require considerable magnifying power to develope them. The leafy stem of the fern (the *frond*) is an object of great interest when viewed on the under side, which exhibits all the seed-vessels arranged in regular dotted lines.

The *mosses* are a numerous family of very minute plants. "They are supposed to be devoid of woody fibre and vascular tissue. When a leaf is carefully examined, the *septa* which divide the different cells that compose it, will in many species be found to consist of a single spiral line, taking a spiral course from one end of the cell to another. To observe this, it will be advisable previously to soak the moss in water, in order to expand the cells. In collecting mosses, it is essential to procure them with the theca (before noticed and illustrated,) "as without it, it is very difficult to determine the genera to which they belong." Plate 35, fig. 37, is a leaf of *sphagnum*, more usually known under the name of bog-moss. By reflected light, and when laid on a dark-coloured stage, it appears delicately white, and the fibrous structure of the septa is readily perceived. When viewed by transmitted light, the regularly disposed hexagonal cells present the appearance of delicate tracery, or lattice work. It is here shown under the low power of 100 on the surface. "Mosses of all kinds are agreeable objects, and appear, by the microscope, to be as perfect in their leaves, flowers and seeds, as the largest plants or trees. Those, particularly, that grow on the rocks and coasts of the sea, exhibit amazing beauties." The order, named *algæ*, includes the lichens, fuci, and confervæ; and those exceedingly minute vegetations which compose the green matter on unfrequented paths, and also the various kinds of mouldiness, may be placed

under this order. The lichens grow on rocks, the trunks of trees, old palings, &c., and are more usually known by the names of wall-moss and tree-moss. Their generic distinctions are founded on a microscopic examination of their organs of fructification, which commonly resemble little cups or shields. The fuci (or sea-weeds) form a most interesting class of microscopic objects; there is a wonderful variety of them, and the structure of every genera is either exceedingly beautiful, or singularly curious in its details. Plate 35, fig. 38, exhibits a species of sea-weed, under a superficial amplification of 100. The confervæ are aquatic vegetations consisting of capillary tubes only, and in many of them the mode of propagation is extremely simple: in the *conferva fontinalis*, it consists merely in "the enlargement of one end of the thread-like plant into a globular ball, which afterwards falls off and expands into a thread of the same kind." The confervæ include the genera *Chara*, and *Nitella*, in which, as before observed, the cellular circulation is distinctly seen. The appearances presented under the microscope, by the different kinds of mouldiness is most remarkable. Every species is resolved into a perfect plant, "bearing," says Baker, "leaves, flowers, and seeds, and increasing in a manner almost incredible: for in a very few hours the seeds spring up, arrive at full maturity, and bring forth seed themselves; so that a day produces several generations of them." The usual form of these minute plants consist of a capillary tube, the stem, and a small round head, the fruit or seed vessel; this latter ripens, bursts open, and scatters the seed around it. The *fungi*, of which the common mushroom is a representative, "consists of plants mostly of a spongy or cork-like texture; they are generally of short duration, and bear their seeds in gills or tubes, or attached to fibrous or spongy substances. Their generic characters are taken from the disposition of their seeds, or from their external figure or appearance. The greater number of the fungi are indigestible poisonous matter, and the edible mushrooms ought to be collected with care."[1] Mr Pritchard observes,—"their structure is simple, and mostly consists of cellular tissue, in which the minute seeds or sporules are disposed. They are found in all damp places in which there is not a free current of air." Before the invention of the microscope, it was believed that the various kinds of fungi "might be generated at any time, and from any kind of putrified substance, either animal or vegetable, *without seed;* merely by the friendly concurrence of either natural or artificial heat and moisture." In reference to this opinion, an old micrographer justly remarks:—"It must be owned, that heat and moisture, and oftentimes a degree of putrefaction in the substance, are requisite to make these little plants thrive; but that such principles should be able to create them, must, I think, be past belief." The destructive fungi of wood, (*merulius destruens* and *vastator*,) more popularly known as the *dry rot*, are singular microscopic objects when examined in detail; as are also the *uredo segetum*, &c., which cause rust, smut, &c., in grain, and whose fructification consists in a mealy powder, under the cuticle of the plants.

With a brief mention of the microscopic phenomena exhibited in the woody formations of trees, shrubs, &c., we shall conclude our survey of the vegetable kingdom. "The stem of trees and shrubs is covered externally with a very fine cuticle, (rind,) under which lie the bark and the liber (Bass,) the latter consisting almost entirely of the most active sap vessels, and consequently, one of the parts most essential to the support of the plant. Placed more internally, is the alburnum (sap;) next to it is the true wood, and next, the medulla (pith) partly within the interstices of the wood, partly down the middle of the stem; its quantity gradually diminishing as the age of the tree increases. In plants of this kind too, one, or more properly, two new layers of wood are produced yearly, probably by the alburnum, whence it is possible, from the number of such concentric layers, to form an estimate of the probable age of the plant. The wood of palms forms an exception to this disposition, in which no such concentric layers exist, the trunk being equally dense throughout, very hard, and apparently traversed by partial tubes of alburnum. This circumstance is of importance in assisting the decision as to the nature of fossil woods." In thin transverse and vertical sections of woods, (such as are prepared by Mr Pritchard for the gratification of the microscopic observer,) all, or the greater part, of the characteristics above named, are clearly distinguishable under a moderate magnifying power. The great points of inquiry and examination in this class of objects, are the form and disposition of the *cellular tissue*, *woody fibre*, and *vascular tissue*. "The *cellular tissue* composes the pith and soft parts of a tree or plant; when minutely examined, it is found to consist of distinct vesicles of various forms cohering together: they vary in size from 1-30th of an inch to 1-600th; the largest are found in aquatic plants and in the gourd tribe." This cellular tissue, or the vesicles of which it is composed, is filled with the nutritive juices of the plant, whether absorbed by the bark or furnished by capillary tubes from the root; and in these small reservoirs, it is probable,

[1] See Botanical Chart in the Popular Encyclopedia.

the fluids undergo a preparation for the purposes they are to serve. "The *woody-fibre* is best observed in the vertical sections, cut either parallel or perpendicular to the medullary rays: it consists of slender tubes gradually diminishing towards the ends. The fibres vary greatly in diameter; the largest are in the coniferæ: in the lime-tree they often exceed 1-50th of an inch. The *vascular tissue* consists of membraneous tubes, with conical extremities, internally furnished with fibre. When the fibre consists of one or more threads coiled spirally like a screw, it is called a *spiral vessel;* when the fibre consists of rings, it takes the name of *annular vessel;* and if in small pieces, *ducted vessels*, either *reticulated* or *dotted.*" The vascular tissue of plants acts in concert with the cellular tissue for the collection and preparation of the nutritive fluids. Our microscopic knowledge of the economy of vegetable organization, is far from being complete; and, perhaps, at present we can do little more than express our admiration at the wonderful operations which *must* be continually going forward in that laboratory, the trunk or stem of a tree. "Every tree," Adams observes, "may be considered as consisting of numerous concentric strata or flakes, forming so many cones, inscribed one within the other, and whose number is almost indefinite. The most exterior contain the rudiments of the bark; the more interior, those of the wood. In the germ they are gelatinous, by degrees they become herbaceous, and in process of time assume the consistence of wood. Thus the stem, the root, and the branch, may be considered as formed of a prodigious number of concentric vertical strata, each composed of different fascicles of fibres; which fibres are again formed of smaller ones. The spaces between these, and among the fibres, are filled up, interwoven with, and connected by the cellular tissue, of which the radial insertions are formed."

Plate 35, fig. 39, exhibits the singular formation of the aloë as developed in a transverse section, under the amplifying power of 100 on the surface. This object discovers the character of cellular tissue in a very pleasing manner.

Fig. 40, shows the fine longitudinal fibres of the palm, under a superficial power of 90,000.

Fig. 49, is a transverse section of the clematis, showing, under a superficial power of 400, the wonderful arrangement and exquisite structure of its tissues.

We come now to consider the minute formations and phenomena of the *animal kingdom.* A large volume would scarcely suffice for a particular and detailed examination of animal minutiæ: all therefore, that we can propose to ourselves in a division of a single chapter, is to take a general and comprehensive survey, particularizing only in a few instances by way of illustration.

We commence with a slight notice of the *bony structures* in animals. These are brought under microscopic examination, in the same way as the cuttings of wood; viz. by obtaining extremely thin vertical and transverse sections, which are to be viewed both in a dry state and moistened with water. We are instantly struck with the resemblance between them and vegetable formations: in the transverse sections we observe the cavity formerly occupied by the marrow, answering to the medulla in plants; the perforations, resembling cellular tissue; and the concentric circles, indicating the process by which the structure is enlarged. In verticle and oblique sections the vegetable analogy is still preserved, in the disposition and character of the fibres. The *muscles* of animals are to be examined in like manner; by cutting thin slices of dried flesh in various directions, and viewing them first in their dry state, and afterwards when saturated with water. The formation of the fibres and muscular vessels, (the latter much resembling the vascular tissue of plants,) is worthy of attentive examination; it is not, however, the mere beauty or singularity of formation that renders them interesting, for from a microscopic investigation of these structures we are enabled to infer with certainty concerning the strength and activity of the animals to which they respectively belong. The *horns*, *hoofs*, *nails*, &c. of animals form a class of objects that are brought under view in the same manner as the preceding. Thin slices cut in two or three directions exhibit the fibres and cellular cavities; and a vegetable structure is farther evidenced by treating them as opaque objects, and observing the character of the exterior. If, for instance, the outer surface of the human nails be attentively examined, it will be found to consist of a vast number of layers; and if we take a hedgehog or porcupine's quill (the structure of which is the same in principle with that of the nails, hoofs, &c.) we shall discover the true nature of these layers, which are, in fact, conical cups shooting successively one out of the other. Plate 34, fig. 27, exhibits a transverse section of a hedge-hog's quill, wherein we see a medulla or pith, cellular cavities, and other vegetable characteristics. We perceive, then, a wonderful analogy in these structures to the woody formations of trees, both in the infernal disposition of parts, and the exterior accessions arising from progressive growth. The *hairs* of different animals are very similar to the horns and nails, &c. inasmuch as they consist of cups inserted within each other, and interiorly exhibit, (so far as micrographers have

succeeded in examining transverse sections,) nearly the same vegetable characteristics. In general, however, the cups are more readily distinguished in hairs than in the nails, or porcupine's quills, and other objects of this class; there is also a much greater variety of structure in the former than in the latter. Plate 34, figs. 1 to 7, exhibit some interesting varieties of hairs, of which we shall speak in order. We give no illustration of the human hair, because in the adult its character is so much defaced by friction, that it exhibits, even under a deep power, little more than the appearance of a polished cylinder. In the hair of an infant newly born, the serratures on the sides, or more properly, the cup shaped processes, are readily distinguished; we had not, however, when engaged on our drawings, an opportunity of procuring a specimen. Hairs may be described *generally* as cylindrical bodies, composed of a vast number of minute fibres, with cellular cavities interposed; some have spiral lines running up the interior; and from observation of a few varieties, it may be inferred that all are furnished with an apparatus resembling the stomata in the leaves of vegetables. We proceed at once to describe the figures before referred to.

Fig. 1. *The hair of the Dermestes.*—This insect belongs to the order coleoptera, and is remarkable for the beautifully formed hair which covers it in the larva state. There is a variety in the structure; some of the hairs resemble an oat beard, and others exhibit the character shown in our specimen. A more delicate and beautiful object than the spear-shaped hair can scarcely be submitted to the microscope. The lowest power by which it can be seen, is 100 linear; but to develope its details satisfactorily, a power of 200 linear is requisite, which is the one we have used. This object is considered an excellent test of the defining power of a good microscope.

Fig. 2. *The hair of a mouse.*—The characteristics of this subject, when viewed by transmitted light, are dark, transverse stripes, some of which are broken, whilst others extend quite across the hair. On closer and more attentive observation, these appearances are discovered to arise from a kind of spiral spring occupying the tube of the hair, and a number of imperforations on the surface.

Fig. 3. *The hair of a bat.*—From the resemblance between the mouse and the bat, it will excite a little surprise to observe the very decisive difference of structure in the hairs of these two animals. That of the latter sometimes presents the appearance of a screw, or of a number of small conical cups inserted into each other; other specimens seem to be formed of two distinct hairs twisted together; and some exhibit in connection with these peculiarities, striped markings resembling those on the hair of the mouse.

Fig. 4. *The hair of a bee.*—This is a very beautiful object, but requires a good defining power to show the structure satisfactorily. The hair itself resembles a jointed bamboo cane; and from each joint small delicate spines shoot out. The hair terminates in a number of these spikes, one of which is uniformly longer than the rest.

Fig. 5. *The hair of a dormouse.*—This is very similar to the hair of a mouse. The points of difference seem to consist in the regularity of the stripes on that of the dormouse, and its greater delicacy.

Fig. 6. *The hair of a mole.*—This is a most singular structure. The interior exhibits the remarkable transverse stripes observed in the hair of the mouse and dormouse, and the exterior presents a formation somewhat resembling that of the bat's hair.

Fig. 7. *The hair of a caterpillar.*—We notice a great similarity between this object and the hair of a bee. The tube of the hair is not jointed, however, in the caterpillar, and the lateral spines curve the contrary way.

These objects are all shown as developed by a doublet linear power of 200.

The next animal appendage to which we shall allude is the *feathers* of birds, wherein we notice very distinctly the same degree of analogy to vegetable formations, as is found to exist in the hair, &c. The microscopic inquirer is frequently called upon to pause and admire the wonderful adaptation of parts in the various structures he examines; and to note the absolute dependency of the largest formations on the microscopic elements of which they are composed. Let us illustrate this remark in the case of feathers.—The feathers of birds unite to form the wing, a locomotive member which must be light, yet at the same time impervious to air; which must have great freedom of motion, and yet not be liable to permanent disarrangement of its parts. The most superficial observer will have noticed the way in which the feathers are disposed in the wing; they over-lap each other through their whole length, and this principle of over-lapping extends to all the divisions and minute subdivisions of the feathers. Another thing also is too obvious to have escaped notice, that the upper side of every feather is convex, and the under side concave, and that the convex side of one feather lies partly within the concave side of another. This principle of formation likewise extends to the most minute parts. Then again there is an elastic force exerted in every feather, and in every part of a feather for preserving and restoring the natural arrangement. There is, in short, a beautiful display of creative Wisdom in the wing of a

bird, whether we regard the material of which it is wrought, the elegance of its several parts, or the admirable dependency of those parts on each other. A feather consists of three distinct parts—the quill, the stem, and the fibres that clothe the stem on each side. The quill is at once the root of the structure, and a reservoir for the nutriment required to sustain it. The stem is the tree trunk; and the literal fibres are the branches which it puts forth. When we examine one of these fibres microscopically, we find smaller fibres arranged along its edges; and if these last be subjected to a very deep power, we discover that they are, in like manner, fringed with fibres correspondingly minute. The most delicate filaments of the feather exhibit a hair-like structure, being composed of cups inserted one within another; or they present the appearance of a jointed cane. The last named peculiarity is illustrated in plate 34, fig. 8, which shows an exceedingly minute filament of feather down as it appears under a linear magnifying power of 300. The exquisite finish of the joints is very remarkable. We shall offer only one general illustration of the structure of feathers, selecting our specimens from the delicate plumage of the humming-bird, as exhibited and detailed in plate 34, figs. 26, 31, 34, 35, 36. Before entering into a description of these objects, we step aside to notice a remark by Mr Pritchard on the *hair of the bird-catching spider* of South Amercia (*Microscopic Objects*, pl. 9.) "That taken from the palpi is branched, and towards the extremity the central stem enlarges, becomes fluted, and assumes a bright orange colour. The use of this augmentation in bulk towards the end is not ascertained; but I may remark that a similar structure, on a larger scale, may be observed in the small feathers from the breast of the *Indian humming-bird.*" Now from observing a number of these feathers in different stages of developement, the writer was enabled to ascertain the real character of the formations to which Mr Pritchard alludes; and the reader will, we think, be disposed to admire their singular use and remarkable structure. Figs. 31 and 35, are perfect feathers, about one-tenth of an inch in length; the latter exhibits the orange-coloured "enlargements" just named and a number of downy fibres of a pearly-gray tint. It forms a most beautiful opaque object for the microscope; the rich colour of the pods contrasting very pleasingly with the other parts of the feather. Fig. 34, is one of the pods much enlarged; and we call particular attention to the lateral fibres which are escaping from crevices or fissures on each side of the pod. We could have given other illustrations on this point, showing the gradual opening of the pod, and the expansion of the fibres therein contained. Fig. 26, exhibits the ultimate character of the pod when it has burst, and suffered the formation within fully to expand itself. In this state it still retains the bright orange tint. Fig. 31, presents a faithful delineation of the feather when all the pods have opened. The three tufts which terminate each division are worthy of regard; and the beautiful regularity of the whole must excite admiration. It will be noticed that in undergoing this wonderful alteration of form, the feather loses much of the fine downy filaments observable in fig. 35. We should likewise remark, that the perfect developement of the feather is in some degree dependent on the position it occupies on the body of the bird; for we observed several specimens in which the pods gave no sign of opening, though the feathers were as mature in other respects as those which were on the point of full expansion. Fig. 36, is one of the finest fibres of fig. 35, magnified 300 times in diameter. In passing from this brief notice of feathers, we would earnestly recommend the admirer of natural beauty, (if he should be a person with sense sufficient *not to despise small things*,) to amuse his leisure hours by attentively examining the structure of the various plumage that adorns the feathered race.

We proceed to remark upon the *scales* and *perspiratory pores* of the *human skin.* The scarf-skin of the human body is covered in all parts with rows of exceedingly minute scales, disposed three deep, that is, the first line of scales is in a good degree covered by the second, and the second by the third. The whiteness of the exterior skin is probably owing to this triplication of the scales, since on the lips, where they scarcely overlay each other at all, the minute blood vessels shine distinctly. Owing to the constant friction of the hands and feet, and their becoming callous by continued use, it is not easy to procure good specimens of the scales from these members; but from any of the unexposed parts of the body they are readily obtained, by scraping the skin with the back of a penknife. To the naked eye they appear a mass of indistinguishable white-dust; but if they be suspended in a drop of water, which causes them to separate, their true form is very pleasingly developed. Their figure resembles the upper half of a spear's head. To obtain a microscopic view of the arrangement of the scales, cut from between the fingers with a very sharp penknife, an extremely thin piece of the skin and submit it to a powerful magnifier. The shortest diameter of these scales does not exceed 1-1500th of an inch; and their number on a square inch of the human body is not less than one million.

The pores of the skin are minute excretory ducts, discharging the superfluous humours of the body; they also convey to the absorbent vessels of the true skin, the fluid and gaseous products of the surrounding atmosphere. Hence it is, that a derangement of these minute valves, or a suspension of their functions, causes serious injury in the animal economy; and it is almost a demonstrable fact, that all the diseases to which the human body is liable, take their origin from a partial or general interruption to the porous machinery of the skin. It will readily be conceived that great disorders must arise in the system when the exhalation of humours is stopped, and those active agents the absorbents, are inactive. As a preservative of health, nothing is more worthy of attention than this simple precept;—wash the skin clean, remove with flesh-brushes all the scales which are daily shed, and which if suffered to remain upon the skin, mat together and impede the action of the pores; when the perspiration is too scanty, as evidenced by extreme dryness of the skin, use medicines that will determine the humours to the surface; when the perspiration is too profuse, as indicated by an excess on the least exertion, take medicines to moderate the activity of the secretory organs. Here is a volume of domestic medicine in a few lines.

To view the pores, it is necessary with a keen-edged penknife, to shave off the outer surface of the skin as thinly as possible, and then to cut a second piece from the same place; there is no fear of inconvenience from the operation, if it be performed with a light hand, and the skin be taken from between the fingers. The pores are covered by the scales; indeed it would appear that the latter are principally, if not wholly designed, as a protecting covering to these minute vessels. The number of the pores dispersed over the human skin is too large for our conceptions; and when we state, that on the lowest estimate, it amounts, in round numbers, to two thousand millions; we offer this announcement, simply as an effective comment on the scriptural declaration, that "we are fearfully and wonderfully made." The process of perspiration may be pleasingly observed on a warm day, in the following manner:—wash the hands with soap and warm water, and dry them thoroughly, then with a magnifier of one half inch focal distance, observe the small ridges in the palm of the hand, and along the edges of these, the perspiration will be seen arranged like rows of pearls, or more properly, like dew drops on a flower.

The *scales of fishes* are objects of great interest to the microscopic inquirer, from the variety of form and texture observable in them. Exceedingly minute scales have been detected by the microscope lying between the epidermis and the true skin of an eel. We extract a few general remarks on this class of objects from Baker. "These scales are not supposed to be shed every year, nor during the whole life of the fish, but have an annual addition of a new scale, growing over and extending every way beyond the edges of the former, in proportion to the growth of the fish; somewhat in the same manner as the wood of trees enlarges yearly, by the addition of a new circle next the bark; and as the age of a tree may be known by the number of ringlets its trunk is made up of, so in fishes, the number of plates composing their scales denote to us their age. Mr Leeuwenhoeck took some scales from an extraordinary large carp, forty-two inches and a half long, and thirty-three and a quarter in the round, which were as broad as a dollar. These he macerated in warm water, to make them cut the easier; and then cutting obliquely through one of them, beginning with the first formed, and very little scale in the centre, he by his microscope, plainly distinguished forty lamellæ or scales, glued as it were over one another; whence he concluded that the fish was forty years of age." To the arguments here used we have sundry objections to offer: in the first place, the scale of a fish increases exactly in the same manner as a crystal, (say the crystal of common salt), by superposition of thin laminæ, and so far as we have observed, it is as impracticable to ascertain the exact number of layers in the one as in the other; and consequently we can derive from the scales no perfect data whence to compute the age of the fish. And in the second place, the *yearly* addition of a layer to the scale, is nothing more than a mere supposition, from an overstrained analogy. If then, the superpositions be effected in other than yearly intervals, the age cannot be determined; neither, we presume, can it be determined by admitting the yearly additions, for we are not assured when using the *deepest* magnifiers, that we see the ultimate divisions. Indeed Leeuwenhoeck himself states, that the scales of fishes are composed of an *infinitude* of layers or laminæ; an admission founded in fact, and altogether fatal to the fanciful hypothesis we have noticed. These objects require to be viewed both by transmitted and reflected light, in order that all their peculiarities of surface and structure may be satisfactorily observed.

The *crystalline lenses of fishes and other animals* exhibit a most astonishing structure under the microscope. We are indebted to Sir David Brewster for a minute and particular description of these formations, which we shall present to the reader in his own words, introducing it by two or three sentences from Mr Pritchard's *Microscopic Objects*. "If the crystalline lens in the eye of a fish, be minutely

examined by the aid of the microscope, it will be found to be composed of concentric strata or layers, somewhat resembling the coats of an onion. One of these laminæ separated, and placed under a powerful microscope, will be seen to consist of flat fibres or bands, arising from each pole of the globular lens, and expanding towards the equator, like the spaces between the meridians on the artificial globe. The edges of these fibres are serrated, and fit into each other like the teeth of a double rack, or the sutures of the human skull." "When the power," observes Sir D. Brewster, "is small, or the microscope not good, or the laminæ too thick and not nicely detached, each row of interlocking teeth appears as a dark line, sometimes as sharp as a black line drawn upon paper with a pen. Sometimes the lines appear rough and ragged, and as the fibres become less in approaching the poles, the black lines are as difficult to resolve into teeth, as the lines on test objects. The following measures will show what a wonderful structure in the eye has been disclosed to us by the microscope. The calculations refer to the lens of a cod, four-tenths of an inch in diameter.

Number of fibres in each laminæ,	2500.
Number of teeth in each fibre,	12,500.
Number of teeth in each laminæ,	31,250,000.
Number of fibres in the whole lens,	5,000,000.
Number of teeth in the lens,	62,500,000,000.

Or the lens of a cod contains five millions of fibres, and sixty two thousand five hundred millions of teeth; and if we reckon the curved end of the tooth as one surface, each tooth will have six surfaces, which come into contact with the corresponding surfaces of the adjacent tooth, so that the number of touching surfaces will be *three hundred and seventy-five thousand millions*, and yet this little sphere of tender jelly is as transparent as a drop of the purest water, and allows a beam of light to pass across these almost innumerable joints, without obstructing or reflecting a single ray." We have here given Sir D. Brewster's description verbatim; but we must enter our protest against the system of wonder-making, into which it appears even this eminent philosopher can occasionally fall. No useful end is obtained by entering into minute numerical details, of which the human mind can conjure up no idea; this practice prevailed with the early micrographers, and the consequence was, that their writings fell into neglect, and ultimately excited little attention, except from those who delighted to number the repetitions of a letter in the Bible, or to resolve the vast bulk of the ocean into separate drops of water. It is this practice, and it only, that has caused a distaste for microscopic inquiry, and exhibited it as a puerile pastime which should give place to loftier pursuits. Let all the wonders of the minute world be unveiled; but let this be done without ridiculous exaggeration or valueless precision. The microscope will never be other than a childish toy, so long as the observer's aim be rather to bewilder than to inform the popular mind. We have deemed it right to make these observations, at a time when the instrument is approaching, possibly, to its highest perfection, and when, in the words of Dr Goring, "a new and golden age of observation may be expected to commence."

The nature of the *blood, and its circulation* through the veins and arteries of animal bodies, can be thoroughly understood only by microscopic observation. "When Dr Harvey made his grand discovery of the circulation of the blood, and first lectured upon it in St Bartholomew's hospital in 1619, he was ridiculed, and lost his practice through maintaining what was then supposed to be so absurd and wild a theory. The idea was suggested to his mind by reflecting on the valves of the heart and veins, which were evidently so planned as to allow a fluid to pass but one way. All the philosophical reasoning, however, of this celebrated man, could not establish what appears to us so plain a truth, until it was evidenced in the circulation of cold-blooded animals by means of the microscope, and thus placed beyond a doubt. Discerning, as we can do, the very forms of the globules of that fluid, as they flow through the capillaries from the arteries to the veins, in obedience to the laws impressed upon them by the Almighty Creator—viewing this sublime phenomenon, by which life itself is diffused throughout, and sustained in every part of the system,—who can resist conviction of the great truth?" The same eloquent writer (Mr Pritchard,) observes in another place: "The globules of the blood may be seen passing rapidly along the capillary ends of the arteries into those of the veins, where the intervening member is sufficiently diaphanous, as in the ear of the young mouse, the fins and tail of the carp, gold-fish, stickle-back, tadpole, and of most small fish; and in the web between the toes of the frog, lizard, eft, &c. In the arachnoida, (spider tribe,) at the joints of the legs, I have observed the circulation very distinctly, the current of dark globules passing rapidly at each pulsation of the dorsal vessel. In the antennæ and wings of terrestrial insects, it has also been seen when they have just emerged from the chrysalis, as in the perla viridis and semblis bilineata. In several aquatic larvæ and small crustacea, the circulating fluid traverses the limbs, antennæ and tail, and thence moves along the dorsal vessel towards the head, and down the sides of the body, in cavities, and not distinct vessels;

hence called *diffused* circulation. The most favourable subjects for viewing this are the larva of the ephemera, larva of hydrophilus, small dysticus, &c. In several of the polypiferous zoophytes, as the tubularia indivisa, sertulariæ, campanulariæ, plumulariæ, &c. Mr Lister has, by means of the achromatic engiscope, discovered a circulation to exist, which in many respects resembles that in plants." We notice in the serum of the blood, when microscopically examined, two distinct kinds of bodies, named *globules* and *discs;* and accordingly as the one or the other preponderate in the fluid mass, the vital stream is healthy or diseased. The globules appear to be the true particles of the blood, and the discs a simple cohesion of a number of these into a circular plane; a certain proportion of these discs may probably give impulse to and assist the circulation, whilst an undue quantity may render the motion either too tardy or too violent. "Upon submitting the blood to the microscope, a remarkable fact will strike every observer, viz. there will be seen a continual motion of the globules, as if they were acted upon by some unknown agency. This motion appears completely vibratory, like a balance which has received an impulse. It is difficult to account for this phenomenon, but the following hypothesis is hazarded; this seeming tendency to motion in the globules may be a material assistance to the impulse given by the heart, whose mere mechanical force, (however great,) appears hardly sufficient to propel the globules through such inconceivably minute ramifications, through which we know it does pass, previous to reaching the organ of circulation by the large veins."

We now direct our remarks to the structure of *insects* and their transformations, from which we shall pass to a slight review of purely microscopical insects, or such as require the magnifier to develope their entire figure: these points accomplished, the present chapter must be taken as complete.

The *eggs of insects* "assume a vast variety of forms: some are furnished with covers, the surfaces of many are elegantly embossed or fluted, whilst others, as those of the bug, (cimex lectularius,) have their surface curiously granulated." "The eggs are contained and arranged in the body of the insect, in vessels which vary in number and figure in different species. It is a general rule, that eggs do not increase in size after they are laid; among insects, however, we find an exception to this; the eggs of the tenthredo of Linnæus increase after they are laid, but their shell is soft and membranaceous. The eggs of insects differ in their colours; some may be found of almost every shade, of yellow, green, brown, and even black." The eggs of the lion puceron are deposited on the leaves of the plum-tree, and several other trees, in clusters of ten or twelve. Each egg has a filament attached to it; and sometimes the egg bursts, in which state it resembles a minute flower with its stem. These flower-like forms are the shells of those eggs from which the insect has emerged. "Divine Providence instructs the insects, by a lower kind of perception, to deposit their eggs not only in safety from their numerous enemies, but also in situations where a sufficient quantity of food is on the spot, to support and nourish the larva, immediately on breaking the shell. Some deposit their eggs in the oak-leaf, producing there the red gall; others choose the leaf of the poplar, which swells into a red node or bladder. The leaves of the veronica and cerastium, are drawn into a globular head by the eggs of an insect lodged therein. In the Lapland Alps there is a fly covered with a downy hair, called the rheindeer gad-fly; it hovers all day over these animals, whose legs tremble under them. They prick up their ears, and flee to the mountains covered with ice and snow, to escape from a little hovering fly, but generally in vain, for the insect but too soon finds an opportunity to lodge its egg in the back of the deer; the worm hatched from this egg perforates the skin, and remains under it during the whole winter: in the following year it becomes a fly. The gnat, the ephemera, the libellula, and the phryganea, hover over the water all day to drop their eggs, which are hatched in the water, and continue there all the time they are in the larva state. The gnat lays but one egg at a time, which she deposits on the water in a very ingenious and simple manner; she stretches her legs out, and crosses them, thus forming an angle to receive and hold the first egg, a second egg is soon placed next the first; then a third, and so on, till the base is capable of supporting itself; these, as they come to maturity, sink deeper. The fecundity of insects exceeds in an astonishing degree that of all the productions of nature. The following is an experiment of M. Lyonet on the generation of a moth which comes from the *chenille a brosse:* out of a brood of 350 eggs, produced by a single moth of this kind, he took eighty, from which he obtained, when they were arrived at their perfect state, fifteen females; whence he deduces the following consequence: if eighty eggs give fifteen females, the whole brood of 350 would have produced sixty-five; these sixty-five, supposing them as fertile as their mother, would have produced 22,750 caterpillars, among which there would have been at least 4265 females, who would have produced for the third generation a million and a half of caterpillars. It is not surprising, therefore, that these insects should

be so numerous in years favourable to their propagation." Few insects, however, long survive their last transformation; and notwithstanding their amazing fecundity, mankind suffer comparatively small annoyance from them, in consequence of the voracity with which they prey on each other, and the avidity with which they are sought and devoured by birds and other animals. The eggs of insects are for the most part opaque objects, and admit only the examination of their outer surface; in some few instances, however, they can be viewed by transmitted light when the interior structure presents not unfrequently the most surprising and interesting phenomena.

From the egg the insect emerges into the *larva*, or caterpillar state, which exhibits a wonderful variety of structure and beauty of detail, wholly dependent upon the microscope for their satisfactory developement. This period of insect existence, with all the interesting phenomena therewith connected, will be rendered perfectly familiar by the instances we have selected for description and illustration.

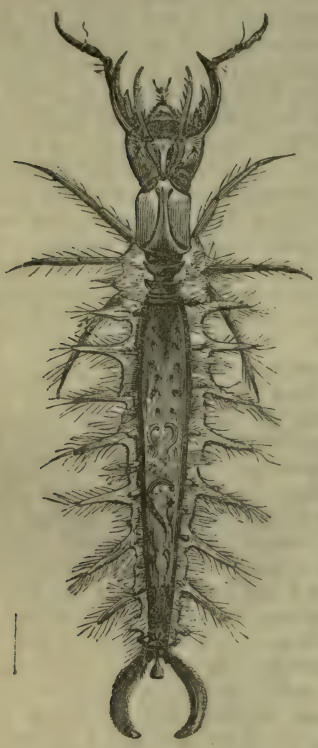
"The larva of the musca chamelion lives in the water, breathes by the tail, and carries its legs within a little snout near its mouth. It appears to consist of twelve annular divisions; by these it is separated into a head, thorax, and abdomen; but as the stomach and intestines lie equally in the thorax and abdomen, it is not easy to distinguish their limits till the insect approaches the *pupa* state. The parts most worthy of notice are the tail and snout. The tail is furnished with an elegant crown or circle of hair, disposed quite round in an annular form; by means of this the tail is supported on the surface of the water, while the worm or larva is moving therein, the body in the meanwhile hanging towards the bottom; it will sometimes remain in this situation for a considerable time, without the least sensible motion. When it is disposed to sink to the bottom by means of its tail, it generally bends the hairs of that part towards each other in the middle, but much closer towards the extremity; by these means a hollow space is formed, and the bladder of air pent up in it, looks like a pearl. It is by the assistance of this bubble, or little balloon, that the insect raises itself again to the surface of the water. If this bubble escape, it can replace it from the pulmonary tubes; sometimes large quantities of air may be seen to arise in bubbles from the tail of the worm to the surface of the water, and there mix with the incumbent atmosphere. This operation may be easily seen by placing the worm in a glass full of water, where it will afford a very entertaining spectacle. The snout is divided into three parts, of which that in the middle is immovable; the two other parts grow from the sides of the former; these are movable, vibrating in a very singular manner, like the tongues of lizards and serpents. The greatest strength of the creature is fixed in these lateral parts of the snout; it is on these that it walks when it is out of the water, appearing, as it were to walk on its mouth, using it to assist motion, as a parrot does its beak, to climb, with greater advantage."

"We shall now consider the external figures of this worm, as it appears with the microscope. It is small towards the head, larger about those parts which may be considered as the thorax; it then again diminishes, converging at the abdomen, and terminates in a sharp tail, surrounded with hairs in the form of the rays of a star."

"This worm, the head and tail included, has twelve annular divisions. Its skin resembles the covering of those animals that are provided with a crustaceous habit, more than it does that of naked worms or caterpillars; it is moderately hard, and like the rough skin called shagreen, being thick set with a number of grains, evenly distributed. The substance of the skin is firm and hard, and yet very flexible. On each side of the body are nine spiracula or holes, for the purpose of respiration; there are no such holes visible on the tail ring, nor on the third ring counting from the head; for at the extremity of the tail there is an opening for the admission and expulsion of air; in the third ring the spiracula are very small, and appear only under the skin, near the place where the embryo wings of the future fly are concealed. The skin has three different shades of colour; it is adorned with oblong black furrows, with spots of a light colour, and orbicular rings, from which there generally springs a hair, as in the figure before us. Only the hair that grows on the insect's side is represented. The difference in colour in this worm arises from the quantity of grains in the same space; for in proportion as there is a greater or less quantity of these, the furrows or rings are of a deeper or paler colour. The head is divided into three parts, and covered with a skin, the grains on which are hardly discernible. The eyes are rather protuberant, and lie forwards near the snout. It has also two small horns on the fore part of the head, and a little above these the eyes are situated. The snout is crooked, and ends in a sharp point.

"The tail is constructed and planned with great skill and wisdom. The extreme verge or border, is surrounded by thirty hairs, and the sides adorned with others that are smaller; here and there the large hairs branch out into smaller ones, which may be reckoned as single hairs. These hairs are all rooted in the outer skin, which in this place is covered with rough

grains. The hairs are very seldom disposed in so regular a manner as they are represented, except when the insect floats with the body in the water, and the tail with its hairs a little lower than the surface, for they are then displayed exactly as delineated in the cut annexed. The tail serves the larva both for the purposes of swimming and breathing, and it receives through the tail that which is the universal principle of life and motion in animals. By means of the hairs it can stop itself at pleasure when swimming, or remain suspended quietly in the water for any length of time. The motion of the insect in swimming is very beautiful, especially when it advances with its whole body floating on the surface of the water; after filling itself with air by the tail. To set out, it first bends the body to the right or left, and then contracts in the form of the letter S, and again stretches it out in a straight line: by thus alternately contracting and extending the body, it moves along on the surface of the water. These larvæ are generally to be found in shallow standing waters, about the beginning of June."



We are permitted by Mr Pritchard to copy from the new edition of his *Microscopic Illustrations* (p. 70 et seq.) the following description and illustration of the larva of a British Hydrophilus (*Hydrophilus caraboides.*)

"In examining the peculiarities of the structure and habits of this larva, what most strikingly attracts our attention is its ferocious and savage disposition, and the fitness of its organs for the exercise of its ravenous propensities. It may be safely asserted that no species of larvæ is known to be provided with weapons of destruction so powerful, so numerous, and so well adapted to their end, as those which this creature possesses. It is on this account that it has been properly called the *Water Devil.* Its size is but little inferior to that of the larvæ of any of the British coleoptera, as it measures, when arrived at maturity, an inch and a half in length, while the superior strength and courage manifested in its attacks on small fish, and other animals larger than itself, is truly surprising.

"About the latter end of April, and during the month of May, small nests of these insects are often found floating among weeds and water plants, in stagnant pools, and are frequently taken in the nets of those who are searching for the early kinds of larva. They are in the form of balls, of a dusky white colour, and a silky texture, and have each a small stem of the same nature as the nest, but more dense. By means of this filament they are attached to the roots or stalks of weeds at the bottom of the water. In this situation they remain during the winter, and are thus effectually preserved from the effects of intense cold. Early in the spring, the stem or cable to which we have referred is detached from the weeds, by the winds which at that time prevail, and the nest rises to the surface of the water, and there floating, receives the genial influence of the sun. These nests may be taken and placed in a basin of water, and, as the season advances, hatched by the heat of the sun. On the larva leaving the nest, which it accomplishes by gnawing a hole in the side, the infant immediately descends to the bottom of the vessel, with its jaws extended in search of prey, and eagerly devours all the small aquatic insects that are within its reach; if however, there is a scarcity of food in the immediate neighbourhood of the nest, they may be seen to attack and devour each other."

"These larvæ, as well as most of those of the larger kind, are found at a greater depth of water than are the smaller ones; although, in their pursuit of small prey, they may occasionally be taken in shallow places. In its infant state, this larva is very transparent; hence its internal structure may be clearly distinguished. When about a quarter of an inch in length, it swims very nimbly. The colour of the head is a strong Indian yellow, with darker shadings of a bright chestnut; the eyes are now bright carmine. It is more sparingly covered with hairs, and its swimming appendages are shorter than at a more advanced period; and the head is larger, in proportion to the size of the body, than when the creature has arrived at maturity. In this respect it resembles many other creatures in its mode of growth, the head seeming to be developed and perfected before the rest of the system."

"The manner in which this larva treats its prey evinces an extraordinary degree of instinct. Many of the creatures on which it feeds are crustaceous about the head and back; hence they are most vulnerable at the under part of the body. This part, therefore, the larva attacks; and, to accomplish its aim, swims underneath the intended victim, and bending back its head, is enabled thus to reach its prey by means of its jointed antennæ. (The illustrative figure represents a magnified view of the larva taken while young.) Its next

operation is to pierce its prey with the curved mandibles. Having thus secured its object, it immediately ascends to the top of the water, and, holding it above the surface, so as to prevent its struggling, shakes it as a dog would a rat. It next inserts the piercer and sucker, (between the mandibles) which are capable of being thrust out or withdrawn at pleasure. When the juices of the victim are not easily procured by suction or exhaustion, the serrated forceps are employed to tear and masticate it, and thus cause the juices to be more easily obtained. If its food be plentiful, this larva arrives at its full growth in the course of three or four months, and is then nearly opaque and covered with hair. It can be kept several days without food, and by this exinanition its structure becomes considerably more transparent; while its natural ferocity is greatly increased, so that it will attack and fight with creatures much larger than itself, and even with its own species. It may be remarked, that it studiously avoids any contest with the *nepa*, or water scorpion."

"On a fine sunny day the larvæ rise to the surface of the water, and delight to bask in the sun; but if watched they remain motionless, with their claws extended. If a stick, or any other substance, be presented to them, they will immediately seize it, and will sometimes suffer themselves to be cut into pieces before they relinquish their hold. Their bite has been considered poisonous by many persons, as it takes a greater length of time to heal than other wounds of the same extent: so that caution should be used in taking them. Touching the anatomy of this creature, it may be observed, that the sucker is contained in a crustaceous sheath, and may be considerably protruded or completely withdrawn at the pleasure of the larva: in the annexed cut it is shown extended to about three quarters of its length. The eyes are compound, but of a peculiar formation, consisting of seven oval apertures ranged like leaves upon a branch. The whole of the head and thorax are curiously marked with a number of lines and spots. The legs are six in number; they are thickly set with rows of hair on their opposite sides, and each is furnished with a sharp claw. The number of swimmers on each side is seven; they are covered with hairs, and to the specimen from which the drawing was taken, a vast number of *vorticellæ convellariæ*, or bell-polypi, were attached. These will be recognized in a subsequent engraving by their bell-shaped figure. They sometimes infest this species of larvæ to such a degree as considerably to impede its motion in swimming. On each side of the abdomen, which commences near the origin of the first pair of swimmers, arise the great tracheæ, or air-vessels, distinguished in the cut by a deeper shade than the other parts; the two approach each other near the tail, where an exceedingly curious process is also distinctly exhibited. The whole surface of the body is thickly covered with hairs, and several tufts are disposed in clusters with some regularity, down the back and sides. The flexible pulsatory organ, or dorsal vessel, situated at the lower part of the body, is in perpetual motion. Its form somewhat resembles the letter S inverted: it however varies a little during its vibrating motions. The use of the curious appendages at the lower extremity of the body is unknown. Its tail is bi-forked and crustaceous, and is marked as shown in the cut. The short line shows the natural size of the larva, at the same period of its growth as that at

which the magnified drawing was made. As it approaches maturity, it casts its skin several times, from each of which it escapes by a rent formed down the back."

"In this larva the air is supplied for respiration by proper orifices situated at the tail; and the creature is obliged to ascend to the surface of the water, and elevate its tail out of it, at every inspiration. When the air thus inhaled has become unfit for inspiration, it is expelled at the same orifice, and a small bubble may frequently be seen issuing from the tail, and ascending in the water. On a careful examination of the skin, which by the bye affords an excellent object for the microscope, there will not appear any spiraculæ along the sides, as in perfect insects."

We have been compelled to abridge Mr Pritchard's description from want of space, and we have likewise made a few necessary verbal alterations to connect it with our wood engraving: in the *Microscopic Illustrations*, the figure is exhibited in a most elaborately executed coloured plate.

The preceding instance has shown us the voracious and fierce propensities of insects in the larva state; we now reverse the picture, and discover the sufferings and inconveniences to which they are themselves exposed. The following are the curious observations of an ingenious naturalist. "As I was observing," says he, "one day some caterpillars which were feeding voluptuously on a cabbage leaf, my attention was attracted to a part of the plant, about which a small ichneumon fly was buzzing on its wing, as if deliberating where to settle: I was surprised to see the herd of caterpillars, creatures of twenty times its size, endeavouring, in an uncouth manner, by various contortions of the body, to get out of its way, and more so whenever the fly poised on the wing as if going to drop; at length the creature made its choice, and seated itself on the back of one of the largest and fairest of the cluster: it was in vain the unhappy larva endeavoured to dislodge the enemy. If the caterpillar had shown terror on the approach of the fly, its anguish at intervals now seemed intolerable, and I soon found that it was in consequence of the strokes or wounds given by the fly. At every wound the poor caterpillar wreathed and twisted its whole frame, endeavouring to disengage itself, by shaking off the enemy, sometimes aiming its mouth towards the place; but it was all in vain, its little, but cruel, tormentor kept its place. When it had inflicted thirty or forty of these wounds, it took its flight with a visible triumph; in each of these wounds the fly had deposited an egg. I took the caterpillar home with me to observe the progress of the eggs which were thus placed in its body, taking care to give it a fresh supply of leaves from time to time, it recovered to all appearance in a few hours from the wounds it had received, and from that time, for the space of four or five days, seemed to feed with its usual avidity. The eggs were all hatched into small oblong voracious worms, which fed from the moment of their appearance on the flesh of the caterpillar, in whose body they were inclosed, and seemingly without wounding the organs of respiration or digestion; and when they had arrived at their full growth, they ate their way out of the sides of the larva, at the same time destroying it. The caterpillar thus attacked by the larvæ of the ichneumon fly never escapes, its destruction is infallible; but then its life is not taken away at once; the larva, while it is feeding thereon, knows how to spare the parts which are essential to its life, because its own is at that time tied up in that of the caterpillar. No butterfly is produced from the caterpillar; the worms that feed on the wretched creature, are no sooner out of its body, than every one spins its own web, and under this they pass the state of rest necessary to introduce them to their winged form."

We conclude our notices of larvæ with an extract from Burt's "Observations on the Curiosities of Nature," which appeared in Chambers' Edinburgh Journal. The details here offered are very similar to those just given; there are, however, several new and interesting facts connected with the present instance, which justify the partial repetition.

"The capada worm, or insect-fly carrier, is produced, like the silk-worm, from the eggs which its mother scatters every where, after she has undergone her metamorphosis into a white butterfly. It begins to live at the end of July, and at its birth is arrayed in a robe of the most brilliant and variegated colours. When on the point of undergoing its metamorphosis in August, it throws off this superb livery, and puts on another of an admirable sea-green hue. This fundamental colour reflects all its various shades, according to the different undulations of the animal, and the different accidents of light; but this new decoration announces the approach of a period when it is doomed to undergo great tortures. It is immediately assailed by a swarm of ichneumon flies, one of which inserts itself into each of the pores of its body, not an opening being left unoccupied. All its struggles to get free of its tormentors are in vain. These flies, which are so small they can only be studied by the microscope, drive their sting into the skin of their victim, over the wild extent of its back and sides. Afterwards all at the same moment, they slip the eggs they have into the bottom of the wounds which

inflicted. No sooner is this operation performed, than the ichneumon flies disappear, and the patient remains for an hour in a drowsy and even motionless state, out of which it awakens to feed with its former voracity. It then appears much larger, and its size increases every day. Its green colour assumes a deeper hue, and the tints produced by the reflection of the light are more strongly marked. About a fortnight after the worm has been encumbered with this factitious pregnancy, the prospect of a numerous progeny begins to be apparent. By the aid of a microscope the eggs may be seen hatching in the body of the animal; and as they are all produced at the same instant, a single glance reveals the capada worm covered with a living robe of (larvæ of) ichneumon flies. They issue from every pore, all the body being covered with them, only the top of the head appearing bare. Its colour then changes to dirty white, and the little worms assume a black appearance to the eye, although their true colour is a deep brown. This operation lasts about an hour, and it is followed by another, which is not much more protracted, but still more singular. Immediately that the ichneumon worms are hatched, without quitting the spot where they separate themselves from the eggs, they yield a liquid gum, which becomes solid on exposure to the air. At the same time, and by a simultaneous motion, they elevate themselves on their lower extremities, shake their heads and one half of their bodies, and swing themselves in every direction. And now they commence a very curious operation. Each of these animalcules works himself a small and almost imperceptible cocoon in the shape of an egg, in which he wraps himself up. The formation of these cocoons occupies only about two hours, and myriads of them being crowded close together, form a white robe, with which the capada worm appears elegantly and comfortably clothed; but while they are thus busily arraying him in his new attire, he remains apparently unconscious of their assiduities; he is then in a state of insect paralysis. As soon as this covering has been completed, and the little artists who wove it have retired to their cells, the worm endeavours to rid himself of his officious guests, and of the robe which contains them, but he does not succeed in the attempt without the greatest efforts. At length he contrives to get rid of the encumbrance; but instead of his former fat and shining appearance, he presents all the decrepitude of extreme old age. He is flaccid and dull; his skin is wrinkled and dirty; and, in short, symptoms of approaching dissolution begin to display themselves. He still makes a desperate effort to gnaw a few leaves, but he no longer devours them with that voracity which indicates a vigorous constitution. Shortly afterwards he passes into the state of a chrysalis, and in giving life to thousands of eggs, he relinquishes his own."

The *pupa* state of insects is the intermediate stage between the larva and the perfect developement, and affords many opportunities to the microscopical observer for detecting curious and interesting formations and phenomena.

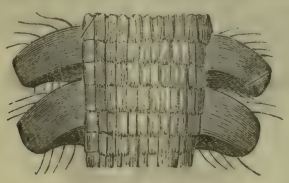
"When the larva has attained to its full growth and the parts of the future insect are sufficiently formed beneath its skin, it prepares for its change into the pupa state; it seeks for a proper place in which to perform the important business. The different methods employed by these little animals to secure this state of rest, may be reduced to four: 1. Some spin webs or cones, in which they inclose themselves. 2. Others conceal themselves in little cells, which they form under ground. 3. Some suspend themselves by their posterior extremity; 4. While others are suspended by a girdle that goes round their body. In proportion as the change into the pupa form approaches, the body is observed often to extend and contract itself; the hinder part is that which is first disengaged from the larva skin; when this part of the body is free, the animal contracts and draws it up towards the head; it then liberates itself in the same manner from the two succeeding rings, consequently the insect is now lodged in the fore part of its larva covering: the half which is abandoned remains flaccid and empty, while the fore part is swollen and distended. The animal, by strong efforts, still forcing itself against the fore part of the skin, bursts the skull into three pieces, and forms a longitudinal opening in the three first rings of the body; through this it proceeds drawing one part after the other, by alternately lengthening and shortening, swelling and contracting the body and different rings; or else, by pushing back the exuvia, gets rid of its odious reptile form. The larva, thus stripped from its skin, is what we call the pupa, chrysalis, or aurelia, in which the parts of the future insect are inclosed in a crustaceous covering, but are so soft, that the slightest touch will discompose them. The exterior part of the chrysalis is, at first, exceedingly tender, soft, and partly transparent, being covered with a viscous fluid; this soon dries up, thickens, and forms a new covering for the animal, capable of resisting external injuries; a case, which is at the same time the sepulchre of the larva, and the cradle of the insect; where, as under a veil, this wonderful transformation is carried on. The chrysalis of the common white butterfly furnishes a most beautiful object for the microscope. Those who are desirous to examine the various members of the insect in its pupa state, should

examine it before the forementioned fluid is dried up, when it will be found to be the perfect insect with the members glued together; these, by degrees, acquire sufficient force to break their covering, and disengage themselves from the bands which confine them. While in this state, all the parts of the insect may be traced out, though so folded and laid together, that it cannot make use of them; nor is it expedient that it should, as they merely pass through this state to be hardened and strengthened."

The exuviæ or cast skins, of insects, in their larva, pupa, or perfect state, form most interesting microscopic objects. "We find in the exuviæ of the caterpillar, the skull, the jaws, and all the exterior parts, both scaly and membranaceous, which compose its upper and under lip, its antennæ, palpi, and even those crustaceous pieces within the head, which serve as a fixed basis to a number of muscles; we further find the spiracula, the claws, and sheaths of the interior limbs, and in general all that is visible of the caterpillar." From an attentive examination of the various exuviæ which are cast off by insects in different stages of their existence, we are led to consider them a compound system of organized bodies, contained one within another; for we not only find in the cast skins all the exterior characters of the insect, but even the coats of the gullet, pulmonary tubes, tracheal vessels, &c. Indeed, there is not in animated nature a more incomprehensible phenomenon than the faculty which insects possess of throwing off, *repeatedly*, the first surface of their exterior members and internal organs. The writer was walking, some years since, on a warm summer evening, along the banks of a river in the south of England, when a number of small *ephemeræ* settled on his dress; he paid particular attention to one that had alighted on his arm, and witnessed, in the course of a quarter of an hour, no fewer than five exuviæ thrown off by the insect. These moultings, as they may be termed, appeared to be effected with much effort and suffering: the body of the insect swelled, and deepened in colour, and seemed to be exerting great muscular energy to detach the exuviæ. Another change of colour to dusky white, indicated the moment when the skin was about to be cast off; the insect appeared to emerge from it easily; and for an instant the rejected covering presented a perfect skeleton, but immediately afterwards collapsed and shrivelled up. What is very remarkable, the insect suffered no apparent diminution of bulk from these repeated skinnings, and at length flew off and joined the countless swarm that hovered about the water, into which, after a very brief interval, they would fall lifeless

The *imago*, or fly state of insects, is the ultimate development of their forms, and usually exhibits structures which for beauty and delicacy are the very antipodes of the larvæ whence they are derived. For instance, the unsightly caterpillar, crawling painfully from leaf to leaf, or gorging itself with gross nutriment, is transformed into the butterfly, that skims lightly over the earth, or mounts with sylph-like wing into the very clouds; which feeds daintily, and sips only the purest nectar of the opening flowers. It was a most happy thought of the early times to make the butterfly an emblem of immortality; it was, however, reserved for latter ages to discover all the pertinence and value of the type. By the aid of the microscope we have ascertained, that not only the ravenous jaws and the whole exterior parts of the larva are thrown off, even to the eyes themselves, but that the internal system, the stomach, lungs and various organs, are all exchanged for other organs, members, and faculties, suited to that higher state of existence to which the insect form is summoned. Surely we may, with no irreverent fancy, admire this lively emblem of the corruptible putting on incorruption, and the mortal putting on immortality.

We proceed to notice the wonderful structure observable in the different parts and members of insects.



The *antennæ* and *palpi* are fine slender articulated horns, movable in nearly all directions, and constituting one of the distinguishing characteristics of the insect tribes. The antennæ are beautiful and various in form, of a delicate structure, and so minutely jointed as to be instantaneously movable at the pleasure of the insect. They are situated on the fore part of the head. The articulations differ in shape, length and number, and vary greatly in different species; the antennæ of the male differ also from those of the female. The greater number of insects have only two antennæ, but some few have four. Regular rows of minute holes are said to have been discovered in the antennæ. Several insects cover their eyes with them whilst they sleep. Many conjectures have been formed regarding the use of these appendages: some have considered them organs of smelling and hearing, others have supposed them to be appropriated to a delicate species of feeling. From the use to which the creature applies them, we are perhaps justified in considering them the organs of touch and hearing. If any sudden noise be made close by an insect provided with antennæ, the motion of these horns sufficiently indicates that they are affected by the vibrations of the air; and, indeed, it is rational to suppose that their delicate structure and articulations must convey a sensation of sound

to the insect. That an acute sense of touch resides in the antennæ, cannot be doubted by any one who has noticed how carefully insects pilot their way with them, and that they never, except when flying, pass from one twig or leaf to another without first testing its security with their horns.

The annexed cut represents one of the antennæ of the *Bombyx antiqua*, highly magnified.

In the following figure, a portion of the antennæ is seen vertically, covered with an imbrication of white scales or feathers, under which the *pectens* issue on each side.

The head of the Bombyx caja, exhibiting one antennæ, and the insertion of the other, is represented by the following figure.

The palpi are small filiform articulated horns, from four to six in number, placed near the mouths of insects. These are usually termed the *feelers*, as the creature is observed to thrust them in every matter, as a hog would its nose, when in search of food. Some have supposed them to be a provision by which the insect is enabled to hold its food near the mouth.

The *eyes of insects* are a wonderful piece of mechanism, differing considerably in their construction from those of other animals. "Among the exterior parts of insects, none are more worthy of minute investigation, and very few persons can be found who are insensible to the beauties of this organ when exhibited under the microscope, which instrument alone can point out to us the prodigious art employed in its organization." The eyes of insects differ in different species; they vary also in number, situation, connection, and figure. "In other creatures they are moveable, and two in number; in insects, the genus *cancri* excepted, they are fixed; they have no eyebrows or eyelids, but the outer coating is hard and transparent. The greater part of insects have two eyes; some have a larger number varying from three to eight. The eyes of insects are of two kinds: the *stemmata*, or single eyes; and the *reticulated*, or clustered eyes." The stemmata were first noticed by M. de la Hire; they are three lucid protuberances placed on the back part of the head of many insects: their surface is glossy, of an hemispheric figure, and a coal black colour. Reaumur made experiments on these eyes, and found that when they were covered the insects flew to a small distance only, and apparently at random; the reticulated eyes appear to be adapted only for long vision, and do not give distinct images of objects close at hand. The reticulated eyes are wonderful structures when examined by the microscope: they are those hemispherical protuberances on the sides of the insect's head, which in the mass are obvious to the unassisted eye, and are even seen, without optical assistance, to be composed of a kind of net work. Each protuberance, in its natural state, is a body cut into a number of faces, like an artificial multiplying glass; but with this superiority in the workmanship, that as there, every face is a *plane*, here, every one is *convex*, immensely more numerous, and contained in a much smaller space. If one of these protuberances be taken from the head of the insect, washed clean, and placed before the microscope, its whole structure is seen, and it becomes an object worthy of the highest admiration. Each separate eye is found to have an hexagonal, a quadrangular, or other regular sided figure, varying in size according to its situation in the head, and including a convex, or in point of fact, a meniscus lens, composed of a number of layers, which may be separated by maceration, and subjected to special examination.

"The eyes of the libellula, or dragon-fly, on account of their size, are peculiarly adapted for microscopical examination; and by the assistance of the instrument, you will find that

they are divided into a number of hexagonal cells, each of which forms a complete eye. The external parts of these eyes are so perfectly smooth, and so well polished, that, when viewed as opaque objects, they will, like so many mirrors, reflect the images of all the surrounding objects. The figure of a candle may be seen on their surface multiplied almost to infinity, shifting its beam to each eye, according to the motion given to it by the hands of the observer. Other creatures are obliged to turn their eyes towards the object, but insects have eyes directed thereto, on whatsoever side it may appear: they more than realize the wonderful accounts of fabulous history: poets gave to Argus an hundred eyes; insects are furnished with thousands, having the benefit of vision on every side with the utmost ease and speed, though without any motion of the eye or flexion of the neck."

The reticulated eyes in some of the fly class are not inferior in appearance to the richest gems: they exhibit nearly every variety of colour under a brilliant and surpassing lustre. In connection with the general description, we have only to add that the number of separate lenses in the hemispherical reticulations of some insects are almost beyond belief: the agrion has no fewer than 12,000 distinct lenses, or separate eyes, the common house fly 8,000, the hawk moth 20,000, the libellula 12,544, the melolontha 8,820, the mordella 25,088, papilio 17,008, phælana cossus 11,300, the scarabæus 3,180. We in vain attempt to reason regarding these lucid points, each of which is a meniscus lens of several layers, connected with a pyramid of fibres and pulmonary tubes whose uses we cannot determine.

The *tongue* or *proboscis* of insects is a taper and compact instrument, by which they obtain the juices of plants or other nutriment requisite for them. Some creatures can contract or expand it, others roll it up with dexterity; in some it is inclosed within a sheath. It is taper and spiral in the butterfly, tubular and fleshy in the fly; in all affording agreeable amusement for the microscope.

The following represents the tongue of the

papioli urticæ taken out and unrolled, displaying two segments, as united with the *rugæ* of which they are composed, and the papillæ or absorbents towards the end.

The following figure on the left hand gives a front view of the mouth without the palpi, the clipeus being raised to show the opening of the mouth and insertion of the tongue.

The right hand figure shows the manner in which the tongue, after the extremity has been applied to the nectary of a flower and has absorbed the juices, is conveyed to the mouth, and the papillæ cleansed by scraping on the under part of it.

Above is represented the under part of the mouth and tongue, with the articulations of the palpi.

"The bee's tongue, for its complex yet finished structure, and the trunk of the common house-fly, with the spiral fibres of the muscles which surround its termination, will amply repay the pains of an attentive and minute examination." These two objects form the principal subjects of our illustrations on this head; and the brief descriptions we are enabled to give of them, will convey a general idea of the wonderful structure and admirable adaptation of parts by which these insect organs are distinguished.

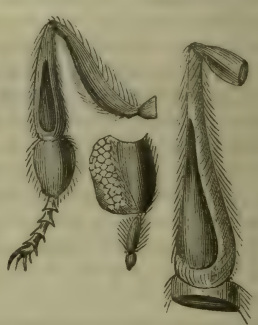


Plate 34, fig. 32, exhibits the tongue or trunk of the common house-fly, as it appears under a considerable magnifying power. This is one of the most interesting and beautiful objects that can be submitted to the microscope, especially when it is mounted in Canada balsam and viewed by transmitted light. Baker thus describes it:—"It consists of two parts folding over one another and sheathed in the mouth. The extremity thereof is sharp like a knife, for the separation of any thing. The two parts can also be formed, occasionally, into a pair of lips for taking up proper quantities of food, and by the fly's sucking in the air, they become a kind of pump to draw up the juices of fruits or other liquors." We call particular attention to the serrations of the tongue; these are separate and perfect teeth,

as may readily be ascertained on examination with a moderate magnifier of good defining power.

Plate 35, fig. 43, represents the trunk of the honey-bee, magnified in the same degree as the preceding object. Swammerdam and Reaumur have described this subject at great length; but as the instruments they used were very deficient in defining power, they were led into hypothetic statements not altogether agreeing with facts more recently ascertained. Their drawings of this insect member are very wide of the truth. Our illustration was copied from a specimen finely prepared in balsam; and it offers the best resemblance to the object of any that has hitherto appeared, taking into consideration the limited scale on which it is drawn, which does not admit of extensive detail. The reader will at once notice the similarity between the trunk of the bee and that of the elephant; their mechanism appear, indeed, to be identical so far as it is intended to facilitate the curvature, contraction, and extension of the member. The trunk of the bee is, however, peculiar in its termination, and seems to be so constructed that the insect may fix it, in the manner of a leech, within the nectarium of the flower, and, by alternately contracting and extending the organ, pump or suck up the juices of the blossom. The surface of the member is marked with a number of parallel rings, and covered with a fine hair. The two bodies, one on each side, are a pair of the palpi.

The *legs and feet* of insects exhibit most curious and elegant structures, worthy of minute examination by all who take interest in the adaptation of animal members and the mechanical powers which they respectively possess. From a microscopic consideration of the limbs of insects, we ascertain that muscular energy increases as the size of the animal decreases. "The motions of animals are proportioned to their weight and structure; a flea can leap to the distance of at least two hundred times its own length; were an elephant, a camel, or a horse to leap in the same proportion, their weight would crush them to atoms. The softness of their texture, and the comparative smallness of their specific gravity, enable insects to fall without injury from heights that would prove fatal to large animals." The legs of insects are named and classed according to the motions for which they appear to be principally adapted. "Thus some are named *cursorii*, from their adaptation for running; these are the most numerous. The *saltatorii* are those that are used for leaping; the thighs of these are remarkably large, by which means they possess considerable strength and power to leap to great distances. The *natatorii* are those that serve as oars for swimming; the feet of these are flat and edged with hairs, possessing a proper surface to strike against the water, as in the *dytiscus*, notonecta, &c. Such feet as have no claws are termed *nutici*. The *chelæ*, or claws, are an enlargement of the extremity of the fore-feet, each of which is furnished with two smaller claws, which act like a thumb and finger, as in the crab. The under part of the feet in some insects is covered with a kind of brush or sponge, by which they are enabled to walk with ease, on the most polished substances, and in situations from which it would seem they must necessarily fall." We give an illustration of this class of objects in plate 34, fig. 24, which exhibits, under a low magnified power, the leg and foot of that voracious aquatic fly, the dytiscus. We have referred principally to the strong claws, or talons, with which it is armed: a more interesting feature in this object is the web that surrounds the foot, this however, from its exceedingly complicate structure, could not have been effectively shown on a small scale.

This cut represents the legs of a bee as developed by a moderate magnifying power.

The *wings and wing cases* (*elytra*) of insects form an exceedingly numerous and a highly interesting class of microscopic objects. "The variety in the form and structure of these insect appendages is almost infinite; the beauty of their colouring, the art with which they are connected to the body, the curious manner in which some are folded up, the finer articulations provided for this purpose, by which they are laid up in their cases when out of use, and yet are ready to be extended in a moment for flight; together with the various ramifications, by which the nourishing juices are circulated, and the wings strengthened, afford a fund of rational investigation highly entertaining; exhibiting, particularly when examined by the microscope, a most wonderful display of divine wisdom and power. The more delicate and transparent wings are covered and protected by *elytra*, or cases, which are generally hard and

opaque. "The wings of moths and butterflies are mostly farinaceous, covered with a fine dust; by the assistance of the microscope, we discover that this dust is a regular assemblage of organized scales. Under the wings of most insects which have only two, there is a small head placed on a stalk, frequently under a little arched scale; these are called *halteres*, or *poisers*; they appear to be rudiments of their hinder wings," or substitutes for them: "it has been supposed that they serve to keep the body in equilibrio when the insect is flying. The elytra, or exterior wing cases, are harder and more opaque than the wings under them; they are generally highly polished, and often enriched with various colours, adorned with ornamental flutings, and studded with brilliants, whose beauties are beyond description. All these ornaments are united in the wing case of the *curculio imperialis*, or diamond beetle, one of the richest and most magnificent creatures in nature. It is said, that in the Brazils, whence they come, it is almost impossible to look at them on a sunny day, when they are flying in little swarms, so great is the glowing splendour of their heightened colours."

Our illustrations of wings will be found in plate 34, figs. 22, 23, and 25. To have given with full effect the remarkable details in these members, they must necessarily have been drawn upon a large scale, and by consequence have limited the variety of our objects. The reader must, therefore, consider these figures as little more than an indication of the wondrous beauty and delicacy observable in these objects when subjected to deep magnifying powers.

Fig. 22. *The wing of a gnat.* This object is remarkable for the delicate *punctæ*, or dots, that cover the entire membrane, and from each of which an exceedingly fine spine, or point, juts out. The fibres of the wing are serrated, or, more properly, armed with thorny projections, similar in character to fig. 9. The outer margin is thickly set with a vast number of small scales, or feathers, much resembling those on the wings of butterflies. The low power under which we have exhibited this object is not sufficient to develope the true character of the minute details.

Fig. 23. *The wing of an ichneumon fly.* This object is shown under the same power as the preceding; and it will be seen that the dots on the membrane, and the spine of each dot, are much less delicate in this wing than in that of the gnat. The upper margin is serrated.

Fig. 25. *The wing of an earwig.* "Though the earwig is so common an insect, yet few people know that it has wings, and fewer yet have seen them; they are of a curious and elegant texture, and wonderful structure. The upper part is crustaceous and opaque, while the other part is beautifully transparent. They fold up into a very small compass, and lie neatly concealed under the elytra, which are not more than a sixth part of the wing in size. The insect shuts up the ribs like a fan; the strong muscles used for this purpose are seen at the upper part of the figure. The ribs are extended from the centre to the outer edge, others are extended only from the edge about half way; but they are all united by a band at a small but equal distance from the edge; the whole evidently contrived to strengthen the wing, and facilitate the various motions thereof; so that in these wings you find all the motions that are in the most elaborate and portable umbrellas, executed with a neatness and elegance surpassing description."

"The wings of butterflies are covered with a fine dust which renders them opaque, and produces those beautiful and variegated colours by which they are so richly adorned, and so profusely decked. If this be wiped off, you find the remaining part, or naked wing, to consist of a number of ribs, like those in the leaves of plants, but of a crustaceous or talcy nature; the largest rib runs along and fortifies the exterior edge of the wing; the interior edge is strengthened by a smaller vessel or rib. The ribs are all hollow, by which means the wing, though comparatively large, is very light. The substance between the ribs, which constitutes the body of the wing, resembles talc, and is surprisingly thin and transparent; as this is extremely tender, one use of the scales may be to protect it from injuries. When the fly emerges from the chrysalis, the wings are soft and thick, and if they be examined in that state, will be found to consist of two membranes that may be raised up and separated, by blowing between them with a small tube: the ribs lie between these membranes. Ever since the microscope was invented, the dust that covers these wings has engaged the attention of microscopic observers; as by this instrument it is found to be a regular collection of organized scales of various shapes, in whose construction there is as much symmetry, as there is beauty in their colours. Their shapes are not only very different in butterflies and moths of various species, but those on the same moth or fly are also found to differ. Of the scales, some are so long and slender that they resemble hairs, except that they are a little flattened and divided at the ends, some are short and broad; some are notched at the edges, others smooth; some are nearly oval, while others are triangular: they are mostly furnished with a short stalk or stem to fix them to the wing." The prodigious number of small scales which cover the wings of papillæ, and their regular arrangement,

covering one another like the tiling of a house, are interesting facts ascertained by microscopic observation.

Many of the improvements recently introduced into the elements of the microscope, are the results of elaborate inquiries respecting the scales on the wings of butterflies, whence the latter have come to be denominated *test* objects, as being peculiarly fitted to test or prove the defining and penetrating power of the best instruments. The information in consequence derived concerning these delicate formations, may be regarded by some as more curious than useful; it is at least *curious*, and we believe few persons will deem it beneath the dignity of science to investigate the minutest atom, since it could be produced only by the same plastic energy that evoked the universe into being. Dr Goring has the merit of being the first to examine into all the details of these objects, which he has developed with much success, though principally with a view to suggest those important improvements in the microscope, which have since been reduced to practice by his talented coadjutor, Mr Pritchard, who by his various writings and optical constructions, has at once stamped himself a philosopher, and if not the first, one of the first practical opticians of the day.

Leeuwenhoeck remarks, when speaking of the scales on the wings of butterflies,—"that if an hundred, or more, of them were to be seen lying together, each would appear of a different shape." Now, though this observation is strictly true, inasmuch as there is the same variety exhibited in the formation of these atoms as in that of the human countenance, still this is not the grand point of admiration: the most wonderful fact connected with them is, that amidst all the variety of individuals, we no more mistake the different species of these scales, than we do the various species of the human race, in consequence of the great variety of features observable in them. Since these objects have been subjected to severe examination, questions have arisen regarding the real nature of their structure, which have perhaps been disputed beyond the point of usefulness. In describing the varieties which are offered in our illustrations, we shall take occasion to remark upon the various opinions that are entertained respecting the striated markings on these scales. It may be necessary to inform the general reader that these minute atoms form that impalpable powder on the wing of a butterfly, which clings to the finger whenever we touch the insect.

We proceed to describe in order figs. 10 to 21 inclusive, in plate 34. The objects are all shown under a superficial magnifying power of 90,000. Fig 10. *Scale of the red under-wing butterfly.*—This is an exceedingly beautiful formation, under a deep power of the microscope. The longitudinal and cross *striæ* (or markings) are easily developed by a good defining power. The cross lines give to the others the appearance of strings of beads. It is asserted that this *apparent* structure in the object under review, and in others of this class, is really the interlocking of the serrated edges of the fibres composing the scale. The opinion is founded on a presumed analogy between these formations and the laminæ in the crystalline lenses of fishes, &c. We are, however, inclined to dispute this opinion, since there is no general resemblance between the structures to justify the argument from analogy in this case; and moreover, a less overstrained analogy may be inferred between different objects of this class, some of which present their details to view, under a powerful magnifier in a manner that dispels all doubt as to their real nature. Of these we shall speak in order; simply observing in this place, that from an attentive examination of various scales, and their probable similarity of structure, we are led to think that, in the formation before us, the longitudinal striæ are fibres, produced on the same principle as the hairs of animals, and consist of a number of minute cups growing out of each other; and that the cross striæ are merely indications of the several insertions. The fibres are connected by a delicate tissue.

Figs. 11, 12, and 13. *Scales of the brassica butterfly.* These are three varieties of scales from the wings of the brassica, or cabbage butterfly. Fig. 11. resembles the object previously described, excepting that there is a marked and decisive difference between the contour of the two scales. Fig. 13. is termed the Brassica *curiosa;* and is no less remarkable for its exterior form, than for the singular disposition of the striæ on its surface. Fig. 13. is a scale from the *pieris brassica*, and we shall connect our remarks upon this object with fig. 17, the scale of the *podura plumbea*, as these two delicate formations are the severest *tests* of microscopic definition and penetration, and the examination of them has led to a lengthened controversy regarding the true character of the lines that cover them. In our illustrations, the delicate longitudinal striæ only are shown; but under a suitable power, and with a due management of the light, these objects exhibit diagonal lines whose real nature, owing to their extreme fineness, can merely be inferred from assumed analogies. The scales of the *lepisma saccharina* offer their details to the eye in a very satisfactory manner, under a linear power of 200 or 300; and we are convinced that they afford the best explanation that can be obtained regarding the podura and brassica. The lepisma distinctly shows a series of

strong longitudinal fibres, from whose sides proceed a number of spines much resembling those in fig. 4. These spines form, we believe, the diagonal lines in other and more delicate scales, such as the podura; for by varying the illumination and moving the object, we can discover in the lepisma all the appearances which perplex the observer when examining the podura and brassica. And, indeed, it is a fair inference that these minute scales have great similarity of structure, and that those most easily developed may justly be taken as an index to others more difficult of examination, when, as in the present case, there is nothing to contradict the analogy. Mr Pritchard seems to hold opinion with us; for he remarks, in his *List of Microscopic Objects*, "In my best engiscopes, under certain illuminations, the markings (of the podura) appear *detached*, like short hairs or *spines* covering the delicate tissue of the scales." The high authority of Sir David Brewster is, however, opposed to our explanation of the phenomena of the *tests;* and we deem it proper to give his theory as a necessary check upon our own.

"After a laborious examination of the lined tests, and the use of every optical resource which he could command, Sir David Brewster has found that the mysterious lines on these test objects are only apparent lines, being composed of a succession of interlocking teeth, by which the fibres to which they are attached form that delicate film that composes the scale of a moth." This is Sir David Brewster's opinion regarding the *longitudinal* striæ; and is the result of his examinations into the structure of the crystalline lenses of fishes. "With regard to the diagonal or oblique lines," it is added, "which have been such a source of perplexity to microscopical observers, we have little hesitation in pronouncing *those which we have seen* to be optical illusions, from the accidental *alignement* of the sides of the teeth in different grooves, when similarly illumined by oblique rays. When the scales are immersed in diluted sulphuric acid, we have never seen the diagonal lines. When the sulphuric acid is too strong, the scales curl up, and often in this state exhibit the lines very beautifully. We have observed diagonal lines singularly developed in the laminæ of the crystalline, and clearly arising from the interference of the rays acted upon by the lines on one side of the laminæ, with the rays acted upon by the lines on the other side, and therefore we have been the more confirmed in our opinion."

Fig. 14. *Scale of the menelaus butterfly.* This object consists of a fine tissue overlaid with strong and well defined lines. The latter are frequently detached from the membrane, as shown in our specimen; and consequently, there can be no illusive misconception regarding these lines, which are evidently fine fibrous cords in relief, upon the surface of the scale.

Fig. 15. This is a very singular scale, observed amongst a miscellaneous group. The longitudinal striæ are strongly defined, and the cross markings arise from a contraction, or shrivelling up, of the membraneous part between each two of the striæ.

Fig. 16. *Scale of the azure blue butterfly.* The light coloured and most diaphanous scales of this species form beautiful test objects for the microscope. The striæ are delicate, but are easily developed by a good doublet.

Fig. 18. *Scale of the lepisma.* The striæ on this object are easily defined, and they have the same character with those on the scale of the menelaus, as is evidenced by the partial detachment of the lines from the membraneous tissue. There is a variety in these scales: the one we have selected, and on which the markings are more delicate, is nearly oval-shaped; but there are others much resembling a shell, and having the upper edge scalloped very regularly. Diagonal markings are perceptible on the latter species, produced by undoubted spiny projections from the longitudinal fibres.

Fig. 19. *Scale of the diamond beetle.* The elytra, or wing case, of the diamond beetle is a splendid opaque object, familiar to every possessor of a microscope. We may compare the appearance it presents to that of the ancient Jewish breast-plate; a number of small cavities regularly disposed over the surface, are filled with a vast number of small scales, which reflect every variety of hue, and exhibit a lustre and magnificence that dims the splendour of the most richly arranged jewellery. Our figure shows one of these minute scales, with its semi-opaque spots and striæ; the latter, it will be noticed, have precisely the same character with figs. 10. and 11.

Fig. 20. *The scale of a moth.* This object is very opaque compared with preceding ones, and it is consequently difficult to trace its structure with much precision. The contour, it will be seen at once, is that of a leaf; and the vegetable analogy would seem to extend much further. This scale appears to consist of a fibrous frame-work, resembling very much the skeleton of a leaf; and the interstices are filled up with a mossy substance, whilst the prismatic reflections and other characteristics of the surface would indicate that smaller scales are scattered over it.

Fig. 21. *Disposition of the scales.* This is a small diagram, intended to convey an idea of the disposition of the scales on the membrane of a butterfly's wing. The double lines of points mark the places where the scales are inserted; and it will be noticed,

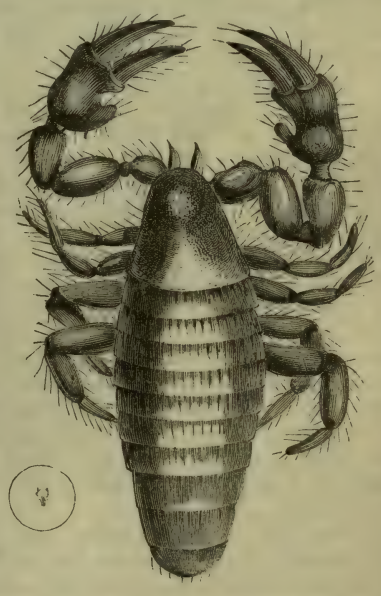
that there are two sets of them, one considerably shorter than the other. The longer scales are inserted in the upper line, overlapping each other, and the shorter, in the line beneath; by which means these extend to the middle of the long scales, and have their extremities covered by the next line.

We shall notice only one other remarkable appendage to some of the insect tribes, namely, the *sting*; the properties and mechanism of which are worthy of consideration. The sting of an insect is a weapon with which nature has armed it for purposes of self-defence; in no instance, we believe, is the sting resorted to unless the insect has an instinctive sense of danger, or has suffered provocation; and, indeed, this may be inferred from the fact, that the creature frequently inflicts fatal injury on itself, when it strikes this weapon into its opponent; for from the barbs on the sides, it is not able readily to disengage the sting, and not unfrequently, by using desperate efforts to obtain release, the insect tears out a portion of its entrails. There are three distinct parts connected with an insect's sting, each worthy of attentive examination; these are, the sheath, the darts with their barbs, and the poison bag. The following description of the sting of a bee, extracted from Adam's Essays on the microscope, will serve as a general exemplification.

"The apparatus consists of two piercers conducted in a sheath, groove, or director. This groove is rather large at the base, but terminates in a point; it is affixed to the last scale of the upper side of the abdomen by thirteen thin scales, six on each side, and one behind the rectum. These scales inclose the rectum all round, and are attached to each other by thin membranes, which allow of a variety of motions; three of them are, however, attached more closely to a round and curved process, which comes from the basis of the groove in which the sting lies, as also to the curved arms of the sting, which spread out externally. The two stings may be said to begin with these two curved processes at their union with the scales, and converging towards the groove at its base, which they enter, and then pass along to its point. The two stings are notched or serrated towards the point; they can be thrust out a little way, and drawn within it. These parts are all moved by very strong muscles, which give motions in almost all directions, but most particularly outwards. It is wonderful how deep they will pierce solid bodies with this sting. To perform this by mere force, two things are necessary—power of muscles and strength of sting; neither of which they seem to possess in a sufficient degree. Mr J. Hunter thinks that it cannot be by simple force, because the least pressure bends the sting in any direction. It is probable that the serrated edges may assist, by cutting their way like a saw. The apparatus for the poison consists of two small ducts, which are the glands that secrete the poison; these lie in the abdomen among the air cells, they soon, however, unite into one oblong bag; at the opposite end of which a duct passes out, which runs towards the angle where the two stings meet, and, entering between them, forms a canal by the union of the two stings at this point. From the serrated construction of the stings, the bee can seldom disengage them, and hence, when they pass into materials of too strong a nature, the bee generally leaves them behind, and often a part of the bowels therewith."

The poison bag is shown in the annexed cut.

We pass on to notice a few insects which are purely microscopical, and require optical aid to render their entire figure sufficiently distinct for observation. And here, it must be obvious, our remarks will necessarily be of a very cursory description, and our illustrative instances few; for this one department of our chapter would furnish, if carried out to its full extent, a large and closely printed volume.



Amongst *microscopical insects*, the monoculus, or water flea, holds a distinguished place. This insect belongs to the crab genus. So numerous is it, in the summer months, that the ponds appear tinged with red or green, owing to the myriads of these minute creatures upon their surface. When full grown, some species of the water flea are about the size of a common flea[1] This insect appears to have but one eye, which, however, is compound, and at the same time movable by muscles in the manner of the human eye. The young, perfectly formed, may sometimes be seen within the parent. Mr Pritchard calls

[1] The *Monoculus Polyphemus* is the largest of all insects, measuring four feet in length; this, however, lies beyond our province, which confines us to the minute.

the attention of the microscopic observer to "the numerous muscles for moving the body, and its elegant branched arms,—the disposition of those for producing a revolution of its compound eye,—the position of those for raising and depressing the respiratory organs, and others for contracting and dilating the pulsatory organ. The curious form of its shell, and the various shapes of the reticulations on different parts of its surface,—the articulations of its arms—the singular construction of its digestive organs—the circulation of its blood, and the delicate fringes appended to its branchiæ, afford ample materials for observation." A very faithful illustration of the *Monoculus quadricornis* will be found in a future page, in connection with the *Vorticella digitalis*, which frequently attaches itself to the body of this insect.

The *Lepisma* forms a genus in that order of the insect class named *aptera;* and includes several varieties or species. The small *book-worm*, as it is popularly called, ranks under this genus: it is one of the most pleasing and interesting microscopic objects known, whether it be viewed in detail or observed entire. No one seems to have examined this little creature with more attention than Hooke, whose description is so popular and curious that we offer it as the best account which can be given of the insect. "It is," says he, "a small, white, silver-shining worm, which I found much conversant among books and papers, and is supposed to be that which corrodes and eats holes through the leaves and covers; it appears to the naked eye a small, glittering, pearl-coloured moth, which upon the removing of books and papers in the summer, is often observed very nimbly to scud, and pack away to some lurking cranny, where it may the better protect itself from any appearing dangers. Its head appears big and blunt, and its body tapers from it towards the tail, smaller and smaller, being shaped almost like a carrot. This the microscopical appearance will more plainly manifest, which exhibits a conical body, divided into fourteen several partitions, being the appearance of so many several shells or shields that cover the whole body; every one of these shells is again covered or tiled over with a multitude of thin transparent scales, which, from the multiplicity of their reflecting surface, make the whole animal appear of a perfect pearl colour. This, by the way, offers a reason for the appearances presented by these scales, as also by mother-of-pearl, and a multitude of other shelly sea-substances; for they each of them consisting of an infinite number of very thin shells or laminated orbiculations, cause such multitudes of reflections, that the composition of them, together with the reflection of others that are so thin as to afford colours, gives a very pleasant reflection of the light. The small blunt head of the book-worm was furnished on either side of it with a cluster of eyes, each of which seemed to contain but a very few, in comparison of what I had observed the clusters of other insects to abound with; each of these clusters was beset with a row of small bristles, much like the *cilia*, or hairs, on the eyelids, and perhaps they served for the same purpose. It had two long horns before, which were straight, and tapering towards the top, curiously ringed or knobbed, and bristled much like the marsh weed, called horse-tail, or cat's-tail, having at each knot a fringed girdle of smaller hairs, and several larger bristles, here and there dispersed among them; besides these, it had two shorter horns or feelers, which were knotted and fringed just as the former, but wanted bristles, and were blunt at the ends; the hinder part of the creature was terminated with three tails, in every particular resembling the two longer horns that grew out of the head: the legs of it were scaled and haired much like the rest." The singular scales of this small insect have already been illustrated and described.

The *lobster insect*, represented in the annexed cut, is figured and described by Adams in

his Essays on the microscope. This insect approximates in form and character to the *phalangium cancroides* of Linnæus; it presents, however, many remarkable points of difference, and forms a microscopic object of great variety and interest. We take Adams' description as the best we can offer,—"This extraordinary little creature was found by my ingenious

friend Mr John Adams, of Edmonton. He was at the new Inn, Waltham Abbey, where it was spied by some labouring men who were drinking their porter. The man who first perceived it, thought it was of an uncommon form; on a more minute inspection it was supposed to be a pediculus with unusually long horns; others thought it was a mite. This produced a debate, which attracted the attention of my friend, who obtained the insect from them for further observation. Mr Martin has given some account of it, in the third volume of the "Young Gentlemen and Lady's Philosophy." Mr Adams favoured me with the insect, that an accurate drawing might be taken from it, which I thought would be highly pleasing not only to the lovers of microscopic observations, but also to the entomologist. It appears to be quite a distinct species from the *phalangium cancroides*, of which a good drawing has been given by Hooke, Rösel, Schæffer, &c. It has also been described by Scopoli, Geoffroy, and other naturalists; not one, however, of these descriptions agrees with the animal under consideration. The abdomen of this is more extended, the claws are larger and much more obtuse; the body of the other being nearly orbicular, the claws slender, and finishing almost in a point, more transparent and of a paler colour. It is very probable that there are several species nearly similar. Mr Marsham has two in his possession, one like the drawings of Reaumur, the other not to be distinguished from that which is represented in the annexed figure, except that it wants the break or dent in the claws, so conspicuous in this. The latter he caught on a flower in Essex, the first week in August, firmly affixed by its claws to the thigh of a large fly, and could not disengage it from thence without considerable difficulty; to accomplish which he was obliged to tear off the fly's leg, and was much surprised to see the bold little creature spring forward full a quarter of an inch, and once more seize its prey, from which it was again with much difficulty disengaged." The insect is shown in the cut considerably magnified; an indication is also given of the natural size.

"According to Aldrovandus, this insect was not unknown to Aristotle, who mentions it as being found in books and papers. Wolphius, on the authority of Gesner, says that a few are to be met with in some parts of Switzerland. Scaliger also notices it, having found two of them in his books. It has been by various systematic writers referred to different genera: De Geer has instituted a new genus for it under the name of *chelifer*; Frabricius has remanded it to that of *scorpio*, to which perhaps it is more nearly allied than any other. Amongst the number of naturalists who have observed and described the insect, it appears rather extraordinary that none have met with one similar to that in the cut, in respect to the break in the claws. In a cabinet of curious microscopic objects which I purchased several years since, and which originally came from Holland, there were four of them in the most perfect condition. A botanical friend, Mr Young, also favoured me with a living one which he found among some plants collected by him in one of his excursions; but as his box contained a variety of plants, and he did not discover the insect till his return, it was imposible to ascertain the particular one on which it was taken. All these resembled the one exhibited, excepting the claws being longer and more slender, and being deficient in the distinguishing characteristic. I have lately seen another, in which the two fangs that are shown highly magnified in plate 85 of the Naturalist's Miscellany, are very apparent, being so large, as to exceed in diameter the thickest parts of the claws. Rösel says, this insect dwells among paper, in old books and their bindings, in chests of drawers, and in the crevices of old buildings. In order to discover whether the insect possessed a sting, he often, by various means, endeavoured to irritate it; but it never showed the smallest inclination to defend itself; on the contrary, it always endeavoured to avoid a contest; if so, it evidently appears that those few met with in this country are of a more bold and warlike disposition. Seba asserts that these insects resemble the large scorpions, the tail excepted, which is small, and usually concealed by being drawn close to the under part of the abdomen; but in this respect he must probably have been mistaken, as it does not appear that this circumstance has been noticed by any other person."

We have now extended this chapter much beyond what was originally intended, yet have found our space insufficient for so particular a detail of the microscopic formations and phenomena of the natural world as we could have wished to give. It will be obvious, that a separate volume alone could embrace a complete survey of the minute in nature: what we have done, however, will present under a systematic form a general outline of the discoveries that have been made by means of the microscope, and may lead the student in natural history to give deep regard to the atomic elements of material bodies; it may also increase his admiration and reverence for the Great Creative Power from whom all things proceed, when he perceives that Deity, unconfined by the relative terms of large and small, can display an equal share of plastic energy in the atom, whose existence the un-

aided eye of man cannot detect, and the most colossal animated structure that walks the globe. An examination into the minute has a manifest tendency to strengthen belief in an universal and particular Providence, and affords a striking comment on the declaration of Holy Writ, that "not a sparrow falleth to the ground without the knowledge of our heavenly Father."

CHAP. II.

INFUSORIAL ANIMALCULES.

The elaborate examinations that have recently been made regarding infusorial animalcules have brought vast accessions to our knowledge of animated nature. Of these atomic germs of vitality, little had been previously discovered beyond the fact of their existence; and indeed, many species, on account of their extreme minuteness, and the vast amplifying power necessary for their developement, had not till very recently been observed at all. It is not however to their mere existence that the microscopist now calls attention, but to all the details of their external form and internal structure; to their habits, modes of action, natural instincts, and to all the economy of their being. The mind is overwhelmed and confounded whilst we read (as Mr Pritchard, in his *Natural History of Animalcules*, has enabled us to do) of the organization and vital properties of a living atom, so inconceivably minute, that five hundred millions of them in a mass, would present little more than a sensible point to the unassisted eye. Such an announcement will be met by much scepticism; and scepticism, in this instance, is indeed pardonable; for with the object before him, the observer can scarcely yield his belief, whilst mathematical truth and actual observation are attesting the fact.

The term *infusorial* is applied to the various species of animalcules discovered in vegetable and animal infusions. They exist naturally in all stagnant waters, wherein vegetable or animal matter is decomposing; and they can be produced artificially by making an infusion of vegetable substances, and suffering it to stand till it has fermented, and become in some degree putrid. The most rational and philosophical way of accounting for the presence of animalcules in infusions, is to adopt the hypothesis that the atmosphere is teeming with minute germs of animal and vegetable life,—that they form part of every thing we taste or touch, but that, for their perfect development, a suitable nidus is necessary, which nidus is presented in an infusion of some kind or other. These animalcular ova, it would appear, depend much for the form they are to assume when evolved, upon the peculiar nidus in which they are deposited; for the same infusion, in different stages of fermentation and putrescence, developes different species of animalcules. Or, perhaps, the ova themselves have distinct characters, and the infusion may become successively adapted for the developement of the various species. Leaving this point as one of mere conjecture, we pass on to observe that optical science has rendered these animalcules legitimate subjects of natural history: and we are consequently to acquaint ourselves, as before observed, not only with their extreme littleness, but with all the peculiarities that constitute their generic and special differences.

Before entering upon a particular description of the various kinds of animalcules found in infusions, we shall lay before the reader Mr Pritchard's lucid and perspicuous summary of their peculiarities.

"The term *animalcule*, which implies nothing more than the diminutive of animal, has been commonly used to denote those living creatures inhabiting fluids, which are too minute to be scanned, or even seen by the naked eye: such, for instance, as those produced in inconceivable numbers from infusions of animal and vegetable matter: it comprehends as well such as are found in, and are peculiar to, the bodies of larger animals: this latter class, however, does not fall within our province.

"In the variety of systems that have been put forth respecting these creatures, the main characteristics of each have referred either to a difference in their size, or to the general appearance of their external forms: the present design, however, is not to investigate the value of these. Until the introduction of vegetable colouring matter into the fluid which supplies them with food—an experiment that has been attended with very successful results—these creatures were commonly supposed to be entirely devoid of internal organization, and to be nourished by the simple process of cuticular absorption. By the application of coloured substances, which, moreover, have been found to invigorate rather than to depress the animalcule, and to maintain it in the full exercise of all its functions, this erroneous notion is set at rest, and an internal structure is discerned in some, equal to, if not surpassing that of the larger invertebrated animals, and comprising a muscular, nervous, and, in all probability, vascular system; all wonderfully contrived for the performance of their respective offices.

"The most obvious portion of their internal structure is undoubtedly that connected

with the digestive functions; and hence it is that Ehrenberg has selected this as the leading feature of his arrangement, denominating his two grand divisions of the Phytozoa,—Polygastrica and Rotatoria; the former of which implies such as are possessed of several distinct stomachs or digestive sacs; and the latter such as have true alimentary canals and rotatory organs provided with a number of cilia aptly disposed for promoting the objects of life: these two grand divisions of the Phytozoa are afterwards subdivided into families and other minor branches. The *cilia*, in their different combinations, supply the means of locomotion, propelling the creature, in many cases, with great rapidity through the water: they are apparently stiff like eye-lashes; and from Dr Ehrenberg's description of some of the larger ones, they issue from bulbous substances at their bases, and being acted upon by muscular fibres, are capable of being moved to and fro in particular directions, so as to occasion a current of the fluid to flow towards the mouth of the animalcule, by which it is furnished with fresh water or food. They are sometimes disposed, as before stated, round certain organs of a circular form, which, on account of their peculiar vibrations, giving the appearance of a rotatory action, are termed rotatory organs. A second curious feature in the construction of some of these minute creatures are the *setæ*, or bristles, attached to the surface of their bodies: these short movable hairs in all probability act as fins, and contribute greatly to their means of motion. The third feature, are the *uncini*, or hooks, setaceous appendages curved at their extremities, and serving the creature to attach itself to any object it chooses. A fourth are the *styli*, jointed at their bases, and differing from the cilia in respect of their being unable to effect a rotatory motion: these, however, are more flexible, and have more play, than the setæ. Independently of these peculiarities, some animalcules possess the extraordinary faculty of thrusting out, or elongating, portions of their bodies at various points, which, assuming the appearance either of legs or fins, are termed *variable processes*, and enable the creature to walk or swim.

"It was a favourite hypothesis, with naturalists, some years ago, that the class of animalcules under consideration was entirely nourished by cutaneous absorption, and that no suitable organs for transmitting and digesting food were discoverable. Baron Gleichen was the first who brought the truth of this theory to the test; for having tinged some water containing animalcules with carmine, he found on the second day that only some distinct cavities, in the interior of their bodies, were filled with the colouring matter, evidently demonstrating the existence of an alimentary structure: here however, he left the subject, and it is to Dr Ehrenberg's further investigation of it that we are indebted for an accurate description of their different forms. In more recent experiments, it has been found advisable to employ vegetable colouring substances in their pure state; such, for instance, as sap-green and indigo, which, together with the valuable accession of an excellent instrument, enabled the doctor to contribute much to our previously imperfect knowledge of this branch of natural history.

"In the selection of vegetable substances for infusions (for procuring animalcules) such as stalks, leaves, flowers, seeds of plants, &c., care must be taken that there be no admixture of quinine (bark) in them, or the intention will be frustrated. Immerse these, whatever they may be, for a few days, in some clean water, when, if the vessels which contain them be not agitated, a thin pellicle, or film, will be discerned on the surface, which, under the microscope, will be seen to be inhabited by several descriptions of animalcules: the first produced are commonly those of the simplest kind, called *monads*. In a few days more, their numbers will increase to such an amazing extent, that it would be utterly impossible to compute those in a single drop of the fluid. After this again, they will begin to diminish in numbers, and I have generally observed them supplanted by others of a larger species and more perfect organization; such as the *cyclidia*, *paramesia*, *kolpodæ*, &c. It is worthy of remark here, however, that in their production they do not pursue any regular order, even in similar infusions. If the vessel be large, and the circumstances under which it is placed sufficiently favourable, a still higher description of animalcules will succeed, viz. the *vorticella*, and lastly the *brachioni*; and thus a single infusion will repay for the little trouble of making it with a great variety of species. Water in which flour has been steeped will be found to abound also with animalcules: and it is remarked by G. Leach, Esq., that the leaden troughs, constantly appropriated for birds to drink out of, contain several descriptions of them, and more especially those of the wheel genus. In ponds, too, especially in the shallow parts, near the edges, and in the immediate vicinity of water plants, prodigious quantities of all kinds may be easily procured; so that possessing as we do such myriads of them all around us, that they impregnate almost everything that we eat, drink, touch, and breathe, an anxiety to know more about them, and the effects they produce, cannot but be regarded as rational and laudable."

"By a careful inspection of the drawings,"

(Mr Pritchard here refers to the elaborate engravings illustrating his *Natural History of Animalcules*), "it will be noticed that some animalcules resemble spheres; others are egg-shaped; others again represent fruits of various kinds—eels, serpents, and many of the invertebrated animals; funnels, tops, cylinders, pitchers, wheels, flasks, &c. &c; all of which are found to possess their own particular habits, and to pursue a course of life best adapted to their peculiar constructions: thus, for instance, whilst some move through the water with the greatest imaginable rapidity, leaping or swimming, others merely creep or glide along; and many are altogether so passive, that it requires long and patient observation to discover any of their movements at all. One description are perceptibly soft, and yield easily to the touch; another are covered with a delicate shell or horn-like coat. Of the latter order there are different degrees of density, as in the volvox, gonium, &c., where the envelope is comparatively thick; and where, strange to say, the internal substance separates by the mode of propagation into several portions, forming so many distinct young ones, which at their birth burst the envelope, and the parent becomes entirely dissipated. In others of this order the shell is merely a plate covering the body, resembling that of the tortoise: sometimes it includes the body, so as to leave only two small apertures at the extremities, and at others it is bivalved, and incloses the creature, like that of the oyster or muscle.

"All vertebrated animals are either oviparous or viviparous, which terms sufficiently designate their modes of production: but it is not so with animalcules; for, in addition to these two methods, 1. Animalcules propagate by a spontaneous scissure, or division of their bodies into two or more portions, each one forming a new creature, which, on its arrival at maturity, pursues the same course. These divisions take place in some genera symmetrically, as in the gonia, &c.; in others by transverse, longitudinal, or diagonal sections. In these latter cases the produce have forms differently proportioned from those of the creatures from which they spring. 2. They propagate, in the manner before mentioned of the volvox, and some other genera, by a distribution of the internal substance of the parent into a proportionate number of young ones, all of which at their birth issue forth, and leave behind them nothing but the envelope, soon to be dissolved. 3. They are produced by germs, shooting forth from the parent's sides. 4. From spawn, which in the act of being shed, carries along with it a portion of the parent animalcule."[1]

We have not space to admit the detail of a variety of additional and highly interesting particulars relative to the infusoria that are recorded by Ehrenberg. We may, however, briefly state that the learned professor has succeeded in developing the mouths and *teeth* of these minute creatures, and has even ascertained the number of the latter, their consistency, and characteristic differences. He has found them to be provided with assistant organs of digestion, respiratory organs, and a perfect vascular and nervous system. Even the eyes of these tiny objects have been made the subject of his examination, and many remarkable particulars concerning them have been ascertained. Regarding their fecundity, it is sufficient to state, on the professor's authority, that a single animalcule will in the course of three or four days become a multitude of separate existences, of whose number the human mind can form no idea.

"Motion," says Adams, "seems to be the great delight of the infusoria; they pervade with equal ease and rapidity, and in all forms and directions, the whole dimensions of the drop, in which they find ample space for their various progressions, sometimes darting straight forward, at other times moving obliquely, then again circularly: they know how to avoid with dexterity any obstacles that might obstruct their progress. Hundreds may be seen in a drop of water in constant action, yet never striking against each other. If at any time the clusters prove so thick as to impede any of their motions, they roll and tumble themselves overhead, creeping under the whole range, force their way through the midst, or wheel round the cluster with surprising swiftness; sometimes they will suddenly change the direction in which they are moving, and take one diametrically opposite thereto. By inclining the glass in which the drop of water is laid, it may be made to move in any direction; the animalcules in the drop will swim as easily against the stream as with it. If the water begin to evaporate, and the drop to grow smaller, they flock impetuously towards the remaining part of the fluid; an anxious desire of attaining this momentary respite of life is very visible, as well as an uncommon agitation of the organs by which they imbibe the water. These motions grow more languid as the water fails, till at last they entirely cease.

"Animalcules and insects will support a great degree of cold, but both one and the other perish when it is carried beyond a certain point. The same degree of heat that destroys the existence of insects, is fatal to animalcules; as there are animalcules produced in water at the freezing point, so there are insects which live in snow."

[1] Natural History of Animalcules, Book I. p. 12—20.

We proceed to give Müller's scientific arrangement of the infusoria, connecting with each genus the individual selected for illustration of special character.

I. Those wanting external organs.

1. *Monas:* punctiforme. A mere point. Drop Monad. Pl. 35, fig. 65.—2. *Proteus:* mutabile. Mutable, or changeable. Melting Proteus, f. 66.—3. *Volvox:* sphœricum. Spherical. Vegetable Volvox, f. 67.—4. *Enchelis:* cylindraceum. Cylindrical. Egg-shaped Enchelis, f. 61.—5. *Vibrio:* elongatum. Long. Stick Vibrio, f. 68.

Membranaceous.

6. *Cyclidium:* ovale. Oval. Azure Cyclidium, f. 62—7. *Paramœcium:* oblongum. Oblong. Paramœcium chrysalis, f. 63.—8. *Kolpoda:* sinuatum. Crooked or bent. Cuckoo Kolpoda, f. 64.—9. *Gonium:* angulatum. With angles. Breast-plate Gonium, f. 69.—10. *Bursaria:* hollow like a purse. Little Swallow-like Bursaria, f. 60.

II. Those that have external organs.

Naked, or not inclosed in a shell.

11. *Cercaria:* caudatum. With a tail. Green Cercaria, f. 59.—12. *Leucophra:* ciliatum undique. Every part ciliated. Bracelet Leucophrys, f. 54.—13. *Trichoda:* crinitum. Hairy. Trichoda vulgaris, f. 55.—14. *Kerona:* corniculatum. With horns. Kerona pullaster, f. 56.—15. *Himantopus:* cirratum. Cirrated, or curled. Himantopus larva, f. 58.—16. *Vorticella:* ciliatum apice. The apex ciliated. Vorticella cyathini, f. 57.

Covered with a shell.

17. *Brachionus:* ciliatum apice. The apex ciliated. Brachionus passus, f. 53.

I. Monads. An invisible,[1] simple, pellucid, punctiform worm.

Among the various animalcules which are discovered by the microscope, these are the most minute, and the most simple. The *monad* is a small jelly-like point, eluding the powers of the compound microscope, and even of the single one until the recent improvements in lenses had added large additional power. "This genus includes the smallest forms in which a voluntary motion has been observed, even under the most powerful microscopes: this motion, till lately, appeared to be the only property of life with which they were endowed; but the observations of Dr Ehrenberg demonstrate an organization equally perfect with animated beings of much larger dimensions. Their forms in general are simple, spherical, or cylindrical masses, devoid of external members, or processes; the mouth, which is with difficulty discerned, is a simple orifice, not furnished with ciliæ, or hairs, (except in one or two species): they are colourless, and transparent as the clearest crystal, yet can no internal organization be seen, excepting that connected with their digestive function, which consists of two or more globular cavities, or sacs, probably communicating with each other by a tubular membrane, as in the larger polygastric animalcules, but which in this genus is too minute to be discerned; indeed, the stomachs or sacs themselves are only to be observed when the animalcule is fed with particles of colouring matter: the food on which they usually exist being as pellucid as themselves, the cavities are invisible. They increase by a spontaneous division of the parent into two or more parts, and those parts, or young, again divide when they have attained their full age. As subjects of observation, the *monads* are principally interesting from their minuteness, being as they are the very limit of man's acquaintance with animated nature. Their diameters vary from 1-24000th of an inch to 1-1200th, and consequently require a very high magnifying power to discern. They are numerous, and generally found congregating at the surface and around the decomposed matter of infusions, either of vegetable or animal substances."

To enter into particular description of the various species included under the monad genus, would require more space than we can devote to the subject: and, indeed, of all the genera, we shall content ourselves with giving one, or at most two or three, special illustrations, adding a list only of the remaining species, with their distinguishing characteristics appended to each.

Plate 35, fig. 65. *The Drop Monad.*—"This animalcule is larger than the *atom* monad, and somewhat globular. On account of its size and transparency, its digestive cavities can be much more distinctly observed. It revolves about its longer axis, and in swimming, that part which contains the coloured particles follows the colourless part. Occasionally, with attentive observation, currents in the water may be seen about the fore part or mouth; it is therefore highly probable that it is furnished with ciliæ or hairs. Those found at Petersburgh measured from 1-3000th to 1-2300th of an inch in diameter: they are represented in the group magnified 380 times."[2]

Monad species.

1. *Monas termo.* A mere point.—2. *Monas atomus, et lens.* Two species, the first appearing a simple white point, and the second presenting a shining talc-like appearance.—3. *Monas punctum.* Mere dark points, assuming under a deep power the form of short cylinders, and sometimes exhibiting a slender filament or tail.—4. *Monas guttula.* The Drop Monad. Described.—5. *Monas mica.* A lucid point, assuming sometimes a spherical, at others an oval form.—6. *Monas tranquilla.* Egg-shaped.—7. *Monas lamellula.* Of a white colour, mostly found in salt water.—8. *Monas pulvisculus.* Transparent, with a green margin.—9. *Monas uva.* In clusters like grapes.—10. *Monas crepusculum.*—11. *Monas*

[1] By invisible, is here meant indiscernible by the naked eye.

[2] Mr Pritchard, to whom we are indebted for much of our information in this department, expresses the magnifying power in linear measure, i. e. by the magnified diameter.

enchelis. Flask-shaped.—12. *Monas erubescens.*—13. *Monas hyalina.*—14. *Monas kolpoda.*—15. *Monas Ovalis.*—16. *Monas polytoma.*—17. *Monas umbra.*—18. *Monas volvox.* Revolving monad.

II. Proteus. An invisible, very simple pellucid worm, of a variable form.

"We now arrive at a larger class of animalcules, whose habits are highly interesting and curious: indeed there are few in the examination of which I have been more delighted. This gratification arises not so much from any complexity in their organization, which in comparison with the Brachionus, and some of the Vorticella, is more simple, but from the great power they possess of dilating their bodies; and their motions being slow, the observer is enabled to examine their changes of form distinctly."

Fig. 66. *The melting Proteus.*—"The drawing of this animalcule was taken from a specimen found in some water containing duck-weed (*lemna major*), in the month of March. Müller states he only saw them twice. Their diameters vary from 1-600th to 1-300th of an inch."

Proteus species.

1. *Proteus diffluens.* Branching itself out in a variety of directions.—2. *Proteus Tenax.* A globular mass, extending a process terminating in a fine point.

III. Volvox. An invisible, very simple, pellucid, spherical worm.

"The animalcules belonging to this genus are of a globular form, and revolve in the water. Some of the species are so large as to be discerned by unassisted vision, while others are very diminutive. Ehrenberg has not demonstrated their digestive organization; but in a note to his table, conceives they ought to follow the monads. In this genus is included that beautiful animalcule, called the *volvox globator*, which forms so interesting a spectacle in the solar and gas microscopes."

Fig. 67. *The vegetable Volvox.*—"This animalcule is rather scarce. Its most interesting character is the short time which it requires in arriving at maturity, and undergoing all its changes. In the space of half an hour, when fed with an infusion of indigo, a single globule may be observed to emerge from a naked branch, increase in size, and divide into a cluster of smaller ones; these increase also, and after revolving, and bringing a current of food towards them, finally separate, and swim away, each of the young ones commencing a similar course. It consists of several opaque branches: at the termination of each is a small congeries of egg-shaped transparent bodies. Müller, who seems only to have seen them once, mistook them for a vegetable production, until he observed the clusters to separate from the branch, and swim about at pleasure."

"These animalcules produce a rapid current of water towards them, as indicated by the arrow in the figure; and if supplied with plenty of coloured food, as indigo, they will not only assume the colour of the particles, but may be seen to increase in size, under the eye of the observer. When the cluster is fully developed, it breaks, off, and swims away, revolving as it proceeds.—After roving about for a few minutes in search of a proper nidus to attach itself to, it spins a very delicate thread, like a spider's web, one end of which it fixes to the substance it has selected; this filament, when drawn out to the proper length, increases in size, and assumes the deep blue colour of the indigo, while the end of the stalk which it left shoots forth a new cluster. The current above mentioned is sometimes produced without any revolution of the cluster of globules; at other times I have observed the whole cluster to revolve. The magnifying power which I employed, while making the drawing of this figure, was nearly 500 times. The medium diameter of the clusters, while attached to their branches, I find to be about the 800th part of an inch; and when fully developed and separate, about 1-400th of an inch. Müller discovered these animalcules in river water in the month of November. Those on which the above observations were made I found in the month of June, in some pond-water."

Plate 27, fig. 35. *Volvox globator.*—Spherical membranaceous volvox.

This is a transparent globule, of a greenish colour; the fœtus is composed of smaller greenish globules. It becomes whiter and brighter with age, moves slowly round its axis, and may be perceived by the naked eye. But to the microscope the superficies of this pellucid membrane appears covered with molecules, as if it were granulated, which has occasioned some observers to imagine it to be hairy; the round pellucid molecules that are fixed in the centre are generally larger in those that are young. The exterior molecules may be wiped off, leaving the membrane naked; when the young ones are of a proper size, the membrane opens, and they pass through the fissure; after this the parent is dissipated. They sometimes change their spherical figure, the superficies being flattened in different places. Most authors speak of finding eight lesser globules within the larger; but Müller says, that he has counted thirty or forty of different sizes. This wonderful capsulate situation of its progeny is well known; indeed, it often exhibits a second and third generation within it. Leeuwenhoeck was the first who noticed this curious animal-

cule, and depicted it ; a circumstance which has not been mentioned by Baker, and other microscopic writers, who have described it. It may be found in great plenty in stagnant waters in spring and summer, and in infusions of hemp seed and tremella. Baker describes it as follows :—This singular minute water animal, seen before the microscope, appears to be exactly globular, without either head, tail, or fins. It moves in all directions, forward or backward, up or down, rolling over and over, like a bowl, spinning horizontally like a top, or gliding along smoothly without turning itself at all. Sometimes its motions are very slow, and at other times very swift ; and when it pleases, it can turn round as upon an axis very nimbly, without moving out of its place. The body is transparent except where the circular spots are placed, which are its young. The surface of the body in some is, as it were, dotted all over with little points, and in others, as if granulated like shagreen. Baker thought also that in general it appeared as if it were set round with short movable hairs. By other writers, they are thus described : These animalcules are at first very small, but grow so large as to be discerned with the naked eye ; they are of a yellowish green colour, globular figure, and in substance membranaceous and transparent. In the midst of this substance several small globes may be perceived ; each of these is a smaller animalcule, which has also its diaphanous membrane, and contains within itself still smaller generations, which may be distinguished by the assistance of very powerful glasses. The larger globules may be seen to escape from the parent, and then increase in size, as has been already observed.

Volvox Species.

1. *Volvox punctum.* Spherical, of a black colour, with a lucid point.—2. *Volvox granulum.* Spherical and green, the circumference of a bright colour.—3. *Volvox globulus.* Globular volvox, the hind part somewhat obscure.—4. *Volvox pilula.* Small round volvox, with immovable green intestines.—5. *Volvox grandinella.* Spherical and opaque, with immovable intestines.—6. *Volvox socialis.* Spherical volvox, with crystalline molecules, placed at equal distances from each other.—7. *Volvox sphæricula.* Spherical volvox, with round molecules.—8. *Volvox lunula.* An hemispherical volvox, with lunular molecules.—9. *Volvox globator.* Described.—10. *Volvox morum.* Membranaceous, orbicular, with Spherical green molecules in the centre.—11. *Volvox uva.* Globular volvox, composed of green spherical globules, which are not inclosed in a common membrane.—12. *Volvox vegetans.* Vegetable volvox. Described.

IV. Enchelis. An invisible, simple, cylindric worm.

" This genus of animalcules, according to Müller, contains twenty-seven species. The size of the different species varies considerably, and therefore requires different magnifying powers to develope them (from 200 to 500 linear.) If the reader have an opportunity of examining any of them, in instruments of different constructions, but of the *same* magnifying power, he will readily perceive there is something beyond mere amplification that is essentially requisite in a microscope, in order to show the details of objects."

Plate 35, fig. 61. *The Egg-shaped Enchelis.*—" This animalcule is distinguished by its pellucid appearance and the longitudinal folds of the external membrane. A few bright spots are also sometimes observed ; these have been supposed to be the ova, but it is more probable they are the sacs of the polygastric structure. The figure is a magnified representation, showing the sacs and folds, neither of which are constant. Found in stagnant water."

Plate 27, fig. 30. *Enchelis punctifera.*—Green enchelis, subcylindric, the fore-part obtuse, the hinder part pointed. This is an opaque animalcule, of a green colour. The hinder part is pellucid and pointed ; an incision is discovered at the apex of the fore-part, which seems to be the mouth. It is found in marshes.

Plate 27, fig. 45. *Enchelis retrograda.*—Transparent enchelis, the fore-part rather smaller, and terminating in a small globule. It has a gelatinous, diaphanous body ; no visible intestines, though a pellucid globule is discoverable near the hinder part ; the body is thickest in the middle, and grows smaller towards each end. It generally moves sideways, sometimes in a retrograde manner ; and if it be obstructed in its motion, draws itself up, as represented in the figure.

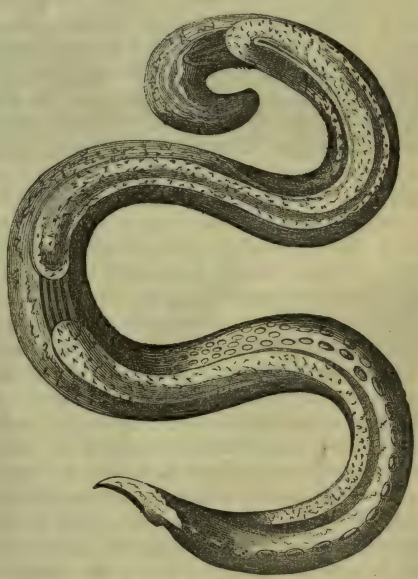
Enchelis Species.

1. *Enchelis viridis.* Green enchelis, of a subcylindric figure, the fore part truncated.—2. *Enchelis punctifera.* Described.—3. *Enchelis deses.* Green, cylindrical, gelatinous, the end somewhat pointed.—4. *Enchelis similis.* Egg-shaped, with opaque movable intestines.—5. *Enchelis serotina.* Partly oval, partly cylindrical, the interior parts immovable.—6. *Enchelis nebulosa.* Oval and cylindrical, with visible movable intestines.—7. *Enchelis seminulum.* Equally cylindric.—8. *Enchelis intermedia.* Cylindrical, transparent, with a blackish margin.—9. *Enchelis ovulum.* Egg-shaped. Described.—10. *Enchelis pirum.* Pear-shaped, the hinder part transparent.—11. *Enchelis tremula.* Oval, cylindrical, gelatinous.—12. *Enchelis constricta.* Sub-oval, crystalline, with a stricture in the middle.—13. *Enchelis pulvisculus.* Elliptic, with a congeries of green intestines.—14. *Enchelis fusus.* Cylindrical, both ends truncated.—15. *Enchelis fritillus.* Cylindric, the fore-part truncated.—16. *Enchelis caudata.* Body long, fore-part obtuse, hinder part diminishing into a kind of tail.—17. *Enchelis epistomium.* Long and cylindric, the fore-part slender and roundish.—18. *Enchelis gemmata.* Body cylindrical, upper part prolonged into a transparent neck, a double series of globules running down the body.—19. *Enchelis retrograda.* Described.—20. *Enchelis festinans.* Oblong, cylindrical, the ends obtuse, the fore-part transparent.—21. *Enchelis furcimen.* Cylindric, crooked and truncated at both ends.—22. *Enchelis index.* Like an inverted cone, one edge of the apex produced and forming an angle with the other part.—23. *Enchelis truncus.* Cylindrical, with a kind of head.—24. *Enchelis Larva.* Long, with two small nipples projecting from the middle of the body, one on each side.—25. *Enchelis spatula.* Striated, the fore-part transparent and of the shape of a spatula.—26. *Enchelis pu-*

pula. Cylindric, the fore-part papillary.—27. *Enchelis pupa.* Kind of ventricose cylinder, with a small nipple proceeding from the apex.

V. Vibrio. An invisible worm, very simple, round, and rather long.

"The extensive range of this genus, in regard to the structure, form, and size of the different species, offers great variety to the observer. It includes animalcules both membraneous and crustaceous: some as slight as a thread, others whose breadth nearly equals their length; some whose organization is so complete that modern naturalists have entirely excluded them from the phytozoa; and others, which are with difficulty distinguished from vegetables. To diminish somewhat the incongruities, without rendering the arrangement complex, I have separated them into three divisions. The first is the simplest, and requires a magnifying power of from 200 to 500 times to examine them; the second and third vary so much in size that some do not require half that power, and a few even less, being just discernible by the naked eye."



First Division,—*Bacillaria.* "These minute and inactive animalcules are covered with a hard, shell-like coat, and appear closely allied to some of the fresh-water algæ, and are not very appropriately classed with the vibrio.

Second Division,—*Phytozoa.* "This term was first made use of by Goldfuss, and is confined by Ehrenberg to those microscopic creatures whose digestive organs are polygastric, or if they possess a simple alimentary canal, it is always accompanied by rotatory organs."

Third Division,—*Entozoa.* Includes those animalcules of the vibrio genus which "possess an alimentary canal, but no cilia, nor occasion currents when immersed in a mechanical solution of coloured particles."

Plate 35, fig. 68, and Plate 27, fig. 30. *Paxillifer Vibrio.*—"This animalcule, or rather congeries of animalcules, for they are mostly attached together in different forms, when magnified appear like pieces of straw, of a pale yellow colour, with the inside of an orange brown. They are nearly round, and if attentively watched, may be seen occasionally to turn upon their longest axis, when a longitudinal line may be observed; this is probably the hinge or opening of their shell. They vary in length from 1-100th to 1-500th of an inch, their diameter is from 1-20th to 1-100th of their length: they require considerable magnifying power, and large angular aperture, to distinguish their structure. I find on reference to my notes, made at different times, that it was not until after I had examined them repeatedly I became satisfied of their animal vitality. They generally reside at the bottom of ponds, but after rain are met with near the surface, giving the water a green tint; in such cases they are found separate, the agitation of the water having broken the clusters." These animalcules are generally found collected together in different parcels, from seven to forty in number, and ranged in a variety of forms, sometimes in a straight line, then in the concave, as in fig. 30. This creature, usually known as the *stick vibrio*, seems to have affinity to the hair-like animal described by Baker.

Plate 27, fig. 44. *Vibrio Lunula.*—The bow, or moon-shaped, vibrio, having both ends similar. The body resembles much the shape of the moon at the first quarter; it is of a green colour, and has generally from seven to ten globules disposed lengthwise; the smaller ones are of a very pale colour, a pale green vacuity may sometimes be seen in the middle: some few varieties may be observed amongst them, which are not easily described; it will be enough to have given the reader their general and distinguishing characteristics.

The annexed cut represents a kind of vibrio found in wheat. These animalcules were discovered by Needham, and described by him in a work entitled New Microscopical Discoveries, and afterwards more fully treated upon by Baker. They are not lodged in those blighted grains which are covered externally with a soot-like dust, whose inside is often little more than a black powder; but abundance of ears may be observed in fields of corn, which have grains that appear blackish, as if scorched: these, when opened, are found to contain a soft white substance, that when attentively examined looks like a congeries of threads, or fibres, lying as close as possible to

each other in a parallel direction, and much resembling the unripe down of some thistles. This fibrous matter does not discover any signs of life, or motion, unless water be applied to it; the fibres then separate, and prove themselves to be living creatures. These vibrios are in general of a large size, and may be seen with a low magnifying power, being about 1-13th of an inch in length, and 1-140th broad. They are in general of a bright chestnut colour; the lower extremity is whiter and more transparent than the rest of the body. The upper end is rather round, the lower one is pointed. A distinguishing mark of these little creatures is a row of transparent globules, which are placed at intervals through the whole length of the body. These creatures increase in size, till at last they may be observed with great ease by the naked eye, being two-tenths of an inch long, and about one hundredth in diameter. The figure represents one of these magnified about seventy times linear. The ovary may be clearly traced almost from the lower extremity to the middle of the body, where the latter becomes so opaque as to prevent its being seen any farther. The eggs, when arrived at their full growth, are nearly of a cylindric shape, both ends rounded; towards the lower extremity there is an opening through which the eggs are extruded. The eggs are formed of a fine transparent membrane; it covers the young vibrio, which is folded curiously therein; these eggs may be frequently found in the grains of wheat containing the animalcules.

One of the most remarkable circumstances in these animalcules is the faculty they have of receiving again the powers of life, after having lost them for a considerable time; for instance, when some of the blighted grains of wheat, that have been preserved for many years, have been soaked in water for ten or twelve hours, living vibrios have been found in it; if the water evaporate, or begin to fail, they cease to move, but on a fresh application, will be again revived. It may be proper to notice here, that according to the observations of Roffredi, those eels which have done laying eggs are incapable of being resuscitated upon being moistened; the same seems to be the case with those that are very young; it is probable the animalcule must attain a certain age and degree of strength before it is endowed with this wonderful faculty.

VIBRIO SPECIES.

1. *Vibrio lineola.* Very small, linear vibrio.—2. *Vibrio rugula.* Like a bent line.—3. *Vibrio bacillus.* Linear, equally truncated at both ends.—4. *Vibrio undula.* Filiform, flexuous vibrio.—5. *Vibrio serpens.* Filiform, the windings obtuse.—6. *Vibrio spirillum.* Filiform, spiral.—7. *Vibrio vermiculus.* Twisted and gelatinous.—8. *Vibrio intestinum.* Gelatinous, round, the fore-part small.—9. *Vibrio bipunctatus.* Linear, both ends truncated, two small globules in the middle of the body.—10. *Vibrio tripunctatus.* Linear, smaller at the ends, with three globular points, the two which are at the extremities being smaller than the one at the middle.—11. *Vibrio paxillifer.* Described.—12. *Vibrio lunula.* Described.—13. *Vibrio verminus.* Linear, compressed, the fore-part narrower than the hinder part.—14. *Vibrio mallæus.* Linear, with a globule at the base, and transverse line at the apex.—15. *Vibrio acus.* Linear, with a neck, the upper extremity obtuse, the lower one terminating in a setaceous tail.—16. *Vibrio sagitta.* Linear, well-marked neck, apex truncated and open, tail setaceous.—17. *Vibrio gordius.* Of equal size, tail terminating in a little tubercle.—18. *Vibrio serpentulus.* Pointed at both ends.—19. *Vibrio coluber.* Filiform, tail setaceous, and bending up nearly to a right angle with the body.—20. *Vibrio anguillula.* Equal size throughout, and somewhat hard, various kinds, of which the wheat vibrio, described, is one, and the eels of vinegar another.—21. *Vibrio linter.* Ventricose oval vibrio, with a short neck.—22. *Vibrio utriculus.* Round, fore-part narrow and truncated, lower part ventricose.—23. *Vibrio fasciola.* Fore part small, middle larger, hind-part acute.—24. *Vibrio colymbus.* Thick, sharpened at the end, the neck a little bent.—25. *Vibrio strictus.* Lengthened out almost to a line, small towards the fore-part, apex obtuse.—26. *Vibrio anas.* Oblong, ends attenuated, neck longer than the tail.—27. *Vibrio cygnus.* Corpulent, with a crooked neck.—28. *Vibrio anser.* Elliptical, with a long neck, and a small lump on its back.—29. *Vibrio Olor.* Elliptical, with a very long neck, and a knob on the apex.—30. *Vibrio falx.* Gibbous, hind-part obtuse, neck crooked.—31. *Vibrio intermedius.* Membranaceous, fore-part small, hinder part somewhat acute.

VI. CYCLIDIUM. A simple, invisible, flat, pellucid, orbicular or oval worm.

"This genus is composed of animalcules of a flat, round or oval form, without any apparent cilia. Like some others, they are so very diaphanous that the most delicately finished engravings of them afford but a faint idea of their exquisitely brilliant, crystal-like appearance, when viewed under a good achromatic microscope of large angular aperture."

Plate 35, fig. 62. *The azure Cyclidium.*—"Is of a flat, oval form. In its usual condition it is pellucid, but when fed with colouring matter, dark spots may be seen as in the engraving, in swimming it sometimes rotates, and exhibits its narrow side to view; if the water be filled with opaque particles, a current may be perceived towards the front part of it, indicating the presence of cilia, which however can only be seen when the animal is expiring. These creatures propagate by division, during the progress of which they alter their form. They require a magnifying power from 600 to 800 times in order to view them distinctly. Length 1-1400th to 1-1800th of an inch."

CYCLIDIUM SPECIES.

1. *Cyclidium bulla.* Orbicular, bright.—2. *Cyclidium milium.* Elliptical, and crystalline.—3. *Cyclidium fluitans.* Oval, crystalline.—4. *Cyclidium glaucoma.* Oval, intestines faintly seen. Described.—5. *Cyclidium nigricans.* Oblong, with black margin.—6. *Cyclidium rostratium.* Oval, fore-part pointed.—7. *Cyclidium nucleus.* Oval, hind-part pointed.—8. *Cyclidium hyalinum.* Oval, hind-part acute.—9. *Cyclidium pediculus.* Oval, convex, the bottom even.—10. *Cyclidium dubium.* Oval, upper part convex, under part concave.

VII. Paramæcium. An invisible, simple, membranaceous, flat, and pellucid worm.

The animalcules included in this genus, together with the kolpoda, are supposed by Ehrenberg to be the same as the monads and cyclidia, at a more advanced stage of their growth.

Plate 35, fig. 63. *Paramœcium chrysalis.*—"These interesting creatures appear like milk-white specks to the naked eye. They are soft, and yield to the presence of any hard substance they may come in contact with. The body is long, and in some positions the cuticle appears to have a diagonal fold, as shown in the figure. The mouth aperture is situated on the inferior side, near the middle, and in some views it appears like a papillary projection. In good microscopes, the body is seen covered with longitudinal rows of hair; by means of these, the creature is enabled to produce a current in the water towards its mouth. They propagate by transverse division. These animalcules are well adapted for showing the structure of the alimentary organs, as they are of sufficient magnitude to render the sacs clearly distinguishable, when filled with coloured particles. On the introduction of indigo into the water they are greatly agitated; in a few minutes, however, they are quiet; and the digestive sacs become coloured, as in the figure, when from 100 to 200 may be enumerated. Length, 1-85th to 1-200th of an inch."

Paramæcium Species.

1. *Paramœcium aurelia.* Compressed, oblong, folded towards the fore-part, hinder part acute.—2. *Paramœcium chrysalis.* Cylindrical, folded towards the fore-part, hinder part obtuse. Described.—3. *Paramœcium versutum.* Cylindrical, lower part thick, both ends very obtuse.—4. *Paramœcium oviferum.* Depressed, with large oval molecules withinside.—5. *Paramœcium marginatum.* Depressed, gray, with a double margin.

VIII. Kolpoda. An invisible, very simple, pellucid, flat and crooked worm. "They vary much in external form."

Plate 35, fig. 64. *The cuckoo Kolpoda*, or *Common Bosom animalcule.*—"Its general contour has some resemblance to a bean; and if we suppose the two convex lobes on the front side equal, and do not perceive the proboscis, which indeed is seen with difficulty, we shall distinguish some likeness to the bosom; from which similitude it has received its name. The mouth, which is more lightly tinted than the surrounding parts, is situated in the hollow between the upper lobe and the proboscis, and marked by a cross, while the termination of the alimentary canal is in the cavity immediately below the proboscis. The margin of the two lobes is furnished with a row of delicate cilia, only observable under favourable illumination. These cilia, by producing a current in the water towards the mouth, perform the same important offices as members in some of the mammalia; as the current brings all the particles of matter in the water to the mouth in regular succession. By feeding these animalcules on vegetable colouring, the polygastric form of their digestive organs is readily distinguished. Length of full grown specimens, 1-280th of an inch. They are found in various vegetable infusions, and especially in those of hay which have been kept a considerable time."

Kolpoda Species.

1. *Kolpoda lamella.*—Elongated, membranaceous, hinder part curved.—2. *Kolpoda gallinula.* Oblong, back towards the fore-part bright and membranaceous.—3. *Kolpoda rostrum.* Oblong, the fore part hooked.—4. *Kolpoda ochrea.* Long, membranaceous, apex attenuated, base bent in a right angle to the body.—5. *Kolpoda mucronata.* Membranaceous, dilated, fore-part smaller than hind-part, with a small incision at one side.—6. *Kolpoda triquetra.* Egg-shaped, one edge turned back.—7. *Kolpoda striata.* Oblong, pear-shaped, white, fore-part pointed, hind-part round.—8. *Kolpoda nucleus.* Egg-shaped, with an acute vertex.—9. *Kolpoda meleagris.* Changeable, the fore-part like a hook, the hind-part folded up.—10. *Kolpoda assimilis.* Depressed, apex in the form of a small hook.—11. *Kolpoda cucullus.* Described.—12. *Kolpoda cucullulus.* Oblong, with an oblique incision a little below the apex.—13. *Kolpoda cucullio.* Flat, oval, bending slightly beneath the apex.—14. *Kolpoda reu.* Thick and curved in the middle.—15. *Kolpoda pirum.* Convex, oval, apex formed into a kind of beak.—16. *Kolpoda cuneus.* Clavated, round, the apex dentated.

IX. Gonium. An invisible, simple, smooth, angular worm.

"The animalcules of this genus are in clusters; they are propagated by several incisions across the body of the parent, dividing it into a number of symmetrical forms. When observed singly, most of the species resemble the volvox. The structure of their digestive organs is not known."

Plate 35, fig. 69. *The Breast-plate Gonium.*—"It consists of sixteen spherical bodies, disposed regularly in a quadrangular form, like the jewels in the breast-plate of the Jewish high-priest. They are all arranged in the same plane; the four centre ones are generally longer than those which surround them; and the diameters of the three smaller balls are only equal to the two larger centre ones to which they are attached; the external corners are therefore vacant. The diameters of the clusters vary from 1-3500th to 1-200th of an inch. They are found near the surface of clear water, and often along with the cercaria viridis. A magnifying power of 200 is sufficient for their examination."

Gonium Species.

1. *Gonium pectorale.* Quadrangular, pellucid, with sixteen spherical molecules. Described.—2. *Gonium pulvinatum.* Quadrangurlar, opaque, with four little pillows.—3. *Gonium Corrugatum.* Quadrangular, white, sunk a little in the middle.—4. *Gonium rectangulum,* Rectangular, hind-part arched.—5. *Gonium truncatum.* Gonium with obtuse corners, hind-part arched.

X. Bursaria. A very simple, hollow, membranaceous worm.

This animalcule takes its name from the resemblance its bears to a purse, or bag. Ehrenberg has noticed only one species, and has not decided as to the situation of the genus.

Plate 35, fig. 60. *The little swallow-like Bursaria.*—"The form of this animalcule, by a little effort of imagination, may be compared to a bird, and its movements appear like the flight of the swallow: hence its name. It is found in stagnant water."

Bursaria Species.

1. *Bursaria truncatella.* Ventricose, the top truncated.—2. *Bursaria bullina.* Boat-shaped, the fore-part formed into a lip.—3. *Bursaria hirundinella.* Described. 4.—*Bursaria duplella.* Elliptic, with the edge bent in and out.—5. *Bursaria globina.* Spherical, very pellucid in the middle.

XI. Cercaria. An invisible, pellucid worm, with a tail.

"If we consider the internal organization of this genus, it comprehends a very wide range; indeed, the different species vary so much that it is difficult to give a general definition of their characters with any degree of accuracy."

Plate 35, fig. 59. *The Green Cercaria.*—"This is a highly interesting creature: the bright green colour of its body; its diaphanous extremities; its well defined orange brown eye; and the numerous transformations of its form, render it a very interesting object for the microscope; in addition to which it is easily procured, and managed with great facility. The length of the specimen was about 1-350th of an inch: Ehrenberg gives 1-280th of an inch as their length. The magnifying power best adapted for viewing them, is from 300 to 500 times, in an achromatic."

Plate 27, fig. 29. *Cercaria inquieta.*—This animalcule so frequently changes its form, that it is not easy to describe it; it is sometimes spherical, sometimes like a long cylinder, at other times of an oval figure, white and gelatinous; the tail is filiform and flexible, the upper part vibrating vehemently; it has no visible viscera. Two small dots, probably the eyes, are sometimes distinguishable; and occasionally there is seen a large circular marking near the tail.

Cercaria Species.

1. *Cercaria gyrinus.* Round, with a sharp tail.—2. *Cercaria gibba.* Oval-shaped, convex, the fore-part rather acute, the tail round. 3. *Cercaria inquieta.* Described.—4. *Cercaria lemna.* Mutable, somewhat flattened, with an annulated tail.—5. *Cercaria turbo.* Globular, the middle contracted, with a tail like a bristle.—6. *Cercaria poduria.* Cylindric, the hind-part sharp and somewhat cloven.—7. *Cercaria viridis.* Described.—8. *Cercaria setifera.* Cylindric, fore-part smallest, hind-part pointed.—9. *Cercaria hirta.* Cylindric, fore-part somewhat truncated, lower part obtuse, finishing with two small points.—10. *Cercaria crumena.* Cylindric, ventricose, fore-part obliquely truncated, tail linear, terminating with two diverging points.—11. *Cercaria catellus.* Three-parted, tail divided into two parts.—12. *Cercaria catelina.* In three parts, with a short forked tail.—13. *Cercaria lupus.* Cylindric, long, the tail furnished with two spines.—14. *Cercaria vermicularis.* Cylindrical, annulated, with a projecting proboscis, two small spines for the tail.—15. *Cercaria forcipata.* Cylindric, wrinkled, with a forked proboscis, which it can extend or contract.—16. *Cercaria pleuronectes.* Orbicular, the tail consisting of one bristle.—17. *Cercaria tripos.* Triangular, two bent arms, and a straight tail.—18. *Cercaria cyclidium.* Oval, hind-part somewhat notched, with a tail that it thrusts out at pleasure.—19. *Cercaria tenax.* Membranaceous, fore-part rather thick, truncated, the tail three times shorter.—20. *Cercaria discus.* Orbicular, with a bent tail.—21. *Cercaria orbis.* Orbicular, with a tail consisting of two very long bristles.—22. *Cercaria luna.* Orbicular, the tail of two short spines, fore-part hollowed like a crescent.

XII. Leucophra. An invisible worm, pellucid, and every where ciliated.

Plate 35, fig. 54. *The Bracelet Leucophra.*—This animalcule is shown with the inner edge ciliated, sometimes the ciliæ are disposed on the circumference. It is scarce.

Plate 27, fig. 54. *Leucophra cornuta.*—This creature requires to be observed some time before its peculiar character can be ascertained; the body is composed of molecular vessels, of a dark green colour; for the most part it is like an inverted cone, the fore-part being wide and truncated, with a little prominent horn or hook on both sides; the hind-part conical, every where ciliated, the hairs exceedingly minute; those in the fore-part are three times longer than the latter, and move in a circular direction. The hinder part is pellucid, and sometimes terminates in two or three obtuse pellucid projections. This animalcule will at one moment appear oval, at another reniform, and ciliated at the fore part; but at another time the hairs are concealed. When the water evaporates, it dissolves or breaks into a number of molecular vesicles.

Leucophra Species.

1. *Leucophra conflictor.* Spherical, opaque, with movable intestines.—2. *Leucophra mamilla.* Spherical, opaque, with a small papillary projection.—3. *Leucophra virescens.* Cylindrical, opaque, the lower part much thicker than the upper part.—4. *Leucophra viridis.* Oval, opaque.—5. *Leucophra bursata.* Green, oval, the fore-part truncated.—6. *Leucophra postluma.* Globular, opaque, and covered with a kind of pellucid net.—7. *Leucophra aurea.* Oval, yellow, both ends equally obtuse.—8. *Leucophra pertusa.* Oval, gelatinous, apex obtusely truncated, one side sunk down.—9. *Leucophra fracta.* Long, with ciliated angles, rather flat.—10. *Leucophra dilatata.* Smooth, changeable, with a ciliated edge.—11. *Leucophra scintillans.* Oval, round, opaque, green.—12. *Leucophra vesiculifera.* Oval, with vesicular intestines.—13. *Leucophra globulifera.* Crystalline, of an oblong, oval shape.—14. *Leucophra pustulata.* Oblong, oval, the lower end obliquely truncated.—15. *Leucophra turbinata.* Like an inverted cone, and rather opaque.—16. *Leucophra acuta.* Oval, round, with the apex acute, mutable, yellow.—17. *Leucophra notata.* Oval, round, with a black point at the edge.—18. *Leucophra candida.* Oblong, one end smaller than the

other and bent back.—19. *Leucophra nodulata.* Oblong, oval, with a double row of little nodules.—20. *Leucophra signata.* Oblong, subdepressed, with a black margin, filled with little molecular globules.—21. *Leucophra trigona.* Thick, obtuse, angular, yellow.—22. *Leucophra fluida.* Kidney-shaped, ventricose. — 23. *Leucophra fluxa.* Reniform, sinuated.—24. *Leucophra armilla.* Described.—25. *Leucophra cornuta.* Described.—26. *Leucophra heteroclita.* Cylindrical, fore part obtuse, hind part furnished with a double tufted organ, which it can thurst in and out at pleasure.

XIII. Trichoda. An invisible, pellucid, hairy worm.

Plate 35, fig. 55. *Trichoda vulgaris.*—This animalcule has a crustaceous covering in the shape of a cup, at the circumference of which radiate several strong spines. Its polygastric structure may be seen in the figure.

Plate 27, fig. 37. *Trichoda sol.*—This splendid creature constitutes a new genus, but as we know of no more of the same kind, it is introduced here. It is a little crystalline, round corpuscule, the upper part convex; it is beset with innumerable diverging rays, which are no longer than the diameter of the body, proceeding from every part of its surface: the inside contains as many as twenty polygastric sacs. The body contracts and dilates, but the animalcule remains confined to the same spot.

Plate 27, fig. 38. *Trichoda cometa.*—A pellucid globule, replete with bright intestines, the fore-part furnished with hairs, the hind-part with a pellucid appendant globule.

Plate 27, fig. 53. *Trichoda bomba.*—A thick animalcule, and of a yellow colour; pellucid, and replete with clay-like molecules; it is very lively, moving about with so much velocity, as to elude the sharpest sight, and most determined observer, and assuming various shapes, sometimes appearing spherical, sometimes reniform, or kidney-shaped, and sometimes as in the figure.

Trichoda Species.

1. *Trichoda grandinella.* Spherical, pellucid, upper part hairy.—2. *Trichoda cometa.* Described.—3. *Trichoda granata.* Spherical, centre opaque, the circumference hairy.—4. *Trichoda trochus.* Pear-shaped, pellucid, each side of the fore part distinguished by a little bunch of hairs.—5. *Trichoda gyrinus.* Oval, round, crystalline, the front hairy.—6. *Trichoda sol.* Described.—7. *Trichoda solaris.* Spheroidal, with a few hairs round the circumference.—8. *Trichoda bomba.* Described.—9. *Trichoda orbis.* Orbicular, the fore part notched and hairy.—10. *Trichoda urnula.* In the form of a water pitcher, the fore part hairy.—11. *Trichoda diota.* Pitcher-shaped, fore part smallest, upper part of the mouth ciliated.—12. *Trichoda horrida.* Somewhat conical, fore-part rather broad and truncated, lower part obtuse, the whole covered with radiating bristles.—13. *Trichoda urinarium.* Egg-shaped, with a short hairy beak.—14. *Trichoda semiluna.* Semiorbicular, fore part hairy underneath.—15. *Trichoda trigona.* Convex, fore part ciliated, hind part apparently torn away.—16 *Trichoda tinea.* Clubbed, fore part hairy, hind part large.—17. *Trichoda nigra.* Oval, compressed, fore part broader and hairy.—18. *Trichoda pubes.* Egg-shaped, oblong, fore part depressed. — 19. *Trichoda floccus.* Membranaceous, fore-part rather conical; three small papillæ project from the base, which are set with hairs.

—20. *Trichoda sinuata.* Oblong, depressed, one margin hollow and hairy, the lower end obtuse.—21. *Trichoda præceps.* Membranaceous, somewhat lunated, protuberant in the middle, a row of hairs on the outside.—22. *Trichoda proteus.* Oval, the lower part obtuse, with a long neck, which it has the power of contracting or extending.—23. *Trichoda versatilis.* Oblong, hind part acute, with a neck that it can extend or contract at pleasure, under part of the extremity of the neck hairy.—24. *Trichoda gibba.* Oblong, with a hunch on the back, the belly hollowed out, the fore part ciliated, both ends obtuse.—25. *Trichoda fœta.* Oblong, with the back protuberant, the fore part ciliated, both ends obtuse.—26. *Trichoda patens.* Long, round, a long hole in the fore part, with the edges ciliated.—27. *Trichoda patula.* Inclining to oval, with a small tube at the fore part, the upper end covered with hairs.—28. *Trichoda foveata.* Oblong, rather broad, three little horns on the fore part, hinder part beardless.—29. *Trichoda striata.*—Oblong, one edge rather curved, and furnished with a row of hairs, both extremities obtuse.—30. *Trichoda uvula.* Rather flat and long, of equal size throughout, fore part hairy.—31. *Trichoda aurantia.* Sinuated, oval, fore part broad, apex hairy to the middle.—32. *Trichoda ignita.* Oval, apex rather acute, the under part furrowed, the furrows hairy.—33. *Trichoda prisma.* Oval, under part convex, upper part compressed into a kind of keel, the fore part small.—34. *Trichoda forceps.* Oval, with a pair of forceps at the fore part, with unequal hairy legs.—35. *Trichoda forfex.* Round and prominent, the fore part formed into a kind of forceps, and two small protuberances.—36. *Trichoda index.* Obovated, under part of the front of the margin hairy, apex formed by the fore part, projecting like the finger on a direction post.—37. *Trichoda* S. Striated, fore part ciliated, the extremities bent in opposite directions.—38. *Trichoda navicula.* Three cornered, fore part truncated and ciliated, hind part acute, and bent a little upwards.—39. *Trichoda succisa.* Flattened, oval, edge hairy, hinder part hollowed out so as to form two unequal legs.—40. *Trichoda sulcata.* Ovated, ventricose, apex acute, with a furrow at the abdomen, and both sides of it ciliated.—41. *Trichoda anas.* Long, the apex of the neck underneath hairy.—42. *Trichoda barbata.* Long, round, the under part from the apex to the middle hairy.—43. *Trichoda farcimen.* Long and thick, surrounded with small bristles.—44. *Trichoda crinita.* Long, round, everywhere ciliated on the upper part, and also on the under part as far as the middle.—45. *Trichoda angulus.* Angular, the apex hairy.—46. *Trichoda linita.* Oblong, with prominences at both extremities.—47. *Trichoda paxillus.* Linear, flat, fore part truncated and hairy, the hinder part obtuse.—48. *Trichoda vermicularis.* Long, cylindrical, with a short neck, the apex hairy.—49. *Trichoda melitæa.* Oblong, ciliated, with a dilatable neck, the apex globular, and ciliated, and a kind of peristaltic motion observable in it.—50. *Trichoda fimbriata.* Obovated, the apex hairy, the hinder part obliquely truncated and serrated.—51. *Trichoda camelus.* Thick, fore part hairy, with notches on the middle and each side.—52. *Trichoda augur.* Oblong, depressed, pellucid, and filled with molecules, vertex truncated, fore part forming a small beak, underneath are three feet, the hinder part is furnished with bristles.—53. *Trichoda pupa.* Hooded, front hairy, the tail inflected, at the lower part of the head is a large pellucid corpuscule.—54. *Trichoda lunaris.* Arched, round, the apex hairy, the tail bent.—55. *Trichoda bilunis.* Arched, flattened, the apex hairy, and two little bristles proceeding from the tail.—56. *Trichoda rattus.* Oblong, with a kind of keel, the fore part hairy, and a very long bristle proceeding from the hinder part.—57. *Trichoda tigris.* Long, and somewhat cylindrical, apex hairy, the tail divided into two long bristles.—58. *Trichoda pocillum.* Oblong, fore part truncated and hairy, the tail articulated, and divided into two bristles.—59. *Trichoda clavus.* Fore part round and hairy, hind part furnished with a sharp tail.—60. *Trichoda cornuta.* Upper part convex, under side plane, apex hairy, tail linear, and simple.—61. *Trichoda gallina.* Long, fore part sinuated, the front hairy, the tail formed of small hairs.—62. *Trichoda musculus.* Egg-shaped, fore part hairy, the tail projecting from the under part.—63. *Trichoda delphis.* Clubbed, front hairy, the tail small

and rather bent upwards.—64. *Trichoda delphinus.* Oblong, fore part hairy, the tail turned back and truncated.—65. *Trichoda clava.* Similar to the preceding in most respects.—66. *Trichoda cuniculus.* Oblong, fore-part hairy, hind part rather acute, filled with molecules and black vesicles.—67. *Trichoda felis.* Curved, large, the fore part small, hinder part gradually diminishing into a tail, under part set longitudinally with hairs.—68. *Trichoda piscis.* Oblong, fore-part hairy, hinder part terminating in a very slender tail.—69. *Trichoda larus.* Long, round, surrounded with hairs, the tail divided into two points.—70. *Trichoda longicauda.* Cylindrical, fore part truncated and surrounded with hairs, the tail long, furnished with two bristles, and having two joints.—71. *Trichoda fixa.* Spherical, the circumference set with hairs, and a small pedicle projecting from the body.—72. *Trichoda inquilinus.* Sheathed in a cylindrical transparent bag, having a little pedicle bent back within the bag.—73. *Trichoda ingenita.* Sheathed, the bag depressed, the base broadest.—74. *Trichoda innata.* Sheathed, in a cylindrical bag, with a pedicle passing through, and projecting beyond it.—75. *Trichoda transfuga.* Broad, fore part hairy, hinder part full of bristles, one side sinuated, the other pointed.—76. *Trichoda ciliata.* Ventricose, the hinder part covered with hair.—77. *Trichoda bulla.* Membranaceous, sides bent inwards, fore and hind parts furnished with hairs.—78. *Trichoda pellionella.* Cylindrical, fore-part hairy, hinder part furnished with bristles.—79. *Trichoda cyllidium.* Egg-shaped, the apex gaping, the base hairy.—80. *Trichoda cursor.* Oval, fore part hairy, hinder part furnished with straight and curved hairs in two fascicles.—81. *Trichoda pulex.* Egg-shaped, with an incision in the fore-part; the front and base hairy.—82. *Trichoda lynceus.* Nearly square, with a crooked beak, the mouth hairy.—83. *Trichoda erosa.* Orbicular, fore-part notched, one side furnished with hairs, the hinder part with bristles.—84. *Trichoda rostrata.* Depressed, mutable, yellow, with long cilia, and feet tapering to a point.—85. *Trichoda lagena.* Round, ventricose, with a long neck, and the lower end set with bristles.—86. *Trichoda charon.* Boat-shaped, with furrows, the fore and hind parts hairy.—87. *Trichoda cimex.* Oval, with a lucid margin, front and hind part hairy.—88. *Trichoda cicada.* Oval, with an obscure margin, fore part covered with hairs on the under side, and the hinder part beardless.

XIV. Kerona. An invisible worm with horns. "Animalcules furnished with hooks (*uncini*), bristles (*setæ*), or horn-like processes."

Plate 35, fig. 56. *Kerona pullaster.*—"The fore part, in addition to the cilia, is stated to have three setæ. The cilia at the opposite extremity are often separated; at other times they are collected in a cluster."

Kerona Species.

1. *Kerona rostellum.* Membranaceous, orbicular, with one projecting point, the upper surface covered with small horns.—2. *Kerona lyncaster.* Rather square, and its disc furnished with shining horns.—3. *Kerona histrio.* Oblong, membranaceous, with four or five black points in the fore part, which are continually changing their situation, thick set, with small globules in the middle, among which four larger ones are perceived, probably the eggs.—4. *Kerona cypris.* Egg-shaped, sinuated towards the hind part, the fore part hairy.—5. *Kerona haustrum.* Orbicular, with the horns in the middle, the fore part membranaceous and hairy, and several bristles in the hinder part.—6. *Kerona haustellum.* Differs from the preceding only in wanting the bristles in the hinder part.—7. *Kerona patella.* With a univalved shell, orbicular, crystalline; fore part somewhat notched.—8. *Kerona rannus.* Oval and rather flat, with one edge bent, the opposite one ciliated; the front furnished with horns, and the hind part with bristles.—9. *Kerona pullaster.* Described.—10. *Kerona mytillus.* Rather clubbed, broad at both extremities, clear and ciliated.—11. *Kerona lepus.* Egg-shaped, fore part hairy, the base furnished with bristles.—12. *Kerona silurus.* Oblong, the fore and hind parts hairy, the back ciliated.—13. *Kerona calvitium.* Rather broad, oblong, with glittering horns on the fore part.—14. *Kerona pustulata.* Oval, convex, one edge of the hinder part sinuated, both ends set with hairs, and several horns placed on the fore part.

XV. Himantopus. A pellucid, invisible, cirrated* worm.

Plate 35, fig. 58. *Himantopus larva.* "This is a very lively creature, swimming and turning in the water in a graceful and diverting manner, inflecting itself, as shown in the figure; the body gradually decreases towards the posterior, and at intervals several hairs appear disposed along it. The margin is fringed."

Himantopus Species.

1. *Himantopus acarus.* Round and prominent, the hinder part cirrated, the fore part sharp.—2. *Himantopus ludio.* Curled, the upper part hairy, the tail extended upwards.—3. *Himantopus sannio.* Crooked, the upper part ciliated, the under part hairy.—4. *Himantopus volutator.* Lunated, the fore-part hairy.—5. *Himantopus larva.* Described.—6. *Himantopus charon.* Boat-shaped, furrowed, the hollow part of the belly cirrated.—7. *Himantopus corona.* Semi-orbicular, flattened, both sides cirrated.

XVI. Vorticella. A small animal with a vascular cup; the mouth is ciliated, and capable of being contracted, the stem fixed.

The variety that may be observed in these minute animals confirms a principle, which, the more it is inquired into, the more it will be found to accord with the general operations in nature, namely, that there is always a pre-existent principle of life necessary to the organization both of animals and vegetables; that the alimentary and other particles which are added to, or apparently belong to them, produce nothing of themselves; they are incapable of forming the least fibre, but they are able to become constituent parts of one organical whole, together with the instruments whereby the former principle is manifested, and rendered capable of acting upon certain orders of creatures. The genus vorticella is very extensive. Müller enumerates no less than seventy-five species, and other observers have added to the number; in this, however, and in other similar instances, it would be better if examination were conducted with a view to lessen rather than increase the number of species, that is to say, if the several *stages of development* were carefully noted, when we believe many apparently distinct species would be found to be one and the same, in its various progressions towards maturity. The vorticella differ considerably in their organization, and Mr Pritchard has, in consequence, separated them into two divisions,—*V. polygastrica*, and *V. rotatoria*; the former of these includes the

* That is, furnished with a tuft, or lock, of hair.

animalcules whose alimentary structure consists of a number of sacs only, and the latter, those which have true alimentary canals and rotatory organs. Of the entire genus, Mr Pritchard remarks, "They are naked, contractile, and possess cilia circularly disposed near the mouth, producing a vortex in the water: in many of them they appear to rotate like a wheel; to account for which, various hypotheses have been invented. According to Dr Ehrenberg, this is occasioned by their peculiar disposition, and not from any difference of structure; for as with the vibrating cilia, the base of each is a bulb (similar to the species of the *Echines*), which by means of muscular fibres it can move in any direction, like a ball and socket joint. Thus each cilium in its revolution describes a cone, the apex of which is the bulb. Now if the cilia are arranged in a circle, and viewed laterally while in motion, the whole wheel will appear to revolve as each cilium passes; first, a little nearer the eye on this side of the cone, and then further off on the other side."

Plate 35, fig. 57. *Vorticella cyathini.*—"This animalcule is shown swimming freely: the edge of the bell is ciliated, though not exhibited in the sketch: it can attach itself by the stem, which it contracts spirally." Its polygastric structure is shown in the figure.

Plate 27, fig. 28. *Vorticella anastatica.*—These polypi form a group resembling a cluster, or more properly an open flower; this flower or cluster is supported by a stem, which is fixed by its lower extremity to some of the aquatic plants or extraneous bodies that are found in the water; the upper extremity forms itself into eight or nine lateral branches, perfectly similar to each other; these have also subordinate branches, whose collective form much resembles that of a leaf. Every one of these assemblages is composed of one principal branch or nerve, which makes with the main stem of the cluster an angle somewhat greater than a right one; from both sides of this nerve the smaller lateral branches proceed; these are shorter the nearer their origin is to the principal branch. At the extremity of the principal branch, and also of the lateral ones, there is a polype or vorticella. There are others on both sides of the lateral twigs, but at different distances from their extremity. These animalcules are all exceedingly small, and of a bell-like figure: near their mouth a quick motion may be discerned, though not with sufficient distinctness to convey an adequate idea of its cause; upon the branches of these clusters are round bodies, which will be more particularly described presently. Every cluster has eight or nine of these branches or leaves; they do not all proceed from the same point, but the points from whence they set out are not far asunder; each of these branches is bent a little inwards, so that all of them taken together form a kind of shallow cup. If the eye be placed right over the base of this cup, the appearance of the whole eight or nine branches is like unto that of a star, with so many rays proceeding from the centre. If the cluster be slightly touched, all the branches instantly fold up, and form a small round mass. The stem which supports the cluster contracts also, at the same time folding up like a workman's measuring rule, that consists of three or four joints. This extraordinary assemblage constitutes one organized whole, formed of a multitude of similar and also particular ones; a new species of society, in which all the individuals are members of each other in the strictest sense, and all participate in the same life.

A few days after one of the clusters is formed, small round bodies or bulbs may be perceived to protrude in several places from the body of the branch; these grow very fast, and arrive at their greatest growth in two or three days. The bulbs detach themselves from the branches out of which they spring, and go away, swimming till they can settle upon some substance which they meet with in the water, and to which they fix themselves by a short pedicle; the bulbs are then round, only a little flatted on the under side, the pedicle continues to lengthen gradually for about twenty-four hours, during the same time the bulbs also change their figure, and become nearly oval. There are in a cluster but few of these bulbs, compared with the number of the vorticellæ, neither do all the bulbs come out at the same time. The bulb then divides lengthways into two smaller ones, (see *figure*) but which are still much larger than the vorticellæ themselves. It is not long before these are separated like the first, and thus form four bulbs on the same stalk; these again divide themselves, and form eight; which again subdivide, and consequently make sixteen. They are all connected with the stalk by a proper pedicle, but they are not all of an equal size; the largest continue to divide and the smallest begin to open, and take the bell-formed shape. Trembley observed from one round bulb, in about twenty-four hours, by repeated divisions, one hundred and ten vorticellæ to be formed.

Vorticella digitalis. This species of the vorticella is very scarce, it seems only to have been seen by Rosel, who found it on the monoculus quadricornis, (see *figure*) till it was discovered in 1784, by Müller, who had sought for it several years before, but in vain. The body is cylindrical, crystalline, and appears almost empty; it has three pellucid points disposed lengthways, the apex is truncated in an oblique direction, the margin bent back. The

upper part contracts itself, and the margin then assumes a conical shape, with a convex surface; there are in general but few branches from the principal stem, and these are short

and thick. It excites an undulatory motion, but neither hairs, nor rotatory motion, have been discovered. The figure represents the vorticella adhering to the monoculus quadricornis.

Vorticella convallaria. These vorticellæ, or bell-animals, as they are termed by Baker,

are generally found adhering to some substance in the water; they are represented here as found by Rosel, fixed to a curious *cornu ammonis*, with points projecting from the back. To the naked eye they appear only as so many little white points, but under the microscope, as little bells, agitating the water to a considerable distance. The stems of these have a particular motion, they draw themselves up and shorten all at once, taking the form of a spiral wire or screw; in a moment after they again extend themselves. Many of them may be seen at times adhering to each other by their tails; the cilia are disposed round the mouth, and require a good defining power to exhibit them satisfactorily. On reference to the figure, it will be perceived that some of the animalcules differ in appearance from others; those which are nearly circular are in a state of inactivity; others, assuming an oval form, and beginning to open, are in the act of stretching themselves out to take their prey; and such as have taken the perfect cup-like shape, are fully extended, with their cilia in action, collecting food. One is drawn on a considerably enlarged scale, to exhibit more clearly the *styli* and cilia.

Vorticella Species.

1. *Vorticella cineta.* In the form of a trapezium, of a blackish green colour, and opaque.—2. *Vorticella sphæroida.* Globose, uniform, and opaque.—3. *Vorticella viridis.* Cylindrical, uniform, green, and opaque.—4. *Vorticella lunifera.* Green, the hinder part luminated, with a point in the middle projecting from the edge.—5. *Vorticella bursata.* Green, the aperture truncated, with a central papillary projection.—6. *Vorticella varia.* Cylindrical, truncated, opaque, of a blackish colour, the fore part ciliated.—7. *Vorticella sputarium.* Round and prominent, with an orbicular aperture, and long hairs radiating as from a centre.—8. *Vorticella nigra.* Black, and top-shaped.—9. *Vorticella multiformis.* Green, opaque, variable, with vesicles scattered about the body.—10. *Vorticella polymorpha.* Many-shaped, green, opaque.—11. *Vorticella cucullus.* Long, round, the aperture or mouth obliquely truncated.—12. *Vorticella utriculata.* Green, the belly round and prominent, capable of being lengthened or shortened; the fore-part truncated, much in the shape of a common water-bottle; the neck is sometimes very long, at others, very short, and filled with green molecules.—13. *Vorticella ocreata,* Nearly of a cubical figure, the under part bent in an obtuse angle.—14. *Vorticella valga.* Cubical, the lower part divaricated.—15. *Vorticella papillaris.* Big-bellied, the fore-part truncated, with a papillary tail, and a splendid papillary excrescence on the side.—16. *Vorticella sacculus.* Cylindrical, the aperture broad and flat, the edge turned down.—17. *Vorticella cirrata.* Big-bellied, the aperture sinuated, two tufts of hair on each side of the belly.—18. *Vorticella nasuta.* Cylindrical, with a prominent point in the middle of the cup.—19. *Vorticella stellina.* Orbicular, with a molecular disc, and ciliated margin.—20. *Vorticella discina.* Orbicular, the edge ciliated, with a kind of convex handle on the under side.—21. *Vorticella scyphina.* Bowl-shaped, crystalline, with an opaque spherule in the middle.—22. *Vorticella albina.* The fore-part cylindrical, the hinder part tapering and ending nearly in a point.—23. *Vorticella fritillina.* Empty, cylindrical, the apex truncated.—24. *Vorticella truncatella.* Cylindrical, stuffed or filled, the apex truncated, with very short cilia.—25. *Vortacella limacina.* Cylindrical, truncated with two pair of cilia.—26. *Vorticella fraxinina.* Gregarious, cylindrical, obliquely truncated, with two pair of cilia, and a fissure or notch at the upper edge.—27. *Vorticella crategaria.* Compound, with globous naked florets, two tentacula, and a branched stem.—28. *Vorticella hamata.* Purse-formed, the edge of its aperture or mouth set with rigid points.—29. *Vorticella crateriformis.* Approaching to a square figure, with fascicles of cilia even at the hinder part.—30. *Vorticella canaliculata.* Dilated, pellucid, with an incision in the side.—31. *Vorticella versatilis.* Long, spear-formed, but often changing into a pitcher-like form.—32. *Vorticella ampulla.* Contained in a pellucid bottle-shaped bag, the head divided into two lobes.—33. *Vorticella folliculata.* Oblong, in a bright cylindrical bag.—34. *Vorticella larva.* Cylindrical, the aperture crescent-shaped, two small thorny points projecting from the hinder part.—35. *Vorticella sacculata.* Like an inverted cone, the aperture crescent-shaped, lower part of the trunk notched, the tail biphyllous.—36. *Vorticella aurita.* Cylindrical and big-bellied, the aperture destitute of hairs, both sides of it are furnished with rotatory cilia, tail biphyllous.—37. *Vorticella tremula.* Conical shape,

mouth divided into two parts and set with small spines, a point projecting from the tail.—38. *Vorticella serita.* Somewhat cone-shaped, the aperture set with spines, the tail short and divided into two points.—39. *Vorticella lacinulata.* Like an inverted cone, the aperture lobated, the tail small and furnished with two bristles.—40. *Vorticella constricta.* Elliptical, ventricose, the mouth undivided, the tail annulated and forked.—41. *Vorticella togata.* Square, the aperture not divided, the tail consisting of two long spines, which occasionally unite and appear as one.—42. *Vorticella longiseta.* Long, flat, the tail formed of two very long bristles.—43. *Vorticella rotatoria.* Cylindrical, with a little organ projecting from the neck, and a long tail furnished with four points.—44. *Vorticella furcata.* Cylindrical, the aperture undivided, the tail rather long, and divided into two parts.—45. *Vorticella catulus.* Cylindrical, the aperture plain, the tail short, bent back, and divided into two points.—46. *Vorticella canicula.* Cylindrical, the aperture plain, with a short articulated tail divided into two pointed parts.—47. *Vorticella felis.* Cylindrical, beardless, with the tail terminating in two long spines.—48. *Vorticella stentorea.* Long-tailed, trumpet-shaped, the arms furnished with rows of short hairs.—49. *Vorticella socialis.* Bearded, thick, and wrinkled.—50. *Vorticella flosculosa.* An aggregated tail, oval-shaped, with a dilated pellucid disc.—51. *Vorticella citrina.* Simple, many-shaped, with an orifice admitting of contraction, and an equally sized foot-stalk.—52. *Vorticella piriformis.* Simple, oval, with a very short retractile foot, which it can draw within itself.—53. *Vorticella tuberosa.* Simple, the upper part broad, the under part small, with two projections at the anterior end, furnished with a number of fibrilla.—54. *Vorticella ringens.* Simple, somewhat oval-shaped, with a small pedicle, and an orifice which it contracts or dilates.—55. *Vorticella inclinans.* Simple, bent, with a short pedicle, and small retractile head.—56. *Vorticella vaginata.* Simple, erect, shaped like a truncated egg, the pedicle contained in a sheath.—57. *Vorticella globularia.* Simple, spherical, with a twisted pedicle.—58. *Vorticella lunaris.* Simple, hemispherical, with a twisted pedicle.—59. *Vorticella convallaria.* Described.—60. *Vorticella nutans.* Simple, with a twisted turbinated pedicle.—61. *Vorticella nebulifera.* Simple, egg-shaped, the pedicle bent back.—62. *Vorticella annularis.* Simple, truncated, with a pedicle twisted at the end.—63. *Vorticella acinosa.* Compound, with ciliated globous naked florets, and an umbellated stem.—64. *Vorticella fasciculata.* Simple, green, bell-shaped, the margin or edge turned back, the pedicle twisted.—65. *Vorticella hians.* The head resembling a citron, the apex truncated, the base narrow; a gaping cleft is observable descending from the apex to one-third of the body.—66. *Vorticella bellis.* Simple, hemispherical, with a margin, which it can contract at pleasure.—67. *Vorticella gemella.* Simple, spherical, with a double head.—68. *Vorticella pyraria.* Compound, with beardless oval florets, two double arms, the stem branched.—69. *Vorticella anastatica.* Described.—70. *Vorticella digitalis.* Described.—71. *Vorticella polypina.* Compound, oval truncated, with a bending, branching stalk.—72. *Vorticella racemosa.* Compound, rigid pedicle, with small branched long feet.—73. *Vorticella cyathini.* Described.

XVII. Brachionus. A worm capable of contracting, covered with a shell, and furnished with rotatory cilia.

Plate 35, fig. 53. *Brachionus passus.*—"A curious little creature, with two long bristles in front, like the antennæ of an insect."

Plate 27, fig. 23. *Brachionus Bakeri.*—The general characteristics of this creature are as follows:—the shell ventricose, four teeth at the apex, two horns at the base, and a long tail terminating in two short points. From each side of the shell there is a curved projection, inclining towards the tail. The upper part of the shell has in general four longer spiculæ, and two shorter ones. From the head, two arms or branches are frequently extended; the circular end of each is furnished with a tuft of little hairs, which sometimes move in a vibratory manner, at other times have a rotatory motion. The eggs are either affixed to the tail, or the curved part of the shell; they have from one to five hanging from them.

Brachionus Species.

1. *Brachionus striatus.* Univalve, the shell oval and striated, six notches or teeth round the upper edge, the base whole or even, without a tail.—2. *Brachionus squamula.* Univalve, shell orbicular, the apex, truncated, and having four teeth, the base smooth, no tail.—3. *Brachionus pala.* Univalve, with an oblong excavated shell, four long teeth at the apex, the base smooth, no tail, the colour yellow.—4. *Brachionus bipalium.* Univalve, the shell oblong and inflected, ten teeth at the apex, the base smooth, and a spurious tail.—5. *Brachionus patina.* Univalve, shell orbicular, the edges regular, and having a long beardless tail.—6. *Brachionus clypeatus.* Univalve, the shell oblong, the apex notched, the base smooth, and the tail naked.—7. *Brachionus lamellaris.* Univalve, the shell extending considerably beyond the body; the base divided into three small horns, with two hairs at the end of the tail.—8. *Brachionus patella.* Univalve oval shell, two teeth at the apex, the base notched, two bristles at the tail.—9. *Brachionus bractea.* Univalve, shell rather orbicular, lunated apex, smooth base, and the tail furnished with two spines.—10. *Brachionus plicatilis.* Univalve, with an oblong shell, the apex hairy, and the base notched.—11. *Brachionus ovalis.* Bivalve, with a flattened shell, the apex notched, a hollow part at the base, the tail formed of two tufts of hairs.—12. *Brachionus tripos.* Bivalve, the apex of the shell beardless, three horns at the base, and double tail.—13. *Brachionus dentatus.* Bivalve, with an arched shell, the apex and the base are both toothed, and the tail formed of two spines.—14. *Brachionus mucronatus.* Bivalve, something of a square form; the apex and base pointed; the tail consisting of two spines.—15. *Brachionus uncinatus.* Bivalve, with an oval shell, the apex even, the base pointed, two thick bristles for the tail.—16. *Brachionus cirratus.* Ventricose, somewhat pellucid, the head conical, with a bundle of hairs on both sides; it has also a rotatory organ.—17. *Brachionus passus.* Described.—18. *Brachionus quadratus.* Capsular, in a quadrangular shell, with two small teeth at the apex, two horns proceeding from the base, and no tail.—19. *Brachionus impressus.* Capsular, the shell quadrangular, a smooth undivided apex, obtuse base, notched margin, and a flexuous tail.—20. *Brachionus urceolaris.* Single, with a short tail, and toothed mouth.—21. *Brachionus Bakeri.* Described.—22. *Brachionus patulus.* Capsular, shell ventricose, eight teeth at the apex, the base lunated or hollowed into the form of a crescent, and furnished with four horns; the tail short, with two small points at the end.

In closing this brief account of the Infusoria, we would again call the attention of microscopists to the propriety of merging *apparently* special differences into one individual, by attentively noting the successive changes which each creature undergoes. From our own observation we are convinced that nothing more is required than a good instrument, extensive leisure, and considerable patience, to enable the philosophical inquirer to simplify the Infusorial arrangement: that this is a desirable object for attainment none will deny, except those who are so enamoured of systematic complexity, that they delight in nothing

so much as in stringing together hard names, and in weaving learned labyrinths which shall be "caviare to the general."

In our first chapter we remarked that molecular activity closely resembles the vitality of the infusorial monads, and stated our intention of returning to the subject. We shall in this place offer only a few incidental observations. So far as the mere activity is concerned, the movements of the monads and molecules are apparently identical; there may, notwithstanding, on a careful examination, be discovered an evident *voluntary* action on the part of the monads, which cannot be detected in the molecules; these latter obviously act upon each other, the former act independently of each other. All supposed identity between molecular and monadic motion, is, however, we conceive, entirely overthrown by the recent discovery of the polygastric structure of infusoria. The monads, it is ascertained, have polygastric sacs similar in principle to those of the larger animalcules, regarding whose animal vitality there can be no question; consequently we have a right to infer, from analogy, that the monads, though placed at the extreme limit on the descending scale of animality, are not mere active atoms, but really organized animal bodies; and indeed it is tolerably well ascertained that these monads pass into other forms and are ultimately developed in the larger and less equivocal animalcular existences.

CHAP. III.

SPERMATIC ANIMALCULES.

Towards the close of the seventeenth century the existence of seminal animalcules was discovered and made known to the world by Leeuwenhoeck and Hartsoeker, each of whom claimed the honour of being the first observer. The former micrographer, if he did not originate the discovery, at least explained and illustrated it to a much greater extent than his contemporary; and he has consequently been considered as the leading authority on the subject. The hypotheses and controversies which arose out of the inquiries regarding spermatic animals, are interesting to the natural historian; and though, in a popular work, the subject must be approached with caution, it is still desirable that some general information should be given concerning these vital germs, whose existence is undeniable, though their relation to the mature animal has not even yet been ascertained.

Before the discovery of animalcules in the *semen masculinum*, the egg system, as it was termed, obtained universal consent. It was asserted that the female ovaria contained eggs, waiting only till a principle of life was communicated to them by the other sex, when the previously formed fœtus would burst through these receptacles and claim their birth. When the existence of spermatic animals was announced, a system entirely opposite in principle was earnestly contended for by many of the leading philosophers of the day. The new hypothesis considered the seminal animal to be identical with the mature fœtus, and that it needed only for its perfect developement, a suitable nidus, which was provided in the uterus of the female. The advocates of each system contended strenuously for its support; but the data in either case were insufficient to decide the problem of generation, and both parties continued to argue hypothetically, advancing with every fresh argument still nearer to the climax of absurdity. At the present day we have no certain knowledge concerning the mysterious process by which the succession of animated creatures is secured, and the intent of the spermatic animals is still matter of perplexity. These vital germs do, however, exist in the seminal fluids of all animals, from the largest to the least; and it is to their mere existence that our further remarks will principally be directed.

Mr Leeuwenhoeck observed in the semen of the human species, not less than ten thousand living creatures, contained in a portion of the fluid equal in surface to a grain of sand. "Their size was smaller than the red globules of the blood, and even less than the millionth part of a grain of sand. Their bodies were roundish, somewhat flat before, but ending sharp behind, with tails exceedingly transparent, five or six times longer, and about five times more slender than their bodies. They moved themselves along by the violent agitation of their tails, in various bendings, after the manner that eels and serpents swim: and sometimes their tails were moved thus eight or ten times in getting forwards the diameter of a hair." Their shape may be more popularly described as being very nearly that of the tadpole. The seminal animalcules of all living creatures, that have been examined, bear strong resemblance to each other; the size likewise does not vary according to the disproportion of bulk in different animals, and hence they are readily discovered in the semen of birds, fishes, and insects.

"Upon viewing the milt, or *semen masculinum*, of a living cod-fish, such numbers of animalcules were found therein, that at least ten thousand of them were supposed to exist in the quantity of a grain of sand. Whence Mr Leeuwenhoeck argues that the milt of that single cod-fish contained more living

animalcules than there are people alive upon the face of the whole earth at one and the same time. To find the comparative size of these creatures, he placed a hair of his head near them, which hair through his microscope appeared an inch in breadth ; and he was satisfied that at least sixty such animalcules could lie within that diameter, whence, their bodies being spherical, it must follow, that two hundred and sixteen thousand of them are but equal to a globe whose diameter is no more than the breadth of such hair."

Mr Leeuwenhoeck assures us that he found a fluid in male spiders, which was undoubtedly their semen, and he therein discovered prodigious multitudes of animalcules so extremely minute, that many millions of them would not equal the size of a grain of millet. " He found them likewise in the semen of the dormouse, in oysters, in silk-worms, in the *libella minima*, or small dragon fly, in the common fly, in the flea, in gnats, and in several other insects." It has been objected to these discoveries, that no organs have been detected in insects for the secretion of a seminal fluid, and that Leeuwenhoeck must consequently have suffered his enthusiasm to deceive him into a belief that he saw what had no existence. Whether, however, secretory organs may be detected or not, no curious inquirer need remain in doubt as to the fact of animalcules existing in insect bodies ; and from the circumstances under which they are obtained, and their striking similarity, both in figure and activity, to the seminal animals of larger creatures, the inference is fairly drawn from analogy that their character and uses are the same.

Buffon asserts that what have been called spermatic animals are not creatures really possessing life, but something proper to compose a living creature, distinguishing them by the name of *organic particles*, and that the moving bodies which are to be found in the infusions either of animal or vegetable substance, are of the same nature. But to this we may add, that all those who have examined the subject with accuracy and attention, concur in the belief that Buffon, and others who adopted his views, had deceived themselves by inaccurate experiments, and that Buffon himself had not even seen the spermatic animals he supposed himself to be describing. We do not altogether adopt this opinion : we are inclined to think that Buffon had occasionally seen the seminal animalcules, but it was through the medium of glasses ill-adapted for their development, that is to say, he observed them under the confused powers of a compound microscope of the old construction, the most unsuitable instrument that could possibly be employed in such researches. It is very evident that he saw nothing distinctly and satisfactorily, or he would not have confounded the spermatic animals with the gelatine masses that are occasionally found in the semen. He says,—" We do not always see, in the human semen, the filaments (tails) I have mentioned : for this purpose, the liquor must be examined the moment it is extracted from the body ; and even then they do not uniformly appear. When the liquor is too thick, it presents nothing but large globules, which may be distinguished with a common lens. When examined with the microscope they have the appearance of small oranges ; they are very opaque and one of them occupies the whole field of the microscope." He proceeds to say that after examining these globules, he diluted the semen and found nothing like life or motion therein. The sum of all this is, that the semen here alluded to was either unhealthy and contained no animalcules, or had been so long removed from the body, that the vital germs had ceased to exist, in which case they would blend with the liquor and be indistinguishable ; for it is a fact familiar to every observer of these creatures, that when their existence is drawing to a close they collect together in large groups, and when dead form nearly a homogeneous mass.

There is a strange degree of confusion throughout Buffon's experiments and observations on the spermatic animals, which can only be accounted for by assuming that his optical resources were inadequate, and that whilst he saw nothing with sufficient distinctness to furnish data for an accurate judgment, he was willing to bend all the phenomena he saw to the purpose of a preconceived and favourite theory. For instance, he speaks of the animalcules as being attached by their tails to some foreign substance, as evidently striving to rid themselves of the tails, and as actually accomplishing this and becoming in consequence more active and lively. The absurdity of these assertions is strikingly shown by observation with the improved microscopic powers of the present day. These animals are now readily seen in all their extent, and in all their movements ; the tail is not, as Buffon says, a mere filament, but an absolute elongation of the body, gradually tapering and terminating in the finest point imaginable ; and the animals evidently could not, if so disposed, free themselves from this appendage. Their motions are, as already noticed, precisely that of an eel or a serpent in water ; and if at any time they *appear* to lose their tails, it is when their motions are about to cease, when they are dying, at which time they not unfrequently coil themselves into a circular mass.

Mr Needham, who was contemporary with Buffon, endeavoured to prove that all seminal animalcules, so called, in place of being really animated beings, are only prodigiously small machines. He will be best understood in his own words, when describing the milt of the Calmar, a species of cuttle-fish, whose seminal animals resemble spiral springs inclosed in a transparent case. "When the small machines," he says, "have come to maturity, several of them act as soon as they are exposed to the air. Most of them, however, may be commodiously viewed by the microscope before their action commences; and even before they act, it is necessary to moisten with a drop of water the superior extremity of the external case, which then begins to expand, while the two slender ligaments that issue out of the case are twisted and contorted in different ways. At the same time, the screw rises slowly, and the spirals at its superior end approach each other, and act against the top of the case, those which are lower seeming to be continually followed by others that issue from the piston; *I say, that they seem to follow; because I believe it to be only a deception produced by the motion of the screw.*" We need not pursue his remarks further, as they would be unintelligible without a diagram. We may, however, add Buffon's remark upon his theory.

Mr Needham concludes that it is natural to imagine that the total action of this machine is occasioned by the spring of the screw. But unfortunately, he proves by several experiments, that *the screw is acted upon by a power residing in the spongy part:* as soon as the screw is separated from the rest of the machine, it ceases to act, and loses all motion." What then is the sum of Mr Needham's hypothesis? Simply this: that spermatic animals, like all other living creatures, considered apart from the vital principle, are machines; but that these machines have *within* them a motive and active force; or in other words, they are endued with vitality, by which they move and act independently of any external agent. The question of vitality, is not perilled by the statement that "even before they act, it is necessary to moisten the upper extremity." Sustenance is necessary to all animals; the organs cannot act without a material on which to act, and the inactivity of the organs is death or a suspension of vitality. The fact of apparent death, and repeated revivescence, at the pleasure of the experimentalist, is strikingly witnessed in the case of some Infusoria, that die when the moisture in which they exist evaporates, and revive again so soon as new fluid is applied to them. This phenomenon, it will also be remembered, is observable in a class of animalcules exhibiting a *peristaltic action*, and consequently identified with animal existences.

Buffon, as an additional argument against the actual vitality of seminal and other animalcules, instances the fact of minute active particles being found in various substances and under circumstances that totally preclude a living principle. These are nothing more than what in the present day are designated the active molecules of matter, those simple inorganized particles of every description of bodies which exhibit a singular and uniform activity, arising, as we have previously supposed, from their mutual action upon each other. And though when the seminal animals are crowded together, their motions appear to be almost the same with those of the molecules, we no sooner thin the multitudes of the former, and spread them over a larger space, than we distinctly perceive that their motions are independent of external causes, and are directed by a principle of volition resident in the individuals.

Having stated and replied to the principal objections that have been urged against the vitality of seminal animals, we shall briefly advert to the wild speculations which arose out of their discovery. Leeuwenhoeck and many others strenuously contended that these animalcules were really miniatures of human kind; "but what is still more amazing, Dalenpatius saw one of these animals break through its coat or covering: it was then no more an animalcule, but a real human body, in which he easily distinguished the two arms and legs, the breast and the head."! The doctrine of *evolution*, as it is termed, seemed to be established by the discovery of the spermatic animalcules: "according to it, all animals have existed from the first creation as *perfect, preformed germs*, within their *ancestors*, the succeeding generations being lodged in the preceding ones like nests of boxes, and progressively developed." There is a point where human reasoning must pause: in the present case, we must be content to know that the prolific animal fluid contains myriads of living creatures whose purpose in the generative economy still remains unknown. What new discoveries may be made concerning them with the vastly improved instruments now in use, it is impossible to say; we may however, venture an opinion that philosophic inquiry cannot be better employed than in eliciting by all the legitimate means which art and science progressively supply, more and more of the mysteries and wonders connected with the continual succession of animated beings.

INDEX.

*** The Italic letter *n* directs to the *note* in the page to which it is affixed.—The Roman numerals, of course, refer to the *volumes* of the work.

Abdominal-fish, characterised by the position of the ventral fins, ii. 294; the prickly finned, 299; the soft finned, 301—307.

Abstinence, benefits of occasional, i. 186; Queen Elizabeth's commands concerning, ib.; how defeated, ib.; of the primitive Christians, ib.; instances of abstinence, ib. *n.*

Acanthopterigii, or prickly-finned fish, ii. 294; the varieties specified and described, ii. 299.

Achilles the second, a Roman tribune, his strength, i. 180.

Acorn, shell-fish, account of the, ii. 374.

Adder, account of the common viper or adder, ii. 418, 419, *n.*; treatment for its bite, 420, *n.*

Adjutant, or gigantic crane, account of the, ii. 172, *n.*

Ægagus, a species of ibex, i. 303, *n.*

Ælian, his relations of the docility of the elephant, i. 519.

Æolipile, an instrument for producing wind, described, i. 116.

Ætna, in Sicily, a volcano, i. 41; eruption of, in 1537, 41; latest eruption of, ib. *n.*; description of, ib.

Africans. See *Negroes*.

Age, the effects of, on the human body, i. 204; on the bones, ib.; on the cartilages, ib.; instances of great age in man, 206; of fishes, how determined, ii. 247.

Agouti, distinguished from the rabbit in form, i. 444; its voracity, ib.; burrows in trees, ib.; habitudes, ib.; flesh, 445; how hunted, ib.; its cry, ib.; parturition, ib.

Ai, a species of sloth, i. 557.

Air, i. 104, its elasticity and weight, 104, 105, and *n.*; expansion, 107; instruments to measure its weight, 106—108, *n.*: analysis of atmospheric air, 109, *n.*; how changed from the elementary body, 108, 109, and 112; its corroding qualities, 109; necessary for vegetation and life, 110; that extracted from plants, &c., fatal to life, 110, 111; effects of, on man, ib.; the unwholesomeness of hot, 112; of cold, ib.; blessings of, 115; supports fire, ib.; conveys sounds, 116; odours, ib.; taste, ib.; instruments to ascertain the quantity of moisture in air, 113, *n.*; necessary to the life of fishes, ii. 246; how breathed by them, ib.

Air bladder of fishes, account of the, ii. 246, 247.

Air pump, account of the, i. 108.

Albatross, described by Edwards, ii. 204; by Wicquefort, 205; characteristics of the albatross tribe, 204, *n.*; its climate, ib.; said to sleep in the air, ib.; voracity and activity, 206; affection for the penguin, ib.; nests of the, on the Falkland Isles, ib.; removed, why, ib.; account of, in the West Indies, ib. *n.*; the chocolate, ib., *n.*; the yellow-nosed, ib.

Albouras, volcano of, i. 44.

Alcatrass, name given by Wicquefort to the albatross, ii. 205.

Aldrovandus, the natural historian, his credulity, liberality, and misfortunes, ii. 227.

Algæ, microscopic examination of, ii. 600.

Algazel, a kind of gazelle, i. 309.

Alligator, the, distinguished from the crocodile, ii. 392, *n.*, and 395; pike-headed alligator, 393, *n.*; alligators of the Ganges, ib.; sports with the, 394, *n.*

Aloë, transverse section of, ii. 602.

Alps, description of a person ascending the, i. 60; rocks fall from them, 63; clefts in them, ib.

Ambergris, a perfume obtained from the cachalot, ii. 264.

Ambrose, St, his credulity with respect to the halcyon, ii. 237.

America, South, Waterton's description of the birds of, ii. 165—167, *n.*

Americans, their pains in dressing their hair, i. 173; native, described, 213; its animals compared with those of the other hemisphere, 242.

Amia, a fish, noticed, ii. 306.

Ammodytes, a soft-finned fish, ii. 299.

———— a reptile resembling the common viper, ii. 421, *n.*

Amour, a river of Tartary, i. 77.

Amphibious quadrupeds, their characteristics, i. 474.

Amphisbæna, or double-headed serpent, ii. 428, and *n.*; its remarkable motions, ib.

Anaconda, a large snake so called, ii. 429, *n.*

Anarchicas, the wolf-fish, ii. 299.

Anatomy of the human body, i. 181, *n.*

Andes, volcanoes in the, i. 45; Ulloa's description of the, i. 60—62.

Anemometers, instruments to measure the velocity of the wind, i. 124; their imperfections, 125.

Angler, or fishing-frog, described, ii. 288, *n.*

Angora, goat of, described, i. 299, *n.*, and 302.

Anhima, a kind of crane found in Brazil, described, ii. 180.

Animalcules, infusorial, ii. 623, *et seq.*; have now become legitimate subjects of natural history, 623; their inconceivable minuteness, ib.; the term *infusorial* explained, ib.; hypothesis accounting for the presence of animalcules in infusions, ib.; Pritchard's summary of their characteristics and economy, 623—625; term *animalcule* defined, 623; discovery of internal structure of infusoria, 628; Ehrenberg's arrangement of them, 624; the cilia, their motions and uses, ib.; the setæ, ib.; the styli, ib.; variable processes, ib.; Baron Gleichen's experiments with animalcules, ib.; preparing infusions for production of animalcules, ib.; variety of shape and figure observable in infusoria, 625; modes of generation or production, ib.; remarkable discoveries by Ehrenberg, ib.; rapid motions of infusoria, ib.; ability to support extremes of heat and cold, ib.; Müller's scientific arrangement, 626; monads, ib.; the drop monad, ib.; monad species, ib., 627; proteus genus, 627; the melting proteus, ib.; proteus species, ib.; volvox genus, ib.; vegetable volvox, ib.; volvox globator, ib.; volvox species, 628; enchelis genus, ib.; egg-shaped enchelis, ib.; enchelis punctifera, ib.; enchelis retrograda, ib.; enchelis species, ib.; vibrio genus, 629; its divisions, ib.; paxillifer vibrio, ib.; vibrio lunula, ib.; wheat vibrio, ib., 630; remarkable tenacity of life in vibrio, 630; vibrio species, ib.; cyclidium genus, ib.; azure cyclidium, ib.; cyclidium species, ib.; paramœcium genus, 631; paramœcium chrysalis, ib.; paramœcium species, ib.; kolpoda genus, ib.; cuckoo kolpoda, ib.; kolpoda species, ib.; gonium genus, ib.; breast-plate gonium, ib.; gonium species, ib.; bursaria genus, 632; little swallow-like bursaria, ib.; bursaria species, ib.; cercaria genus, ib.; green cercaria, ib.; cercaria inquieta, ib.; cercaria species, ib.; leucophra genus, ib.; bracelet leucophra, ib.; leucophra cornuta, ib.; leucophra species, ib.; trichoda genus, 633; trichoda vulgaris, ib.; trichoda sol, ib.; trichoda cometa, ib.; trichoda bomba, ib.; trichoda species, ib.; kerona genus,

634; kerona pullasta, ib.; kerona species, ib.; himantopus genus, ib.; himantopus larva, ib.; himantopus species, ib.; vorticella genus, ib.; vorticella cyathini, 635; vorticella anastatica, ib.; vorticella digitalis, ib.; vorticella convallaria, 636; vorticella species, ib.; brachionus genus, 637; brachionus passus, ib.; brachionus Bakeri, ib.; brachionus species, ib.; concluding remarks, ib., 638. See, also, *Spermatic Animalcules.*

Animal Kingdom, discoveries therein by the microscope, ii. 602—623; bony structures, 602; muscles, ib.; horns, hoofs, nails, ib.; hedge-hog's quill, ib.; hairs, general description of, ib., 603; hair of dermestes, 603; of a mouse, ib.; of a bat, ib.; of a bee, ib.; of a dormouse, ib.; of a mole, ib.; of a caterpillar, ib.; feathers, general description of, ib.; filament of feather down, 604; bird-catching spider, hair of, ib.; humming bird, feathers of, ib.; singular formations connected with them, ib.; scales and perspiratory pores of the human skin, ib.; remarks thereon with reference to the preservation of health, 605; method of viewing the pores by the microscope, ib.; scales of fishes, ib.; of an eel, ib.; of a carp, ib.; hypothesis concerning these scales, and objections thereto, ib.; crystalline lenses of animals, ib.; Pritchard's remarks thereon, and Brewster's observations of the same, ib., 606; objections to Brewster's statements, 606; the blood and its circulation, ib; Pritchard's observations thereon, ib.; objects suited to exhibit the circulation of the blood, 607; peculiar motion of the globules of the blood, ib.; globules and discs in the serum of the blood, ib.; insects, their structure and transformation, ib.; eggs of insects, ib.; how and where deposited, ib.; eggs of the rhein-deer gad-fly, ib.; of the gnat, ib.; M. Lyonet's observations on the fecundity of a moth, ib.; larva, or caterpillar state of insects, 608; of the musca chamelion, ib.; extended description of, ib.; larva of a British hydrophilus, 609; Pritchard's description of same, 609—611; ichneumon fly deposits its eggs in the body of caterpillars, 611; capada worm, its sufferings from the attacks of the ichneumon fly, ib.; larva of ichneumon fly, 612; pupa state of insects, ib.; exuviæ, or cast-skins of insects, 613; singular instance of insect moultings, ib.; imago, or fly state of insects, ib.; the butterfly discovered by the microscope to be a beautiful emblem of immortality, ib.; members of insects, ib.; antennæ and palpi, ib.; their number and use, ib.; antennæ of bombyx antiqua, 614; of bombyx caja, ib.; feelers, ib.; eyes of insects, ib.; their varieties and numbers, ib.; stemmata, or single eyes, ib.; reticulated eyes, ib.; particular description of, ib.; eyes of the dragon-fly, ib., 615; other varieties, 615; tongue or proboscis of insects, ib.; of the papilio urticæ, ib.; tongue, or trunk of the common house-fly, ib.; Baker's description, ib.; trunk of the honey-bee, 616; legs and feet of insects, ib.; various kinds, ib.; leg and foot of dytiscus, ib.; legs of a bee, ib.; wings and wing cases of insects, ib.; elytra, ib.; the poisers, 617; wing case of diamond beetle, ib.; wing of a gnat, ib.; of an ichneumon fly, ib.; of an earwig, ib.; membrane of a butterfly's wing, ib.; dust which covers it, ib.; scales or feathers on the wings of butterflies, ib., 618; Goring's observations thereon, 618; characteristics of these objects, ib.; scale of red under-wing butterfly, ib.; of the brassica butterfly, ib.; of the podura, ib.; microscopic tests, ib.; scales of the lepisma, ib., 619; observations regarding the singular markings on these objects, 619; Brewster's theory, ib.; scale of menelaus butterfly, ib.; of the azure-blue butterfly, ib.; of the diamond beetle, ib.; of a moth, ib.; disposition of the scales on the wing, ib.; stings of insects, 620; poison bag, ib.; microscopical insects, ib.; monoculus, or water-flea, ib.; its eye, ib.; Pritchard's remarks on this object, 621; four-horned monoculus, ib.; lepisma, ib.; the lobster insects, and Adam's description thereof, ib., 622; singular peculiarity in the one described, 622; Seba's assertion regarding insects of this class, ib. See, also, *Animalcules.*

Animal remains, i. 19. See *Fossils.*

Animals distinguished from vegetables, i. 146; how they blend together, ib.; resemblance of animals and vegetables in affection, ib.; in the climates in which they luxuriate, 147; comparative number of animals and plants, ib., *n.*; in the ocean, 148; how few useful to man, 149; consume one another, ib.; the small numerous, the large ferocious, ib.; different generative powers of animals and plants, 150, *n.*; their generation, 151; distinguished thereby, 152; some multiplied by cutting, ib. (see *Generation*); their comparative perfection, 160; great variety of, 229; use of systematic divisions of, 230; defects of, ib., 231; systems of different authors, 231, 232; the classification used in this work, 233—236; the wild and domestic, 240; affected by food, climate, &c., 241; size of, in different continents, 242.

Ant, ancient fame of the, ii. 535; modern doubts, ib.; varieties of appearance, ib.; the body of the, described, 536; display of forces, 539; divisions in respect of sex, ib.; male and female, ib.; the working class, ib.; their hills, ib.; objects of labour, ib.; contests with one another, ib.; female and eggs, ib.; maggot state, 540; care of the female, ib.; loss of wings, ib.; preparations of the workers for winter, ib.; size of the hills in tropical countries, ib.; the African species, 541; migrations, ib.; the wood-ant or pismire described, 535, *n.*; carpenter ants, 536, *n.*; sugar ants, 537, *n.*; white ants, or termites, ib.; singular structure of their nests, ib., 538, *n.*

Ant-bear, one of the animals that live on ants, i. 555, and *n.*; varieties, ib.; described, ib.; its snout, 556; mouth, ib.; tongue, ib.; helplessness, ib.; residence, ib.; food, ib.; method of taking ants, ib.; manner of defence, ib.

Antelope, animals of that kind, i. 304; the class scientifically described, ib., and *n.*; the antelope described, 309; the Indian, ib. *n.*; striped antelope, 310, *n.*; pigmy, 311, and *n.*; African antelopes, ib., *n.*

Antennæ and palpi of insects, ii. 613.

Antioch, earthquakes there, i. 49.

Antiparos, grotto of Magnis, account of a visit to, i. 33—35.

Antlers of the elk, described, i. 335; of the rein-deer, ib.; of the stag, 319, 320; technical names of the, 324.

Ant-Lion. See *Lion-Ant.*

Ape, the, i. 497; the long-armed, or gibbon, ib.; described, ib., 498, and *n.*; Barbary ape, 498, *n.*

Aperea, or Brazilian rabbit, i. 426.

Aphides, or plant lice, ii. 460, *n.*

Apicius, his method of dressing a hare, i. 433.

Apodal fish, what, ii. 294; prickly-finned, ib.; soft-finned, 299.

Arabia, the wild horse of, i. 246; estimation and treatment of the horse there, 247, 248; its breed of horses introduced into England, 258.

Aratoo, the goliath aratoo parrot, ii. 119, *n.*

Archimedes, his method of determining the purity of gold, i. 72.

Arequipa, a burning mountain in Peru, i. 45.

Argali, a wild mountain sheep, described, i. 297, *n.*; Asiatic argali, ib.; American argali, ib.; bearded argali, ib.

Argentine, the fish described, ii. 302.

Argonaut, a small shell-fish, ii. 364, and *n.*

Aristophanes, his advice about lions, i. 369.

Arlotta, a sleep walker, story of, i. 190.

Armadillo, or Tatou, an inhabitant of the new continent, i. 468, 469; its shell described, 469, 470; method of rolling itself up for defence, 470; bears our climate, ib.; burrows, ib.; their strong resistance when burrowing, ib.; how taken then, ib.; rolls down precipices, ib.; roots like the hog, ib.; lives with the rattlesnake, how, ib.; varieties of the, ib.; the pig-headed, 471; the weasel-headed, ib.

Arms, human, their shape, i. 175.

Arnee, a species of buffalo, described, i. 283, *n.*

Artedi, his classification of fishes, ii. 293.

Asiatics, the southern, described, i. 211, 212.

Asp, a venomous snake, ii. 423.

Asperea, by some called the Brazilian rabbit, described, i. 446.

Aspic Viper, so called, ii. 424, *n.*

Ass, its similitude to the horse, i. 258; distinctness of the species, 259; the wild ass, ib.; hunting the wild ass, ib., *n.*; habits of the, 260, *n.*; effect of internal emotion on the, ib.; flesh of the wild ass eaten by the Persians, ib.; wild in America, how hunted, 261; anecdote of the sagacity of the ass, ib., *n.*; Sterne's illustration of the patience of the, ib.; patience of the

tame, 262; habits of the, ib.; bad treatment of the ass general, ib.; highly esteemed in early times, ib., 263, *n.*; its strength and other qualifications, 263; esteemed by the Spaniards, ib.; once lost in England, now common, ib.; of different countries, ib.; its diseases, age, &c., ib.
Asterias, or star-fish tribe, described, ii. 561.
Astronomy, definition of, i. 1; comparative sizes of the planets, ib., 2, and *n.*; account of the different planetary systems, the Ptolemaic, the Egyptian, the Tychonic, the Copernican, and the Newtonian, ib., 3, *n.*; description of the sun and planetary bodies, 5, 6, *n.*; of comets, 7, *n.*; of fixed stars, ib., 8, *n.*
Atalantis, island of, disappeared, i. 56.
Athanatus, his strength, i. 180.
Athelstan, his attention to the improvement of the horse, i. 255.
Athenians, cock-fighting among the, ii. 62; quail-fighting, 85.
Atherine, description of the fish, ii. 301.
Atmosphere. See *Air*.
Attitudes of the body express passion, i. 171, 172.
Attraction and *Impulsion*, influence of, i. 3—5; nature and effects of the attraction of gravitation, ib. *n.*
——, —— how it produces the tides, i. 90.
Auk, characters of the class, i. 219; the great auk, ib., *n.*
Aurelia or *Chrysalis*, state of ephemera, ii. 486; of the caterpillar, 491; operations in that state described, 494, 495.
Aurora Borealis, phenomena of the, i. 136, *n.*
Aurora Monkey, i. 307, 308.
Avosetta, description of the, ii. 189, and *n.*; its extraordinary bill, 190.
Axis Deer of eastern Asia, i. 327, *n.*

B

Baboon, relative position among animals, i. 499; the, described, ib.; its facial angle, ib. and *n.*; disposition in the savage state, ib.; account of the, at the Cape of Good Hope, 500; tamed there, ib.; ferocity of one described by Buffon, ib.; food, ib.; internal structure, ib.; varieties, mandril, ib.; wanderow, 501; maimon, ib.; dog-faced baboon, ib. *n.*
Baby, a dwarf, account of, i. 221, 222.
Babyrouessa, or Indian hog, why classed among the hog kind, i. 351; the, described, ib.; its tusks, ib.; herd together, ib.; dispositions, ib.; food, ib.; country, 352.
Back, shape of, in man, i. 176.
Bacon, his remarks on the age of fishes, ii. 247.
Badger, its appearance, i. 551, and *n.*; habits, ib.; habitation, ib.; carnivorous, ib.; gestation, ib.; the young tameable, ib.; instances of attachment of the, ib. *n.*; the spotted badger, 552, *n.*; the American badger, ib.
Bag of some animals. See *Pouch*.
Bahama Islands, poisonous quality of the fish caught near one of the, ii. 324; by what caused, ib.
Bait for fish, what the best, ii. 275; what shell fish used for, 352; white, account of it, 318.
Balance, hydrostatical, i. 72.
Baldness, where it first takes place, i. 168.
Balearic Crane, ii. 178. See *Crane*.
Baltic Sea, its inundations, i. 99.
Bantam Cock and Hen, ii. 64, *n.*
Barbary Hen. See *Hen*.
Barbel, fish, account of the, ii. 320, *n.*
Barbs, or *Barbary horses*, i. 248; Italian sport with the, ib., 249.
——— of certain flat fish, ii. 277.
Baris, a small tribe of the oran-outang, account of the, i. 495.
Barnacle, distinguished from the wild goose, ii. 229.
Barometer, instrument to measure the weight of the air, i. 107; ascertains the height of mountains, 108.
Barretiere, Philip, his long sleep, i. 189.
Basilisk, a species of lizard, account of the, ii. 403, *n.*
Bass, the resort of the solan goose, described, ii. 209.
Bastard wing of birds, what, ii. 2.
Bat kind, animals of the, where placed by different naturalists, i. 471; most resemble quadrupeds, ib.; the, of England described, ib.; its appearance and habits, ib.; a tame one seen by Mr White, could rise from the ground, ib.; is torpid in winter, 472; its retreats, ib.; makes no nest for the young, ib.; similitude to birds, ib.; that of our country harmless, varieties of the, 473; the long-eared, horse-shoe, and rhinoceros bats, ib.; that of the East and West Indies, ib.; formidable, ib.; numerous, ib.; the great, of Madagascar, ib.; described, ib.; voracity, ib.; American vampyre, ib.
Bear, varieties, i. 544, and *n.*; the brown, where found, ib. and *n.*; solitary animal, ib.; its den, 545; sleeps during the winter, ib.; gestation, ib.; voice, ib.; capable of instruction, 546; not tameable when aged, ib.; hunted, ib.; bear baiting, 545, *n.*; black bear of America, habits and manners of the, ib. *n.*; bear hunting in America, 546, *n.*; description of the grizzly bear, 547, *n.*; Bengal bear, 548, *n.*; the white Greenland, distinguished, ib. *n.*, and 549; sagacity of the, 548, *n.*; its size in cold climates, ib.; how shot, ib.; abundance, ib.; haunts, 550.
Beard, customs of nations in the manner of wearing the, i. 172, 173, and *n.*
Beauty, female, when it is perfected, i. 166; tastes of different nations in regard to, ib.; of the human figure, 176.
Beaver, the remains of brutal society, i. 477, and *n.*; its disposition, 478, and *n.*; singularities in its form, ib., 480; their assembling, ib.; formation of a dike, ib.; their apartments described, ib., 481; provisions, ib.; how caught, ib.
Bee, Reaumur's diligent researches into the history of the, ii. 513; the three kinds in every hive, ib.; the labouring, ib.; the drone, ib.; the queen bee, ib.; structure of the bee, 514; teeth, ib.; how it collects wax, 516; Hunter and Huber's experiments, ib., *n.*; the belly described, ib.; honey-bag, 517; sting, ib.; community of the, ib.; four companies in constructing cells, ib.; form of the cells, ib.; passages, ib.; uses of the cells, ib.; manner of constructing the combs, ib.; honey cells, 518; food, ib.; stomachs, ib.; bee bread, ib.; honey, whence extracted, ib.; eggs, 519; the bee's care of the worm, 520; labours of the worm, ib.; transformations, ib.; the young bees, 521; swarming, 522; settling, ib.; labours, ib.; slaughter of the drones, 523; number of swarms, ib.; rearing of bees, ib.; floating bee-houses in France, ib.; their wax, 524, and *n.*; arts in using the propolis, ib.; honey, 525; the bee of Gaudaloupe, ib.; the humble, ib., and *n.*; the wood, 526; the ground, ib.; the leaf-cutting, 527; the wall, ib.; inmates of a hive, 513, *n.*; functions of the queen, ib.; functions of the worker bee, ib.; functions of the drone, 514, *n.*; on the conversion of the larva of a worker into a queen, 519, *n.*; description of different hives, 521, 522, *n.*; the carpenter-bee, 526, *n.*; the poppy-bee, 528, *n.*; the carding-bee, ib.
Beetle, characteristics of the class, ii. 541; transmutations, ib., 542; cases of their wings, ib.; differences in size, ib.; dorr-beetle, (see *May-bug*); general characteristics, 542—547; the elephant, where found, 547; general description of the class of beetles, ib., 548, *n.*
Bell. See *Diving-bell*.
Belly of the Oppossum. See *Pouch*.
Beluga, or *White Whale*, ii. 260, *n.*
Beroe, a molluscous animal, described, ii. 376, *n.*
Bewailer. See *Sai*.
Bezoar, German, a concretion found in the stomach of the chamois, its supposed properties, i. 307; described, 308, 309; oriental and occidental, 44; hog, ib.
Birds, their adaptations, ii. 1; conformation, 2, and *n.*; feathers, ib.; wings, ib.; head, 3; their internal structure, 4, 5; incubation, 7; nest, 8; professor Blumenbach's summary of the characteristic qualities of birds, 7—10, *n.*; construction of nests, 10, *n.*; different styles of nests, 11, *n.*; immense number of insects destroyed by birds, 12, 13, *n.*; migration of birds, 15, 16, *n.*; classification of, 17; according to Linnæus, 18; their use, 28; adaptation, 29; habits, 30; their fecundity small, ib.; superiority of the female, ib.; classification of, ib., 31; of the poultry kind, their utility, 59; characteristics, ib.; sociability, ib.; love of eating, ib., 60; sensuality and infidelity, ib.; habit of dusting themselves, 61; of the pie kind, 86; of the sparrow kind, 130; time of song of British birds, 132, *n.*; voices of birds, 133, *n.*, and 137; of the crane kind, 170; influence of birds on the imagination, 239.

Bird-catching, how performed, ii. 131.
Biscayneers, their method of whale fishing, ii. 256.
Bison, described, i. 276, *n.* and 277; where found, 278 and *n.*; usefulness among the Hottentots, 280; diversities of, ib.
Bitch. See *Dog*.
Bittern, dismal note of the, ii. 104—105; the bird described, ib.; its windpipe, ib.; habitudes, ib.; flesh, ib.
Bivalve shell fish, ii. 352, and 365; compared with univalve.
Blackbird, the, described, ii. 141 and *n.*
Blackcap, its loud note, ii. 152; migration of the, ib.; incubation, ib.; note of the, ib.; description of, 153, *n.*
Black vomit, fatal symptom of the Chapotonadas, i. 112.
Bleak or *Blay*, river fish, notice of the, ii. 320, *n.*
Blenny, account of the fish, ii. 295.
Blindness, progress of the perceptions of a person having it removed, i. 193.
Blindworm, a harmless reptile, described, ii. 427, 428; motion, 428; eyes, ib.; viviparous, ib.
Blood, how affected by the air, i. 115; its colour, ib.; its circulation, ii. 606; subjects in which it is most readily seen, 607.
Blood hounds, English, i. 393.
Bluebird, its colour and change of, i. 142; note and articulations, 143; how caught, ib.; haunts, ib.
Blushing, how produced, i. 171.
Boa constrictor, account of the, ii. 429, *n.*
Boar, wild, described, i. 341; their strength and method of defence, ib.; how hunted, 342 and *n.*; a native of Britain, 344.
Bobak, the marmout in Poland, i 444.
Body, human, its figure, i. 176; size, ib.; weight, 177; strength; 177—180.
Boiguaca, a great serpent, described, ii. 430; habits, ib.
Bonasus, a name of the bison, i. 277.
Bones, the, visited by the blood, i. 204; experiment proving this, ib.; how affected by age, ib.
—— microscopic examination of, ii. 602.
Bonet chinois, a kind of monkey, i. 506.
Bonito, the fish, described, ii. 306.
Bottle-tit, or *long-tailed titmouse*, ii. 154, *n.*
Bottom of the sea, changes produced there, i. 102; nature of, in the Red sea, ib.; near America, ib.; nature of, in general, ib.
Boyuna, serpent of Ceylon, how regarded there, ii. 428.
Brachionus genus of infusoria, ii. 637.
Brain, first seen in the embryo, i. 192.
Brambling, a kind of finch, ii. 159, *n.* and 161.
Bramins, sensibility of their sense of smell, i. 201.
Bream, river fish, notice of the, ii. 297 and 320, *n.*
Breast, human, its form, i. 175, 176; female, ib.; its beauty, ib.; Darwin's theory that it is the origin of our ideas of beauty, 175, *n.*
Breezes. See *Land and Sea Breezes*.
Brisson, his classification of animals, i. 233.
Bubalus, of the ancients, of the cow kind, i. 277; a kind of gazelle, described, 310.
Buffalo, distinguished from the cow, i. 281; described, ib. *n.* and 283; Cape buffalo described, 282, *n*; Indian and Chinese buffalo, 283, *n.*; domestic buffalo, ib.; native country of the buffalo, 284; dangers from the, in a wild state, ib.; method of escaping, ib.
Buffon, his theory of the earth, i. 16; character of, 18; his opinion concerning the formation of fossils, 27; his speculations concerning generation, 152; his description of the perceptions of a man imagined newly created, 202; his errors regarding the sperm animals, ii. 638.
Bug, account of the, ii. 461; the bed bug, ib. *n.*; the leek green bug, 462, *n.*; the harvest bug, ib.
Bull, musk, the wild or urus, described, i. 276.
Bull-dog, the, described, i. 391, *n.* and 394, 395.
Bullfinch, one of our finest cage birds, ii. 156, *n.*; its vocal powers, habits, &c. ib.
Bullhead or *Cottas*, a fish, ii. 298, 320, *n.*
Bungai or *rock serpents*, ii. 430, *n.*
Buntings, description of the, ii. 151, *n.*; the yellow bunting, ib.; the foolish bunting, 152, *n.*; the cirl bunting, ib.; the reed bunting, ib.; the common bunting, ib.; the ortolan bunting, ib.; the snow bunting, ib.
Burnet, Thomas, his theory of the earth, i. 13, 14.
Burrampooter, its source, size, and course, i. 77, *n.*
Bursaria genus of infusoria, ii. 632.
Bustard, its size and properties, ii. 76; where found, ib.; food, ib.; difficulty to be shot, and why, ib.; chased by grayhounds, ib.; the pouch of, a reservoir for water, ib.; incubation, 77; different species, ib. *n.*; food in winter, 77; age, ib.; the little, described, ib. and *n.*; how taken, ib.; habitudes, ib.
Butcher bird, the species classed, ii. 50; otherwise called shrikes, ib. *n.*; the lesser or red-backed, 50, 51, *n.*; the greater, 50, 52, *n.*; marks of the, ib.; its intrepidity, 51; prey, ib.; method of catching its prey, ib.; nest of the, ib.; varieties.
Butterfly, transformations of the, ii. 495, *n.*; account of the butterflies and moths, 499—505 and *n.*; butterfly a beautiful emblem of immortality, 613.
Buzzard, a kind of falcon, the common, described, ii. 49 and *n.*; varieties, ib.; rough legged, ib. *n.*; honey-buzzard, ib. *n.*

C

Cabiai, i. 350. See *Capibara*.
Cachalot, distinctions among the varieties of the tribe, ii. 263 and *n.*; size, ib.; properties, ib.; pursued for its spermaceti and ambergris, ib.; how these substances obtained from it, ib. 264.
Caqui. See *Saki*.
Calabria, earthquake at, 1638, i. 49, *n.* and 51, 52.
Calandre, a bird resembling the lark, ii. 151, *n.*
Calao or *horned Indian raven*, ii. 96.
Calf, the young of the stag, i 319.
Call birds, how used by the bird-catcher, ii. 131.
Callitrix, kind of monkey, noticed, i. 507.
Callyonomus or *Drogonet*, account of the fish, ii. 295.
Calmucks, a Tartar race, described, i. 201.
Camel, two species of, i. 535, 536; and *n.*; fitness for travelling in desert countries, 537, 538, and *n.*; does not multiply in cold countries, 538; uses to the Arabian, ib. 539; docility, ib.; structure of its stomach, ib.; use in commerce, ib.; patience, ib.; Buffon's opinion concerning the, ib.; the hump, 540; produce of the animal to the Arabian, ib.
Cameleon, the, described, ii. 403; swelling and contraction of itself, ib.; the skin, ib.; protuberances, ib.; account of some by Le Bruyn, 404; seldom opens its mouth, ib.; turns one eye towards a different direction from the other, ib.; general description of, ib. *n.*
Camelopard, or *giraffe*, its extraordinary size and appearance, i. 534; description of, ib. *n.*; habits of the, 535, *n.*; account of four brought to England, ib.
Campagnol, economic, a species of mouse, i. 452, *n.*
Canary bird, whence brought, ii. 155; original colour and varieties, ib.; food and habits of the domesticated canary, ib. *n.*; its song, 156; rules for choosing the bird, 159; breeding of the bird, ib.; method in Germany, 160; common apparatus, ib.; mixed breed with the linnet, ib.
Cane Del Grotto, noxious effects of the atmosphere in, i. 39.
Cantharis, the, or Spanish fly, a kind of beetle, described, ii. 549; where found, ib.; food. Cantharides, how prepared, 551; their effects, ib.
Capada worm, its sufferings from the ichneumon fly, ii. 611.
Capercailzie or *cock of the wood*, ii. 78, and *n.*
Capibara, account of, the hog kind, i. 350; its resemblance to the hog, ib.; description of the, ib.; frequents rivers and lakes, ib.; taste of its flesh, 351.
Capons, used for clutching chickens, ii. 63.
Caracal, where found, i. 381, 383; how connected with the lion, 383; prey of the, ib.; account of one which died in the Tower, ib.
Carbonic acid gas, a compound of air, i. 109, *n.*
Carcajou, name of the glutton in North America, i. 425. See *Glutton*.
Carli, Father, how tended by monkeys, i. 504, 505.
Carp, the, described, ii. 305, and *n.*; habitudes of, ib.; fed out of water, 308; growth of the, 318; how fished for, 320 *n.*; gold and silver carp, 306, *n.*
Carpenter or *wood bee*, described, ii. 338; choice or formation of her hole and nest, ib., 339; eggs and young, 340, 341.
Carrier pigeon, described, ii. 127; whence so named, ib.

Carthagena, unwholesomeness of the air there, from heat, i. 112.
Cartilaginous Fishes, why the tribe so named, ii. 268; distinctions of the, ib.; double capacity of breathing, and organs for, ib.; generation, ib.; various methods of bringing forth, 269; anomalous, 286; characteristics and classification of, 268; flat fish, 273.
Cashmere Shawl Goat, account of the, i. 299, 300.
Cassique, a bird of South America, ii. 166, *n.*
Cassowary, its country and climate, ii. 25, and *n.*; description of the, ib.; its remarkable head, 26; its internal parts, ib.; quiet disposition, ib.; voracity, 27; scarcity, ib.
Cat, dispositions of the, i. 356; form and habits, ib.; generation, ib.; prey, ib.; patience, 357; form of their eye, ib.; how far tamed, ib.; other habits, ib.; use of cats' whiskers, 355, *n.*; reason of cats alighting on their feet when falling, ib.; British wild cat distinct from the domestic cat, 357, *n.*; varieties of the domestic cat, 359, *n.*; moral qualities of the cat, ib., 360, *n.*; cat of the New Continent, 359.
—— wild, how distinguished, i. 357, *n.*, and 358; its abodes, ib.; internal characteristics, ib.
Cat Fish, notice of the, ii. 185, 298, *n.*
Cat kind, animals of the, their properties and distinctive peculiarities, i. 353, and *n.*; their resemblance to one another, 355; their claws, ib.; teeth, ib.; manner of seizing their prey, ib., 356; dispositions, ib.; animals of the, difficulty of distinguishing the, 376.
Cat Lion, or of Angora, described, i. 359.
Catacombs, Egyptian sepulchres, account of the, i. 226.
Catamountain, or tiger cat, described, i. 379, 382, *n.*
Cataracts of rivers, i. 81.
Caterpillars, account of, ii. 490; their transformations, 491—499, and *n.*; leaf-rolling caterpillars, 496, 497, *n.*; of the enemies of the caterpillar, 505.
Caverns in the earth, i. 32; description of several, ib., 35; origin of, ib.
Caviar Sturgeon, discriminated, ii. 283; the caviar, whence furnished, ib., 285; how prepared, ib.
Cayman, the, a species of crocodile, ii. 395, and 393, *n.*
Cellular tissue of Plants, ii. 601.
Centipede, a name of the scolopendra, ii. 466; the great centipede, 467, *n.*
Cepola, the fish described, ii. 290.
Cerastes, a reptile of Africa, ii. 421, *n.*
Cercaria, genus of infusoria, ii. 632.
Cetaceous Fishes, called the great beasts of the ocean, ii. 249; why ranked as fishes, ib.; analogy to quadrupeds, ib.; manner of breathing, ib.; senses, 250; young, ib.; maternal tenderness of, ib.; distinctive marks of the tribe, ib.; and of its subdivisions, ib. See *Whale*.
Chætodon, or *Cat Fish*, discriminated, ii. 297.
Chaffinch, their migration described, ii. 137; its habits, vocal powers, &c., 156, 157, *n.*
Chamois, its properties, i. 304, and *n.*; where found, 304; acuteness of its senses, 305; its voice, ib.; its actions when alarmed, ib.; beauty of its eyes, ib.; the animal described, ib.; its motions, ib.; how hunted, 306, 307; its skin, 307; what parts of the, said to be medicinal, ib.; account of the chamois hunters of the Alps, 306, *n.*
Channel of Rivers, the form of the, i. 75; effect of incumbrances on the, 76; rendered navigable, 81.
Chapotonadas, a malignant distemper, i. 112.
Charles I. of England, his body found embalmed, i. 229.
——— *XII.*, his action on being shot, i. 208.
Chase of the Stag, in Scotland, i. 322; in England, 323, 326; technical language employed in the, 324; the chase anciently, ib.; in Sicily, 326; in China, ib.
Chasms in the Earth, i. 31, 32; in mountains, 63.
Chat genus of birds, ii. 153, *n.*
Chatterer, account of the, ii. 99.
Cheselden, his account of the perceptions of a boy who was restored to sight, i. 193.
Chetah. See *Leopard*.
Chevrotin, or *little Guinea Deer*, i. 311.
Chickens, method of hatching in stoves, ii. 63; clutched by capons, ib.
Chigoe, a troublesome insect, account of the, ii. 456, *n.*
Child in the womb, history of the, i. 158; state of when born, 161.
Childers, the horse, speed of, i. 253, and *n.*
Chimpanse, a species of oran outang, i. 491, *n.*
Chinese, the, described, i. 211.
Chochi, or *Thrush of Paraguay*, ii. 139, *n.*
Chough, Cornish, account of the, ii. 94.
Chrysalis, change of the caterpillar into that state, ii. 494, 495; meaning of the term, 494.
Chub, fish, description of, ii. 307, *n.*; how fished for, 320, *n.*
Cicada, the ancient, how distinguished from the grasshopper, ii. 476, *n.*
Citrel Finch, account of the, ii. 159, *n.*
Civet, varieties of the, i. 423; its form and colours, ib.; its pouch described, ib.; how the perfume obtained, ib.; where reared, ib.; the perfume at Amsterdam reckoned the best, ib.; quantity of perfume obtained, 424; commerce in its perfume, ib.; its food, ib.; its dispositions, ib.
Classification of animals, by different authors, i. 231, *n.*, 232; that used in this work, 233—235; remarks on its utility, ii. 166; of fish, remarks on the, 347.
Clavicles, or *Collar Bones*, to what animals peculiar, i. 175.
Clematis, transverse section of, ii. 602.
Clouds, how produced, i. 128; how converted into rain, 129.
Coal, mode of working coal mines, i. 37, *n.*
Coan, a dwarf, account of, i. 221.
Coati, a kind of monkey, i. 308.
Coatimondi, a kind of weasel, i. 553; its description, ib., and *n.*; is tamed, ib.; mode of sleeping, ib.
Cobra di Capello, or *Hooded Serpent*, ii. 424, *n.*; the petro de cobra, or serpent stone, 426.
Cochineal, the insect described, ii. 551.
Cochlearia, the snail sties of the Romans, ii. 362.
Cock, early domestication and varieties of the, ii. 61; original country, ib., and *n.*; where found wild, ib.; ancient estimations of its colour, ib., 62; boldness of several breeds, ib.; salacity of the, ib.; varieties of the domestic cock and hen, 64, *n.*; the dunghill cock and hen, ib.; the Dorking cock and hen, ib.; the Poland cock and hen, ib.; the every-day cock and hen, ib.; the bantam cock and hen, ib.; the Chittagong, or Malay hen, ib.; the shack-bag, or duke of Leed' breed, ib.; the improved Spanish cock and hen, ib.; instructions regarding breeding, 65, *n.*
Cock of the wood, ii. 78, and *n.*; cock of the plain, 80, *n.*
Cock fighting, early practised, ii. 62; an ungenerous amusement, ib.
Cockatoo, the tri-coloured crested, ii. 118, *n.*
Cockle, shell-fish, notice of the, ii. 365, *n.*
Codfish, the, discriminated, ii. 299, and *n.*; its peregrinations, 309, 310; easily taken, 320.
Cold, effects of, on water, i. 69; on the atmosphere, 112; how it acts in increasing and refining fur, 414.
Colouring of Shells, how accounted for, ii. 349.
Colours, aid our ideas of distance, i. 194; the variable, of the cameleon, described, ii. 403.
Comets, account of, i. 6; theories regarding, 7, *n.*
Complexion, different, of the human race, i. 214; which colour preferable, ib.; how produced, 215; four varieties of the complexion of the skin, ib.; darkened by cold, &c., 216.
Compression of water, i. 70.
Conchology, sketch of the different systems of, ii. 350—353, *n.* See *Shells*.
Condoma, or *Striped Antelope*, described, i. 310.
Condor of America, whether of the eagle or vulture kind, ii. 37; size and strength, 38; description of, as seen by Condamine, ib.; Labat's account, 39; account of one by Mr Strong, ib.; by P. Feuille, ib.; whether the same as the Arabian Roc, and others, ib.; its true character first made known by Baron Von Humboldt, ib., 40, *n.*; its habits described, 40.
Conepate, a variety of the stinkard, i. 421.
Confervæ, ii. 601.
Congelation, ii. 583.
Coot, the, discriminated from the water-hen and other birds, ii. 197, 198; habitudes of the, 198.
Coral, what kinds found in a fossil state, i. 22; description of islands of, 55, *n.*; plants, where found, ii. 571; their appearance, 572; to what kingdom they belong, ib.; different opinions, ib.; the plant examined, ib.; its inhabitants, ib.; account of the formation of coral, 571, 572, *n.*
Corbet, Peter, superintended the destruction of wolves in England, i. 402.

Cordier, M. his investigation concerning subterraneous heat, i. 48.
Corin, a kind of gazelle, i. 308.
Cormorant, size and description of the, ii. 206 and *n.* appetite, ib.; fetid odour, ib.; how used in fishing, ib.; bird's activity in pursuing its prey, 208.
Cornaro, his life prolonged by temperance, i. 205.
Corn-crake or *land-rail*, described, ii. 197, *n.*
Corrira, a bird of the crane kind, its long legs, ii. 190.
Corruption of dead bodies, how caused, i. 226; how prevented, ib.
Corryphæna, or *Razor fish*, noticed, ii. 296.
Cotingas, birds of South America, ii. 165, *n.*
Cotopaxi, volcano of, i. 45.
Cottus or *Bullhead*, a prickly finned fish, ii. 298.
Couando, distinguished from the porcupine, i. 467.
Cougar or *Red Tiger of America*, described, i. 374; formidable nature, ib.; its habits, 375; how encountered, ib.; combats with the crocodile, 376; where found, 375, 376; flesh of the, 376.
Coughing, how caused, i. 171, *n.*
Coulterneb, the puffin, why so called, ii. 219.
Cow kind, animals of the, i. 269; usefulness, 270; food, ib.; teeth, ib.; age, how known, ib.; horns, 271; native wild breed, description of, ib. *n*; English breed of the cow, how improved, ib.; how affected by its pasture, ib.; differences in its size, ib.; form, 272; originally of a common stock, ib.; different breeds of the, ib. *n.*; in Tartary, Egypt, Abyssinia, Denmark, the Crimea, Germany, France, &c. ib.; different breeds in Britain, ib.; the long-horned or Lancashire breed, ib.; the short-horned, ib.; the middle-horned, 273, *n.*; the Devonshire cattle, ib.; the Sussex and Herefordshire cattle, ib.; the polled or hornless breed, 274, *n.*; the Galloway breed, ib.; the Suffolk duns, ib.; the Ayrshire breed, ib.; cattle of the highlands of Scotland, 275; the Argyleshire breed, ib.; the cattle of Orkney and Zetland, ib.; the Fifeshire cattle, ib.; cattle of Aberdeenshire, 276; Welsh cattle, ib.; Alderney cattle, ib.; Irish cattle, ib.; in Iceland, 277; other countries, ib.; that with the hump, ib. (See *Bison*); how to distinguish the classes of this kind, 285; an animal uniting the characters of the hog and, 285.
Crab, the resemblance of its habits to those of the lobster, ii. 327; where found, 332; the, described, ib.; account of the violet land-crab, ib.; strength of its claw, 334; orderly society and march, ib.; casting of the spawn, 335; return, ib.; casting of the shell, ib. and 329, *n.*; in the mountains impregnable, 335; uses of, ib.; general characteristics of the crab, 332, *n.*, and 334, *n.*; the fleet running crab, 332, *n.*; the land crab, 333, *n.* the soldier crab, ib., and 337, 338; modes of taking crabs, 335, 336, *n.*
Crabs-eyes, improperly so called, what they are, ii. 330.
Crane kind, birds of the, ii. 171; their distinctive qualities, ib.; legs, ib.; bill, ib.; not domesticated and why, 172; food, ib.; tribes, ib.; smaller birds of the, distinguished, 190; enumerated, ib.; their properties, 191, 193; food, 193; adaptations, 194; climate, ib.; migrations, 195; residents, ib.; nestling, 196; method of taking, 197.
—— real dimensions of the, ii. 172; different species, ib. *n.*; fables concerning the, and their origin, 173; countries of the, ib.; migrations, ib.; scarcely ever seen with us, and the reason why, ib.; favourite climate of the, ib.; depredations, ib.; aerial journeys, 174; loud cry and its use, ib.; the wind-pipe, tamed, 175; affection for man, ib.; popular respect for the, ib.; Balearic, doubts concerning the, 178; its remarkable appearance, 179; its country, ib.; habitudes, ib.; cranes distinguished from storks and herons, 180, 181, *n.*; Numidian, the Demoiselle, 180.
Cray or *craw fish*, a species of lobster, described, ii. 331 and *n.*
Creepers, birds resembling woodpeckers, ii. 108, *n.*
Cricetus or *German rat*, the, described, i. 454; its pouches, ib.; voracity, ib.; construction of its abode, 455, 456; its stores, 456; propagation, ib.; fur, ib.
Cricket, account of the, ii. 481, 482 and *n.*; the mole-cricket, 482, 483.
Crocodile, distinguished from the alligator, ii. 392, 393, *n.*; double-crested crocodile, ib.; its resorts, 395; where largest and fiercest, ib., two varieties, ib.; size of the, ib.; description taken from one, ib.; the internal parts, 396; its habitudes, ib.; strength, ib.; on what occasions it seeks the land, ib.; manner of seizing its prey, ib.; contest with the tiger, 397; how killed by the negro, ib.; how taken by the Siamese, ib.; managed like a horse, ib.; Waterton's ride on a crocodile's back, noticed, ib. *n.*; how taken in Africa, ib.; state of the, in Egypt, 398; accounted for, ib.; where inoffensive, ib.; musky smell of the, ib.; flesh, ib.; eggs, and manner of breeding, ib.; whether it devours its young, 399; age of the, ib.; produced in the Roman amphitheatres, ib. and 395.
Crow, the, its characteristics, ii. 87—96; different species of crows, 87, *n.*; carrion crow, 89, *n.* and 93; hooded crow, ib.; rook, 90, *n.* and 93 and 94, *n.*
Crustaceous shell-fish characterised, ii. 326; classified, ib. and 575—578.
Crystalline lenses of animals, ii. 605.
Crystallization, ii. 589.
Cuckoo, the, described, ii. 110, 111 and *n.*; habits of the, ib. *n.*; its call, ib.; female makes no nest, 112; its food, ib.; its migration, ib.; varieties, 113; the honey guide, ib. and *n.*
Cuckoo spit or *Froth worm*, account of the, ii. 275, 276.
Cud, class of animals that chew the, i. 268. See *Ruminating animals.*
Curassows, American birds of the poultry kind, ii. 71, *n.*; the crested curassow, ib.; the galeated curassow, 72, *n.*; the razor-billed curassow, ib.
Curlew, description of the common curlew and little curlew, ii. 190, *n.*
Currents of the ocean, their causes, i. 92; where most violent, 93; that in the Mediterranean, ib.; various, 96.
Currents of air, some double, i. 124. See *Wind.*
Cuticle of plants, ii. 597.
Cuttle fish, the, described, ii. 561, 562; spurts forth a dark liquor when pursued, ib.
Cuvier, his classification of dogs, i. 38; the same explained, 388.
Cyclidium genus of infusoria, ii. 630.
Cyclosis or *circulation in plants*, ii. 596, 597.

D

Dab fish, described, ii. 301, *n.*; lemon dab, ib.
Dace, *dart*, or *dare*, how fished for, ii. 321, *n.*
Dagenham in Essex, trees discovered by an inundation of the sea there, i. 100.
Damp or *deleterious air*, fatal effects of, in mines, i. 37. See *Gas.* See *Lamp Safety.*
Danube, its course and depth, i. 77; rivers received by, 80.
Darkness, how far the eye accommodates to, i. 195; story illustrating the subject, ib.
Deafness, causes of, i. 199; perceptions of one recovered from, ib.; state of one born deaf, ib.; case of James Mitchell, born blind and deaf, 200, *n.*
Dead Sea, its saltness, i. 85.
Death, many causes of, i. 207; generally calmly endured, ib.; not really terrible, 208; reflection in the article of, ib.; gradual approach of, ib.; uncertainty of the signs of, ib.
Death-watch, beetle, described, ii. 552, *n.*
Decoys for ducks, how managed, ii. 235; value of some, 236; those in China, ib.
Deductor or *ca'ing whale*, ii. 261, *n.*
Deer kind, properties of the, i. 319; the stag, ib. &c.; red, or wild stag, 322; red deer in Scotland, 323, *n.*; fallow deer in ditto, 324, *n.*; axis deer of the East Indies, 327, *n.* See *Stag*, *Fallow deer* and *Rein deer.*
Defence, methods taken by animals for their, i. 240.
Demoiselle, why a kind of crane so called, ii. 180; account of the, ib.
Depona, a great serpent of Mexico, the mouth described, ii. 427; the body, 430; harmless, ib.
Description of animals, its utility and method, i. 235.
Desman, the, a kind of musk rat, i. 454.
Dew, how produced, i. 130 and *n.*; how its remaining on bodies is affected by their conducting powers, ib.
Dixbleret, fall of a part of the mountain of, i. 63.
Diamond, microscopic examination of, ii. 592.
Diamond beetle, wing case of, ii. 617
Digester, ascertaining the elasticity of air, i. 108.
Diseases from heat, i. 111; from cold, 112; from moisture,

ib.; from effluvia, 113; Boyle's reasons for revolutions in, 115.
Disposition of animals affected by climate, i. 241.
Disruptions of mountains, i. 63.
Distance, whence our notions of, i. 193.
Diver, the great Northern, its size and colours, ii. 219, and *n.*; speckled diver, ib., *n.*
Diving-bell, Dr Halley's, i. 103.
Dodo, its body, bill, legs, &c., described, ii. 27; country, ib.; flesh, ib.; whether the bird of Nazareth, ib.; a now extinct animal, 28, *n.*
Dog, the, why not generally used in the chase in Eastern countries, i. 382; intelligence, courage, and affection of, 385; anecdotes of dogs, ib., *n.*; important uses of the, 385; to the shepherd, 386; in the chase, ib.; the wild, described, ib.; fidelity of the dog, ib.; diversities of the breed, ib.; original sameness, ib., 387; internal structure the same, ib.; which the original kind, 388; proofs, ib., 391; a new classification of dogs from Cuvier, 387, *n.*; these divisions and their varieties described, ib., *n.*; the New Holland dog, the Dhole, the South American dog, the North American dog, ib., *n.*; the French matin, the Irish greyhound, the great Danish dog, the common greyhound, the Scotch greyhound, the Russian greyhound, the Italian greyhound, 388, *n.*; the shepherd's dog, the terrier, the wolf-dog, the Siberian dog, the Esquimaux dog, 389, *n.*; the spaniel, the setter, the Alpine spaniel, the Newfoundland dog (with anecdote), 390, *n.*; the smaller spaniel, the Maltese dog, the great water spaniel, the hound, the pointer, the turnspit, the bulldog, 391, *n.*; the pug-dog, the mastiff, 392, *n.*; old classification, the hound, harrier, and beagle, 391; gray matin, 393; mastiff, ib.; English, classified by Caius, 393, 394; the Turkish dog described, 394; the Irish wolf-dog described, ib., 395; Indian dogs, fortitude of the, shown to Alexander the Great, 395; flesh of the, where eaten, 396; instances of the enmity between the dog and wolf, ib.; and the fox, ib., 397; description of the dog when whelped, 397; its generation, ib.; madness of the, 398.
Dog kind, characteristics of the, i. 384; habitudes, ib.; qualifications of the, ib.; sense of smelling, ib.
Dog-butcher, in China, attacked by dogs, i. 266.
Dog-fish, the spotted, ii. 270, *n.*; the small spotted, 273, *n.*; the large spotted, ib.
Dogger Sands, a bank formed by two tides meeting, i. 97.

Don, its course, i. 77.
Dorado, the, beautiful colours of the fish, ii. 319; pursues the flying fish, ib.
Doree, a prickly-finned fish, noticed, ii. 298.
Dormouse, its varieties, i. 453; habits, 454; sleeps in winter, ib.
Dorr-beetle, or *May-bug*. See *May-bug.*
Douc, monkey of Cochin China, i. 307.
Dragon-fly, account of the, ii. 470; the depressed dragon-fly, 472, *n.*; the black winged dragon-fly, ib.
Drawings of animals, Locke's opinion of the advantage of, i. 235.
Dreams, how fashioned, i. 187; effects of, 189; sleep-walking, 190; how accounted for, ib.
Dress, savages careful with respect to, i. 173; observations concerning, 174; objects pursued in, ib.
Drill of Purchas, the oran-outang, i. 491.
Dromedary, its distinction from the camel, i. 535, and *n.* See *Camel.*
Duck, the domestic, easily reared, ii. 231; hatched by the hen, ib.; rearing of ducks in China, ib., *n.*; distinguished from the wild, 232; wild duck, or mallard, characteristics and habits of, 231, 232, *n.*; sea ducks, ib.; pond, 232; eider, ib., and *n.*, 235; tufted, 233; nest of the wild duck in the Arctic regions, 234; the down, how obtained, ib.; appearance of the, when it comes among us, 235; choice of residence, ib.; the call of the, ib.; nocturnal adventures, ib.; how taken by a decoy, ib.; manner of taking them in China, 236; summer, the, of America, builds its nest on a tree, 235; and perches, ib.
Dunlin, the, described, ii. 194, *n.*
Dwarfs, i. 220; account of several, ib.; of the marriage of two celebrated by Peter of Russia, ib.; of Jeffrey, ib.; of Baby, ib.—222.
Dwina river, its course, i. 77.
Dziggtai, a species of the horse, described, i. 264, *n.*

E

Eagle, description of the, and its affinities, ii. 31; the abode of the, ib.; habits, ib.; not entirely tameable, ib.; flight of the, 32; eye, ib.; strength, ib.; prey, ib; instances of the, taking away children, ib.; localities in England and Scotland where the golden eagle is to be found, ib., *n.*; manner in which the eagle hunts for its prey, ib.; formidable when rearing the young, ib.; instances of retaliation in the, ib.; the nest of the, described, 33; plumage and change of colour, ib.; food, ib.; varieties, 31—33; the golden, ib; the common, 34; bald, ib.; Wilson's description of the bald-headed eagle, ib., *n.*; white, ib.; rough-footed, ib.; white-tailed, ib.; favourite haunts on the northern coasts of Scotland, ib., *n.*; erne, 35; black, ib.; sea, ib., and *n.*; bird of Washington, a species of sea eagle, described, 36, 37, *n.*; osprey, 36, and *n.*; Jean de blanc, ib.; that of Brazil, 36; Oroonoko, ib.; crowned African, ib.; that of Pondicherry, ib.; martial eagle, or griffard, 38, *n.*; balbuzzard, ib.; great harpy, ib.; wedge-tailed eagle, ib.
Ear, human, remarks on the, i. 172; construction of the, 198.
Earth, its magnitude, i. 1; its comparative insignificance in the great scale of creation, ib., *n.*; its situation in the solar system, 9 and 7, *n.*; its motions, ib.; proofs of its rotundity, 9; exact shape, ib.; its regions, 10, 11; appearance of its surface, 11, 12; internal structure, 12; theories of the, 13—17, and 16, *n.*; strata of the, 28 and *n.*; their order, 30; fertility of the, 29—31; chasms in the, 31, 32; changed by the ocean, 96; its defences against the sea, ib.; considered in relation to the Deity, 144, 145; varieties of its provisions, 145; the earth gloomy without man, ib.; fitted for his abode, ib.; how subdued to his use, 149.
Earthquakes, i. 46; different kinds of, ib.; causes of, 46, 47, and *n.*; several mentioned, 47—52; concomitant circumstances, 52; swallow mountains, 64.
Earwig, the, described, ii. 483 and *n.*; wing of, 617.
Ecacoalt, the Indian name of the rattle-snake, on what supposition given, ii. 623.
Echineis, or sucking fish, the, ii. 300.
Echini, ii. 373. See *Urchins.*
Echo, cause of the, i. 198; cannot be made by art, ib.
Education, different methods of, i. 163; what the best, 164; how to be pursued, ib.; when most rapid, ib.
Eel, electric, account of the, ii. 279, *n.*; anecdotes of the, 280, *n.*.
Eels, Mr Yarrell's account of, ii. 286—288, *n.*; how fished for, 320, 321, *n.*; descends towards the sea to spawn, 309; viviparous, 318.
Egg, what animals produced from the, i. 154; disposition of substances in the, 155; progress of the animal in the, traced by Malpighi and Haller, 154, 156, 157; analogies between it and the embryo, 156—158.
Eggs, sea, ii. 373. See *Urchins.*
Egyptians, their embalmings described, i. 224; their sepulchres, 226; present superiority of their horses, 249.
Eider-duck, account of the, ii. 232 and *n.*
Ehrenberg's discoveries relating to infusoria, ii. 625.
Elasticity of the air, i. 107.
Elephant, its appearance, i. 515; size, ib.; description, 516; distinction between the African and Asiatic elephant, ib., *n.*; strength of the, 516; peaceableness, ib.; gregarious habits, ib., 517; haunts, 517; movements of the, ib., *n.*; food, 517; excellence of its senses, ib., 518; the trunk and its uses described, 518—520, and *n.*; strong sense of smell, 518, *n.*; habits of the, ib.; its difficulty of motion and encumbrances, 519; tusks, ib.; its method of eating and drinking, 520; its hide, ib.; the elephantiasis, ib.; where found and how used in different countries, 521; first elephant seen in England, ib., *n.*; the white esteemed, 521; propagation, ib.; reproduction of the elephant

when domesticated, 522, *n.*; violently affected during rutting time, ib. *n.*; different methods of capturing the elephant, 523—525, *n.*; how hunted by Indian princes, 522, 523; hunted in Africa, 523; at the Cape of Good Hope, 527, 528; method of taking the goondah or male elephant by means of the koom-kees or females, 524; docility when tame, 523, 526; instances, 526; used in war, ib.; and in sports, 527, *n.*; in carrying burdens, ib.; in executions, ib.; instance of the fatal exertions of one, ib.; of retaliation, ib.; of gratitude, ib.; ancient and modern commerce in its ivory, ib. and *n.*; its teeth or tusks, 528; the fossil species, ib., and *n.*

Elephantiasis, or Arabian leprosy, i. 520.

Elizabeth, Queen, her regulations concerning fasting, i. 186; encouraged the woollen manufacture, i. 288.

Elk, its country, i. 332 and *n.*; description of the, ib.; its haunts, ib.; how pursued by the Indians, ib.; easily tamed, ib.; size of the, 332, 333; description of one shown at Paris, 333; the American, ib.; their climate, 334; a hunt of the, described, ib.; its flesh, horns, ib. &c.; diseases, 335; mistakes concerning the, ib.

Elops, or *Sea serpent*, ii. 299.

Ely, country round, deteriorated by the sea, i. 99; said to be so named from rents being formerly paid there in eels, ii. 288, *n.*

Embalming, early practised, i. 224; how performed by the Egyptians, ib.; by the Guanches, 225; by the Peruvians, ib.; in France, 228.

Embryo, progress of the embryo in lower animals, i. 157; in man, 157—160.

Emigration of birds. See *Birds*.

Emu or *American Ostrich*, ii. 23; the term now applied to the New Holland ostrich, ib. *n.*; description of the, 23, 24, *n.*

Enchelis genus of infusoria, ii. 628.

Encoubert, a kind of armadillo, i. 471.

England, dogs of, Dr Caius' classification of the, i. 394.

Ephemera, account of the, ii. 485, and *n.*

Equator, earth at the, i. 10.

Ermine, its size and description, i. 413; its fur and its change of colour, 413, 414; when called the stoat, ib.; why its fur refined by cold, 413; its scent and food, 414; where found and how caught, ib.

Erne, a species of eagle, ii. 35.

Eruptions. See *Volcanoes*.

Esculapian, serpents of Italy, how regarded there, ii. 428.

Esox. See *Pike*.

Eunuchs, barbarous policy in making, i. 165; in Italy, ib.; described, 166.

European race of men, described, i. 213.

Eustachian tube, hearing by the, i. 199.

Evaporation, investigations regarding, i. 94, *n.*; of water, how it produces clouds, 129; Hamilton's theory concerning, ib.; how affected by heat, ib.; frost, &c. ib.; how affected by night, 130.

Expression of the different parts of the human body, i. 167; the face, ib.; the eyes, &c. 167—172.

Exuviation, process of, in shrimps, lobsters, and crabs, ii. 328, 330, *n.*; in insects, 613; singular instance of, ib.

Eyes, state of them, in man at birth, i. 161; their expression, 167; their motions, ib.; colours, ib.; alone varied, ib.; early formed, 191; not exercised immediately after birth, 192; invert objects, ib.; another error in sight, ib.; benefit of having two eyes, 193; state of the, at different ages, 195; accommodate to light and darkness, ib.; physiology of the, ib. *n.*; of a cat, i. 356; of birds, their conformation, ii. 3; of insects, their varieties and numbers, 614.

Eyebrows, and eyelashes, their expression, i. 168.

Eyelids, their use, i. 168.

F

Face, human, its energy, i. 167; on what its expression depends, ib.; form of the human, how affected, 217.

Falcon kind, used in hawking, ii. 44 and *n.*; what varieties used in the sport, 44; the generous, how distinguished, 45; the gyr falcon, 45, *n.* and 46; peregrine falcon, 45, *n.*; the falcon, 46; falcon gentil, ib.; the lanner, 47; kestril and merlin, 45, *n.* and 47; their spirit, ib.; method of training the, 47; method of pursuing and taking different animals, 45; the ignobler varieties, 48; the secretary falcon, 50, *n.* See *Kite Buzzard*.

Falcons, the gentle, used in hunting gazelles, i. 314; their manner of pursuing, 315.

Falconry, an ancient sport, ii. 44; the hawk on hand in paintings a mark of rank, ib.; expences of the sport, ib.; how the bird trained for the sport, 47; how distinguished, 44.

Fallow-deer, in Scotland, 324, *n.*; distinguished from the stag, i. 328, and *n.*; their properties, ib.; contest of the, 328; tamed, ib.; their gestation, ib.; the chase of the, 329; their varieties, ib.; those of Guiana, ib.

Fangs, venomous, of the serpent, account of the, ii. 416.

Farina of flowers, as seen by the microscope, ii. 598.

Fascination, the, of the rattle-snake, account of, ii. 423.

Fashion, influence of, i. 174, *n.*

Fauvette, winter, ii. 153, *n.*

Fawn, the young of the fallow-deer, i. 329; of the roebuck, 331.

Feathers of birds, their position and beauty, ii. 1, 2; for beds, whence obtained, 230; how cured, ib.; examined under the microscope, ii. 603, 604; feathers of humming birds, 604.

Female sex, how treated by savages, i. 165, 166; their privileges in polished countries, 166; shape of the, 167; their comparative weakness, 181; in general live longer than men, why, 205.

Ferns, their seed vessels, &c., as seen by the microscope ii. 600.

Ferret, its country, i. 414; the, described, ib.; its climate, 415; prey, ib.; how used in hunting rabbits, ib.; parturition of the, ib.; sleep of the, ib.; its smell and bite, ib.

Field-fares, a species of thrush, ii. 133, *n.*; field-fare of Canada, 140, *n.*

Figure, human, its proportions, i. 176.

File-fish, ii. 374, 375. See *Pholas*.

Finches, account of the, ii. 136 and 156—159, *n.*

Fins of fishes, described, with their uses, ii. 242.

Fire, supported by air, i. 115.

Fires of St Helmo, meteors in Jamaica, description of, i. 134.

Fire-flare ray, ii. 273; its spine, ib.; terrible to fishermen, 275—277; ancient fables concerning it, 278; used to head arrows, ib.; whether venomous, ib.

Fishes, their abodes, ii. 240, 241; numbers, ib.; form, 242; fins, ib.; glutinous covering and scales, 243; smelling, ib.; tasting, ib.; hearing, ib. and *n.*; seeing, 243; eye described, ib.; appetite, 244; maws and digestion, ib.; can endure want of food, 245; yet voracious, ib.; their hostility to one another, ib.; migrations, ib.; require air, ib.; proofs, 246; use of the gills, ib.; the air bladder and its use, ib.; their age, 247; methods of determining, ib.; extreme fecundity of, 248; generation, ib.; spawn, ib.; classification, ib.; whether nourishing, ib.; why not salt to the taste, 249 and *n.*; professor Blumenbach's summary of the characteristic qualities of fishes, 240, 241, *n.*; comparison by baron Cuvier between fishes and birds, 244, *n.*; account of the fish usually taken by anglers in Great Britain, 320—323, *n.*

Fishing-frog or *Angler*, described, ii. 288, *n.*

Fistularia, the fish described, ii. 301.

Flamingo, its class, ii. 187; properties, ib.; haunts, ib.; in what state found by the Europeans in America, ib.; disposition now, 188; venerated by the negroes, ib.; untameable, ib.; flesh, ib.; flocks of the, ib.; manner of feeding, 189; nests and young, ib.

Flat-fish, cartilaginous, ii. 273.

Flea, account of the, ii. 455 and *n.*

Floss, the external coating of the silk cone, ii. 511.

Flounder or *Fluke*, described, ii. 301, *n.*; bearded flounder, ib.

Flower, microscopic examination of a, ii. 597.

Fluidity, by what bodies possessed, i. 70.

Flur-birds, how used by the bird catcher, ii. 131.

Fly, account of the house-fly, ii. 487, 489, *n.* See *Dragon-fly*.

Flying-fish, a soft-finned abdominal fish, ii. 303; Captain Basil Hall's account of the, ib. *n.*; pursued by the dorado, 319; in the air by the albatross, ib.

Fœtor, the horrible, of some serpents, ii. 408, 113.
Fongwang, the Chinese, description of that bird, ii. 75.
Fontenelle, his long life, i. 206.
Food, necessity of, to man, i. 183; its influence on animals, 242.
Foot, human, shape of the, i. 176.
Forehead, human, its proportions, i. 168.
Forests, found beneath the earth, i. 99.
Fossils, opinions concerning their formation, i. 19—21 and *n.*; 22; in what countries found, 21, 22; their varieties, 22; found in the stones of one of the pyramids of Egypt, 25; elephants, an account of, i. 528; (see *Mammoth*); shells, in what condition found, ii. 358.
Fouine, name given by M. Buffon to the yellow-breasted martin, i. 417. See *Martin*.
Foumart or *polecat*, described, i. 415 and *n.*
Fox, its resemblance to the dog, i. 403 and *n.*; distinguished from it, and the wolf, 404; its cunning, ib.; in choosing a residence, ib.; in taking and conveying its prey, ib.; its food ib.; chase of the, 403, *n.* and 405; generation, 405; antipathy of animals to the, ib., 406; different kinds of the, 406.
Frog, the, adapted to live on land or in water, ii. 377; distinguished from the toad, ib.; its appearance, ib.; its internal parts described, ib.; Raesal's plates of the, 378; copulation of the, ib.; impregnation, ib.; eggs from a female, 380; their appearance, ib.; progress of the, to perfect frog, 379, *n.* and 380; manner of life, 381; season of enjoyment, ib.; age, ib.; food, 382; manner of catching it, 383; vivacity, ib.; one kept eight years in a glass, ib.; tenacious of life after the head off and other injuries, ib.; croaking described, ib.; season of, ib.; adheres to the backs of fishes, 384; story of one clinging to a pike and eating out its eyes, ib.; different developements of embryo of frogs, 378—380, *n.*; various species of frogs, described, the common frog, the green frog, the bull frog, the tree frog, and the fire frog, 381—383, *n.*
Frog, the fishing, described, ii. 283 and *n.*; how it takes its prey, 289; doubts, ib.
Froth-worm, the, account of, ii. 484.
Fungi, as seen by the microscope, ii. 601.
Furs, of northern quadrupeds, why so abundant and fine, i. 414.

G

Gad-fly, injurious to the rein-deer in Lapland, i. 337.
Gagal, a species of bison, described, i. 279, *n.*
Gall insect, its residence, ii. 553; how introduced into the gall nut, ib.; how nourished, ib.; its escape from the nut, ib.
Galley-fish, appears like a bubble, ii. 291; described, ib.; whether it moves, ib.; size in America, ib.; colours and transparency, ib.; causticity of the, ib.; poisonous nature of the, 325.
Gally worm, the, how distinguished from the Scolopendra, ii. 467; appearance, ib.; how produced, ib.
Game laws, arbitrary nature of the, ii. 82.
Ganges, its origin and course, i. 77 and *n.*; venerated by the Indians, 78.
Gannet or *solan goose*, described, ii. 208, and *n.*; haunts of the, 209; migrations, 210; quickness of sight, ib.; its eyelids, ib.; eggs and young, ib.; profit from the sale of the, ib.
Gar-fish, described, ii. 290, *n.*
Gartar-fish, the, distinguished, ii. 300.
Gaur, a species of bison, described, i. 279, *n.*
Gaze hounds, the English, described, i. 393; how employed, ib.
Gazelles, a species of antelope, i. 304, *n.*; their distinguishing marks, 307 and *n.*; beauty, ib.; Buffon's varieties of the, 308, 309; additional varieties, 310; their general properties, 311, 312; method of hunting them, 314, 315.
Gekko, a kind of salamander, ii. 400; reported to be poisonous, ib.; probably not so, ib.
Generation of animals, i. 150; different generative powers of animals and plants, ib., *n.*; whence the fecundity, ib.; Harvey's theory of, 151; Leuwenhoeck's, ib.; Buffon's speculations concerning, 152; objections to, ib.; distinction of animals in respect of their, ib.; by cutting, 153; from the egg, 154; traced, 156; from embryo, 157; in man, ib.; comparative perfection of, in different animals in respect of, 160; of animals, 243.
Genet, its beauty and perfume, i. 422; described and distinguished, ib.; its glands, ib.; tamed at Constantinople, ib.; scarcity of the, 423; its character, ib.
Genettes, Spanish, described, i. 250.
Geology. See *Earth*.
Geranda, a serpent of the East Indies, how regarded by the natives, ii. 428; that of Africa also worshipped, ib.
Gerboa. See *Jerboa*.
Giants, existence of a race of, ascertained, i. 222, 223.
Gibbon, or *long-armed ape*, described, i. 497, 499; several species noticed, 497, 498, *n.*
Gilthead, or *ophidium*, the fish described, ii. 295.
Giraffe. See *Camelopard*.
Glow-worm, difference of the male and female, ii. 548; the female described, ib.; its light whence, and how emitted, ib., *n.*
Glutton, differences of opinion concerning the, i. 424; Klein's account of one from Siberia, ib.; considered, ib.; where found, ib.; discription of the, ib.; its manner of taking its prey, ib., 425 and *n.*; prefers putrid flesh, 425; pursues the beaver, ib.; its stratagems, ib.; its impudence, 426; parturition, ib.; value of its skin, ib.
Gluttony, its injuries, i. 186.
Gnat, injurious to the rein-deer, i. 337; manner of laying her eggs in the water, ii. 554 and *n.*; change of form, ib.; into a nymph, ib.; the fly, ib.; its trunk, ib.; stings, ib.; method of using them, ib.; state during winter, ib.; their formidable nature in America, 556; wing of a gnat, 617.
Gnu, a singular species of African antelope, described, i. 312, *n.*
Goat, nearly allied to the sheep, i. 286, *n.*; characteristics and properties of the, i. 299; their qualities, ib.; acuteness of their senses, 300; fitted for a life of liberty, ib.; natural attachment to man, proof of its, 301; propagation of the, ib.; qualities of its milk, ib.; flesh ib.; pasture, ib.; varieties of the, 302; Angora goat, described, ib. and 299, *n.*; the Assyrian, ib.; African, ib.; the blue, 302; the Juda, ib.; diversities and analogies of the different kinds, ib.; the ibex and chamois, 302, 304, *n.*; goats of Wales, 299, *n.*; Cashmere shawl goat, ib.; singular dexterity of a goat, 300, *n.*; goats used in suckling children, 301, *n.*
Goatsuckers or *nocturnal swallows*, ii. 162, *n.*; European goatsucker, ib.
Gobius. See *Gudgeon*.
Godwin Sands, i. 99.
Godwits, distinguished from snipes and woodcocks, ii. 192, *n.*
Gold, not corroded by the atmosphere, i. 109.
Goldfinch, habits, vocal powers, &c. of the, ii. 157, *n.*
Gonium genus of infusoria, ii. 631.
Goose, characteristics of the wild, ii. 227, 228, and *n.*; where it breeds, 229; flight described, ib.; fecundity of the tame, 230; its valiant defence of its young, ib.; flesh of the young, ib.; goose feathers, ib.; commerce in, ib.; varieties of the bird, the barnacle, 229; account of the Canadian goose, ib. *n.*; the spur winged goose, 230, *n.*
Goose, solan. See *Gannet*.
Goose kind, characteristics of the, ii. 222; bill, ib.; food, ib.; fecundity, ib.; flesh, ib.; domestication, 223.
Gooseander, account of the, ii. 222 and *n.*
Goosehawk, a species of falcon, ii. 46, *n.*
Gottenburge, in Sweden, cataract near, i. 81.
Gouan, Mr, his classification of spinous fishes, ii. 294—307.
Graaf, his investigation of the growth of animals in the womb, i. 157.
Grampus, how distinguished, ii. 264; its agility, 265.
Grasshoper, account of the, ii. 475—478.
Grayling, fish, ii. 303, *n.* and 321, *n.*
Gravitation, account of the nature and effects of the attraction of, i. 3, 5, *n.*; Sir Isaac Newton's great discovery on this subject, ib.
Grebe, analogies of the bird, to the web-footed and crane class, ii. 198; account of the bird, 198, 219, *n.*; use of its skin, 199.
Greenlanders, &c. described, i. 209; their pride, 211; hardihood, ib.

Greyhound. See *Dog.*
Grounding, or *Loach*, ii. 321.
Grouse, and its affinities, ii. 77; numerous species in North America, ib., *n.*; European grouse, ib.; the cock of the wood, or capercailzie, formerly plentiful in Scotland, now extinct, 78 and *n.*; description of its habits, ib; endeavours to restore it to Scotland, 79, *n.*; the black grouse, or black cock, ib.; the red grouse, or muirfowl, ib.; the white grouse, or ptarmigan, 80, *n.*; the rock grouse, ib.; the sand grouse, ib.; the heteroclitus grouse, ib.; the cock of the plain, ib.
Growth of the human body traced, i. 162; of the mind, 163, 164.
Grubs, account of various kinds of, ii. 543—546, *n.*
Guan, a bird of the poultry kind, described, ii. 72, *n.*
Guanches, their method of embalming, i. 225.
Gudgeon, the, noticed, ii. 295; how fished for, 321, *n.*
Guiba, a kind of gazelle, i. 310.
Guillemot, a sea bird, described, ii. 219, *n.*; the black guillemot, ib.
Guinea Pig, its country, i. 446; the animal described, ib.; its helplessness, ib.; domesticated, ib.; habits and food in that state, ib.; cleanliness, 447; manner of sleeping, ib.; salacity and generation of the, ib.; contentions of the, ib.; timidity, ib.; is tamed, ib.; grunt of the, ib.; flesh of the, ib.
Gulls, characteristics of the class, ii. 201 and 212, *n.*; of the smaller kind, 210, 211; haunts, 212; sublimity of the scenes in which they often appear, ib., 213; contests while breeding, 213; nests and eggs, ib.; the birds how taken, 214; varieties, 210.
Gurnard, properties of the fish, ii. 298.
Gymnotus, or *Electric Eel*, account of the, ii. 279, *n.*, and 299.

H

Haddock, a species of cod, described, ii. 300, *n.*
Hæmorrhois, a viper, why so called, ii. 423.
Hag-fish, or *Borer*, a species of lamprey, ii. 282, *n.*
Hail, how produced, i. 130, and 131, *n.*; storm in Hertfordshire, 1697, description of the, 132; of the one in France, 1510, ib.
Hair of the human head contributes to beauty, i. 169; different modes of wearing the, ib., *n.*; what fails soonest, ib.; its diversities, 169; structure, ib., and *n.*; colour, ib.; in different nations, ib.; its relation to temperament, ib., 170; effect of the atmosphere on, ib., *n.*; practices of different nations with respect to, 172, 173.
Hairs of different animals microscopically examined, ii. 603.
Halcyon, the king-fisher, ii. 237; fables and poems concerning the, 238.
Halley's theory to explain the constant east winds near the tropics, i. 121.
Halo round the moon, i. 136.
Hamster, name given by Buffon to the German rat, i. 454; the anomalous hamster, 455, *n.*
Hand, the connection between the hand and intellect, i. 202.
Hare, its adaptation for flight and swiftness, i. 427; description of the common hare, the Irish hare, and the white hare, 428, 429, *n.*; its numerous enemies, 429; fertility, 430; extraordinary arrangement for this, ib.; treatment of young, ib.; food, ib.; sleep, ib.; pairing, ib.; motion in flight, ib.; age, 431; voice, ib.; instincts for self-preservation, ib.; shifts to escape, 432; their furs, 433; effect of heat on the, ib.; flesh of the, by what nations not eaten, ib.; by what esteemed, ib.; decrease of numbers, 434; Cowper's description of three hares which he domesticated, 430—432, *n.*; difficulty of finding a hare by the eye, 432, *n.*; terms used in hare hunting, 433, *n.*; Brazilian hare, ib.
—— *kind*, swiftness of the, i. 426; characteristics of the, ib.; method of determining, ib.; their food, ib.; motion of their lips, ib.; prolific propagation, ib.
Harfang, great Hudson's Bay owl, ii. 55.
Harrier, the, described, i. 391, 393.
—— a species of falcon, ii. 49, *n.*; marsh-harriers, ib. *n.*; hen harrier, 50, *n.*; ash-coloured harrier, ib., *n.*
Hart. See *Stag.*
Harvey's theory of generation, i. 151.
Hatching Eggs, artificial method of, i. 154, *n.*
Hatfield Chace, in Yorkshire, reduced to cultivation, i. 101.
Hawk, the, and hawking, ii. 44. See *Falcon*, *Falconry*, *Goshawk*, and *Sparrowhawk.*
Hawk-moths, account of, ii. 499—501, *n.*
Head, state of, in man at birth, i. 162.
Hearing, i. 195; errors to which liable, ib.; its object sound, ib.; defects of, 199; inequality of, with different ears, ib.; necessity of, to man, ib.; how the sense of, supplied in birds, ii. 5.
Heat of atmosphere, variation of, in descending mines, i. 36; causes of this, ib.; its effects on water, 69; produces a noxious quality in the air, 111.
Hecla, volcano of, i. 42.
Hedgehog, characteristics of the species, i. 461; prickles of the, 462; harmlessness, ib.; varieties, ib.; method of defence, ib., 463; habits and food, 463; habits in a tame state, described by Buffon, ib.; propagation, ib.; blood, ib.; said to be proof against poison, ib. *n.*; prey or live on animals, ib.; anecdotes of, 464, *n.*; sea, discriminated, ii. 291; hedgehog's quills, as seen under the microscope, 602.
Helmo. See *Fires of St Helmo.*
Hen, hatching of the, and number of its eggs, ii. 62; affection for her chickens, 63.
—— *Guinea* or *Barbary*, ii. 79. See *Pintado.*
—— water, account of the, ii. 197, 198.
Hermaphrodites, all snails such, ii. 360; sea snails peculiar, 362; bivalve shell-fish, 365.
Hermits, abstinence and long life of several, i. 186.
Herodotus, his description of the Egyptian method of embalming, i. 224.
Heron, the, distinguished from the crane and stork, ii. 180—182, and *n.*; the common heron described, 181, *n.*; its habits, ib.; how taken, 182, *n.*; the night heron, ib.; the crested purple heron, ib.; crab-eaters and egrets, ib.; varieties, 182; the common purple, ib.; heron hawking, 183; prey of the, ib.; flesh of the, esteemed in France, 184; heronries, ib.; longevity of the, ib.
Herring, the, characterised, ii. 303; where chiefly found, 310; why it migrates, ib.; destructive enemies of the, ib.; progress of the phalanx of the, ib.; arrival on our coasts, 311; its columns, ib.; detachments, ib.; whether any return, ib.; frequents a favourite bank for many years, and then seeks another, ib.; general account of its habitudes, 311—313, *n.*; mode of taking and curing herring, 313, *n.*; the Dutch herring fishery, 314, *n.*
Hiera, a new island, i. 53; has increased, 54.
Himantopus genus of infusoria, ii. 634.
Hind, female of the stag, i. 219; her cry, 321; courage and sagacity, 322.
Hippocampus, a fish, account of the, ii. 290.
Hippopotamus, description of the, i. 532; head of the, ib., *n.*; haunts, ib.; manner of life and prey, 533; strength, ib.; manner of escape, ib.; flesh of the, ib.; propagation, ib.; where found, 534.
Hoanho, river in China, i. 77; receives thirty-five rivers, 80.
Hoar-frost, what, i. 130.
Hobby, a species of hawk, ii. 45, *n.*
Hog kind, animals of the, their distinguishing properties, i. 342; hunting the wild hog in India, 343, *n.*; hog trained as a pointer, 345, *n.*; domestic breeds of swine, 346, *n.*; flesh of swine unwholesome in hot climates, ib.
Holibut, flat fish, described, ii. 301, *n.*
Holland, gained from the sea, i. 98; inroads of the sea on, ib., *n.*
Honey. See *Bee.*
Honey-dew, notice of, i. 131, *n.*
Hooded Serpent, account of the, ii. 423—426. See *Cobra.*
Hooper, the wild swan, why so called, ii. 226.
Hoopœs, birds resembling woodpeckers, ii. 108, *n.*
Horns, *Hoofs*, and *Nails*, microscopic examination of, ii. 602.
Horse, its relative station, i. 245; its beauty, ib.; where found in native state, ib.; habits when in droves, ib.; its original country, 246; American, ib.; Tartar wild horses, ib.; African, ib.; Arabian, ib.; Arabian tamed horse, 247; diffusion of the Arabian breed of the, 248; Barbary horse, ib.; horse-racing at Rome, ib., *n.*;

Persian, 249 and *n.*; Italian, Danish, &c. 250; French, described, ib. and *n.*; German, ib. *n.*; tame of America, 251; wild horses of South America, ib. *n.*; of the Archipelago, ib.; of Media, 252; India, ib. and *n.*; one presented to our Queen, described, ib.; of Guinea, ib.; of China, ib.; Tartars live with their, ib.; Grecian, 253; English, ib.; swiftness of the, ib.; Flying Childers, ib. *n.*; English hunting, 254; number of, in England at different times, ib.; different breeds of horses in Britain, ib. *n.*; coach-horse, ib.; draught horses, 255, *n.*; cavalry horses, ib.; race horse, ib.; the hunter, 256, *n.*; the Galloway, ib.; the Welsh pony, ib.; the Exmoor pony, 257, *n.*; the Highland pony, ib.; the Shetland pony, ib.; the Irish horse, ib.; instructions for purchasing horses, ib. and 258, *n.*; description of a perfect, ib.

Hottentots, their encounters with the lion, i. 361.

Houtou, a bird of South America, ii. 166, *n.*

Howlet, a kind of owl, ii. 55.

Huber, his experiments on bees, ii. 516.

Hudson, name given by Buffon to the Urson, i. 467.

Human Semen, animalcules in, ii. 638.

Humber, an island formed at the mouth of the, i. 56.

Humble bee, an account of the, ii. 525; its cells, 526; females, ib.; method of putting the colony into motion, ib.

Humming bird, beauty of the colours of the, ii. 165 and *n.*; varieties, 167; the, described, ib. and *n.*; visits flowers, whether it extracts honey from them, ib.; bar-tailed humming bird, 168, *n.*; topaz-throated humming bird, 169, *n.*; account of its nest, ib.; of the nest in America, 170; disappears in the winter, in cold climates, ib.; note of the, ib.; plumage, ib.

Hunger, causes and consequences of, i. 134, *n.*

Hunting, American horses, how employed in, i. 251.

Hurricane, description of the, i. 125.

Huso sturgeon, account of the, ii. 285; its isinglass, ib.

Hyæna, distinguished from the wolf, 408 and *n.*; its fierceness, 409; cry or moan, ib.; a solitary animal, 410; dispositions of the, ib.; fables concerning the, ib. the stripped hyæna described, 408, *n.*; spotted hyæna described, 409, *n.*; found in a fossil state in Britain, ib.

Hydras, reptiles so called, ii. 431, *n.*

Hydrostatics—See *Water*—paradoxes in, i. 71; metals, how weighed hydrostatically, 72; laws of hydrostatics, 71, 72.

I

Ibex, the, supposed by Buffon to be the source of the goat, i. 303; their resemblance, ib.; described, ib. *n.*; Abyssinian ibex, ib.; Caucasian ibex, ib.; Ægagrus, ib.

Ibis, venerated by the Egyptians, ii. 178 and *n.*; characteristics of the genus, ib. *n.*; the scarlet ibis, ib. and 179, *n.*

Ice, i. 69; its elasticity, 70; mountains and sheets of, at the polar regions, 88; how formed, ib.; of what composed, ib.; mountain ice, description of, 89; Crantz's account of the formation of, ib.

Ichneumon, the, where found, i. 419; its size, shape, and colour, ib.; agility and courage, ib. and *n.*; its prey, 420 and *n.*; destroys the crocodile's eggs, ib.; fables concerning, ib.; its habitudes, ib.; physiognomy, ib.; glands, ib.; account of one sent from Ceylon, 420; veneration of the Egyptians for the, ib.

Ichneumon fly, the, inserts its eggs into the grasshopper, ii. 534, 611; into the caterpillar, ib.; its formidable nature, ib.; whence the name, ib.; the, described, ib.; its weapon of offence, &c. ib.; manner of depositing its eggs, ib.; progress to the fly state, ib.; its uses, 535; wing of, 617.

Ignis Fatuus, notice of the, i. 134, *n.*

Iguana, size and description of the, ii. 402; common American iguana, ib. *n.*; the slate coloured iguana, 403, *n.*; the horned iguana, ib.; the iguana fasciata, ib.; how taken and killed by the Americans, ib.

Illusions, meteoric, i. 139, 140.

Imago or *fly state of insects*, ii. 613.

Incubation of birds, account of the, ii. 7.

Indians, American, how they palliate hunger, i. 136; their method of charming serpents, described by Philostratus, ii. 415.

Indicator or *honey-guide cuckoo*, ii. 113, *n.*

Indus, tides at the mouth of the, i. 92.

Infancy of man, history of the, i. 160; sensations during, 161; vivacity of negroes during, ib.; infants when newly born, their appearance, ib.; their voracity, 162; endurance of hunger, ib.; their life precarious, ib.; their growth, 163; progress of their understanding, 163, 164.

Infusions for production of animalcules, ii. 624.

Infusoria, fossil, ii. 593.

Insects, Blumenbach's description of, ii. 436—438, *n.*; Swammerdam's notions of their dignity, 437; their real imperfection in formation, 438; instincts, ib.; utility, ib.; their numbers uninstructible, ib.; definition of insects, 439; numerous distinctions among, ib.; similitudes among, ib.; classification of, 440; sketch of the history of, 440—442, *n.*; Lamarck's classification of, 442—447, *n.*; fossil remains of, ii. 593; structure and transformation of insects, 607; their eggs, ib.; microscopical insects, 620.

Instinct, discovered in the incubation of birds, ii. 12.

Inundation of rivers, different effects of, i. 81; diurnal, ib.; of the sea, 99.

Isatis, the, compared with the dog and fox, i. 408; climates in which found, ib.; change of colour with the year, ib.

Isinglass, from what kind of sturgeon furnished, ii. 274, 285; its uses, 285; how prepared, ib.; commerce in, ib.

Islands, new, i. 53; islands formed by rivers, 56; disappeared, ib.

Ivory, the commerce in, an account of the, i. 527.

J

Jabiru, a large bird of the crane kind, ii. 179; the Jabiru guacu, discriminated, 180 and *n.*

Jackal, a species widely diffused, i. 406; its habits, 407; packs of the, ib.; manner of hunting, ib.; followed by beasts of prey, ib.; its antipathy to the dog, ib.; cry of the jackal, described, 408, *n.*

Jackdaw, account of the, ii. 93.

Jaculus of America, a swift serpent, ii. 423.

Jaguar of America, distinguished from the panther, i. 374, *n.*; description of the, ib.

Jamaica, earthquake in, 1692, i. 50; meteoric phenomena there, 135.

Japan, volcanoes in, 44; Japanese tribe, described, 211.

Jaw, human, motion of the upper, and under, i. 170; position of the under in different ages and nations, ib.

Jay, description of the, ii. 98; common jay, ib. *n.*; red-billed jay, ib.; blue jay, ib.

Jeffery, little, a dwarf, i. 220.

Jenisca, river in Tartary, i. 77.

Jenkins, his longevity, i. 206.

Jerboa, an animal between the kangaroo and rat, account of the, i. 455, *n.* and 559, 560.

Jevraska, the marmout in Siberia, i. 444.

Jucatan, a peninsula, left by the sea, i. 98.

Jugular fish, what, ii. 294; prickly-finned, 295; soft-finned, 300.

K

Kabassou, kind of armadillo, i. 471.

Kangaroo, discovered by Sir Joseph Banks, in New South Wales, i. 560; description of the, ib. *n.*

Kermes, the insect, where produced, ii. 551; female described, ib.; the male, ib.; how prepared, ib.

Kerona genus of infusoria, ii. 634

Kettering stone, examination of, ii. 592.

Kestril, a species of falcon, ii. 45, *n.*

Kevel, a kind of gazelle, i. 308.

King-fisher, its appetites and beauty, ii. 237 and *n.*; the bird described, ib.; its rapacity and activity in seizing its prey, ib.; fables and poems with respect to its power of allaying a storm, ib.; nest of the bird, described, 238; female and young, 238, 239.

Kite, the, a kind of hawk, ii. 48; localities and habits, ib., *n.*, and 49.

Kitten, its playfulness, i. 357; laws of Howel about the price of a, 358.
Klein, his method of classifying animals, i. 233.
Koh, and *Koba*, two kinds of gazelles, i. 308.
Kolpoda genus of infusoria, ii. 631.
Koomkee, or female elephant, how employed in hunting the male, i. 524.

L

Labrus, a prickly-finned fish, notice of the, ii. 296.
Lakes, i. 75.
Lamprey, characteristics of the, ii. 280, *n.*; the marine lamprey, 281, *n.*; the river lamprey, ib.; that at present served up among the Italians, 280; account of those known among us, 281; the fish described, ib.; its manner of swimming, ib.; its adhesive quality, 282; mucus, ib.; spawn, ib.; short life, ib.; how taken, 283; esteemed among the ancients, ib.
Lamprey-pie, one presented at Christmas by the city of Gloucester to the king, ii. 283.
Land-breezes, i. 128.
Lands, new, formed by the sea, i. 97, 98.
Lapland, the country of the rein-deer, described, i. 336; rein-deer, chief riches of the natives of, ib.; their method of defending the rein-deer from its enemies, ib., 337; their method of spending the winter with the rein-deer, 337; their comfortable life, 338; their profit from the misfortunes of the squirrel, 439; draw omens from the contests of the leming, 457; the people described, 209, 210.
Lapwing, or *Peewit*, described, ii. 194, *n.*; green lapwing, ib.
Lark, song of the, what it depends on for its agreeable nature, ii. 150—152, and *n.*; its nest, 152; female, ib.; habits in winter, ib.; the crested lark, 150, *n.*; the wood-lark, ib.; the short-toed lark, ib.; the clapper lark, ib.; the red-backed lark, ib.; the Alpine lark, 151, *n.*; the double-crested lark, ib.
Larva, or *Caterpillar state of Insects*, ii. 608; larva of musca chamelion, ib.; of British hydrophilus, 609.
Laughter, how produced, i. 171 and *n.*
Launce, a soft-finned fish, ii. 299.
Lawrence, St, course of the, i. 80; cataract of the, 82.
Leaf-cutting Bees. See *Bee*.
Leaves of plants as seen by the microscope, ii. 599; of stinging nettles, 600.
Leech, the, its class, ii. 467; the medicinal leech, ib. *n.*; the useless varieties, 468; that used in medicine, ib.; its description, ib.; its internal construction, 469; breathes through the mouth, ib.; viviparous, ib.; size in America, ib.; how leeches should be applied, ib.; the h[illegible] leech, 468, *n.*
Legs of quadrupeds, i. 238; of insects, 616.
Leming, boldness and numbers of the, i. 456; propagation, 457; manner of its migration in troops, ib.; destroy one another, ib.; their contests considered ominous by the Laplanders, ib.; propagation, ib.; flesh, ib.
Lemurs, a group of quadrumanous animals, described, i. 511, *n.*
Leopard, distinguished from the panther, i. 376 and *n.*; [illegible] of Senegal described, ib.; Chetah, or hunting leopard, 518, *n.*
Lepadogaster, the fish, described, ii. 299.
Lepisma, the, ii. 621.
Lerot, a kind of dormouse, i. 453.
Letters, what most easily pronounced by infants, i. 163.
Leucophra genus of infusoria, ii. 632.
Leuwenhoeck's theory of generation, i. 151; his discovery of the seminal animals, ii. 638.
Leymmer, a mongrel dog, described, i. 393.
Libella, or *Dragon-fly*, ii. 470. See *Dragon-fly*.
Liboya, a great serpent of Brazil, ii. 428, 429; size of the, 429; habits of the, 430.
Lichens, seen under the microscope, ii. 601.
Lidme, a kind of gazelle, i. 309.
Life, destroyed by withdrawing the air, i. 110; duration of, in an animal, how it may be determined, 205; prolonged by management, ib.; by what affected, 206, 207; love of, in man, 207, 208; its cessation, 208.
Lightning, how produced, i. 130; phenomena of, 133, *n.*
Limpet, a small shell fish, ii. 369.
Ling, a species of cod, described, ii. 300, *n.*
Linnæus, his classification of animals, i. 223; of fishes, ii. 293.
Linnet, description of the, ii. 158, *n.*; identity of the red and gray linnet, ib.
Lion, the, affected by climate, i. 360; description of the, 361, *n.*; courage of the, 362, *n.*; anecdotes of the, ib.; lion of Africa and mount Atlas, 361; their number diminished, ib.; how attacked by the Hottentots, ib.; boldness of the African, 362; feebleness of the Indian, ib.; disposition of the, ib., 363; outward form, hair, muscles, &c., 364; mane, ib.; imperfection of sight and smell, ib.; method of seizing his prey, 365; lion hunting in Africa, ib., *n.*; roar and action, when furious, 365; combat with the wild boar, 366; rencounters with lions in South Africa, 366, *n.*; action when pursued, 367; its desperate sallies, ib.; their combats for the female, ib.; the lioness, 368; their age, ib.; attachment of the female to the young, ib.; the, of Bildulgerid, ib.; none in America, ib.; Aristophanes' advice with respect to trusting the lion, ib.
Lion-ant, account of the, ii. 472—475, and *n.*
Lion, sea, described by Anson, a kind of seal, i. 486.
Lips, human, their expression, i. 170.
Lisbon, earthquake at, i. 49, *n.*, and 50.
Lithophytes, account of, ii. 570.
Littorales, shell fish cast on shore, ii. 355, 356.
Lizard kind, opinions of naturalists concerning their rank in nature, ii. 391; differences among the tribe of the, ib.; colours, ib.; figure various, ib.; distinction from the manner of bringing forth the young, 392; three classes thus formed, ib.; distinguishing properties of the, ib.; beauty of some, 402; the flying, of Java, 405; the Chalcidian, the step between the lizard and the serpent, ib.; the variegated lizard, 404, *n.*; the green lizard, ib.; the nimble lizard, 405, *n.*; the sand lizard, ib.; the frilled lizard, ib.; lizards in general, 433, *n.*
Llama, the camel of the new world, i. 540 and *n.*; colours of the, 541 and *n.*; habitation, 542 and *n.*; size and description, ib.; usefulness of the, to the American Indians, ib. and *n.*; description of the, in the wild state, ib.
Loach, the, described, ii. 304.
Lobster insect, ii. 621, 622.
——— resemblance of the, to the crab, ii. 327; manner in which it casts its shell, ib., *n.*, and 328, 329, *n.*; description of the, ib.; the ovary and young, ib.; its food, 328; changes the shell once a year, ib.; how performed, 329; state after change, 330; eats its own stomach and shell, ib.; concretion, within its body, ib.; sudden increase of size, 331; contests, ib.; the loss of a claw repaired, ib.; the extraordinary properties of the animal enumerated, ib.; varieties, ib.; how taken, ib.
Lochawe, great gray trout of, ii. 302, *n.*; how angled for, 323, *n.*
Locust, account of the, ii. 479—481; number of locusts, 480, *n.*; their ravages, ib.; mode of dispersing them, ib.
Loggerhead Turtles, described, ii. 342.
Loir, a kind of dormouse, i. 453.
London, number who die in, of destitution, i. 185.
Longevity, causes of, i. 205, 206; instances of, 206 and *n.*; of the patriarchs, 207; why diminished, ib.
Lori, its singular figure, i. 510.
Loricaria, account of the fish, ii. 301.
Lories, a species of parrots, ii. 114; purple-capped lory, 119, *n.*
Lorikeet, blue-bellied, ii. 119, *n.*
Louse, account of the, ii. 456—461, and *n.*; wood-louse, 463.
Luminous appearance of the waves by night, i. 89, 90.
Luminous Insects, account of, ii. 548—550, *n.*
Lump-fish, the, account of, ii. 289; where found, ib.
Lynx, Ray's mistake concerning the, i. 379; distinguished from the panther kind, ib.; described, ib., *n.*; where found, 383; method of taking its prey, ib.; its eyes, bad memory, &c., ib.
Lyre bird, or *Menura*, ii. 110, *n.*

M

Macaguo, a kind of monkey, i. 505, 511, *n.*
Macaw, the great green, ii. 117, *n.*

Mackarel, the fish noticed, ii. 296; account of its habits and the mode of taking it, ib., *n.*
M'Laurin, Professor, his jaw said to be dislocated by yawning, i. 170.
Madness, case of, caused by music, i. 197; one cured by music, 198.
Maelstroom, a dreadful whirlpool, description of the, i. 96.
Maestricht, stone-quarry of, its size and beauty, i. 32.
Magellan, his voyage, and discovery of giants, i. 222, 223.
Magot or *Barbary ape*, i. 498, *n.*
Magpie, general characters of the tribe, ii. 96; description of the, 97; insolence of the, ib.; food, ib.; architecture, of its nest, ib.; its character in the tame state, ib.
Mahometans, their treatment of women, i. 165; of their wives, 166.
Maid and *Magpie*, a drama, its origin, ii. 97.
Maimon, a kind of baboon, noticed, i. 501.
Maki, a kind of monkey, described, i. 509.
Malacopterigii, soft-finned fish, ii. 294; varieties specified, 199—304.
Malbrouk, a kind of monkey, i. 505, 506 and *n.*
Malpighi and *Haller*, their examination of the progress of vivification in the egg, i. 156.
Mammoth, tusks of the, where found, i. 528; skeletons of the, ib.; diversities of the, ib.
Man, nature of his powers, i. 144; history of, in the womb, 157; in infancy, 160; in puberty, 165; in manhood, 167; his shape, ib.; features, 167—176; figure, 176; size, ib.; weight, 177; strength, 177—183; anatomy of the human body, 181, *n.*; his necessities, 183; of food, ib.; of sleep, 187; senses of, 191; old age and death, 204; various races of, 209; varieties of the human race, 213, *n.*; different colours of the, 215, *n.*; his conquest of the lower animals, 236; his influence over, 240, 241.
Manati, the link between quadrupeds and fishes, i. 487; described, ib.; tail like a fish, ib.; organs, ib.; where found, ib.; propagation, ib.; fat and flesh, 486.
Manchineel apple, a deadly poison, ii. 324; whether it infects the fishes of the seas about it, ib.
Mangabey, a kind of monkey, i. 506, and *n.*
Manril, a kind of baboon, described, i. 500.
Maræna, of the ancients, whether the lamprey, ii. 281; celebrated at Rome, 283; dreadful manner in which a senator fed the, ib.
Marmose, a kind of opossum, i. 514; peculiarity in its pouch, 515.
Marmout, a species of the, i. 441 and *n.*; analogies to the hare, ib.; its head, hair, and claws, 442; where found, ib.; its antipathy to the dog, ib.; its habits when domesticated, ib.; its food, ib.; and flesh, ib.; extraordinary suspension of animation in the, for more than half the year, ib.; its retreat for this purpose described, 443; the watchfulness of the, when abroad. ib.; the lodging of the, how rendered convenient, ib.; their abode secured, ib.; in what condition it reposes, ib.; account of the torpor in which it continues, ib.; breeding of the, 444; countries, and names in different, ib.;
Marikina, monkey, i. 509.
Marsupiata, or *pouched animals*, account of the class of, i. 511 and 511—513, *n.*
Martin, its size, characteristics and beauty, i. 417; described, ib.; the yellow-breasted, described, ib.; its graceful motions, &c. ib.; formidable to animals larger than itself, ib.; account of one kept by Buffon, 418; where the varieties of, found, ib.; method of taking its prey, ib.; its nest, litter, &c. ib.; care of the young, ib.; country, ib.; skin, furs, and the commerce in them, ib.; the guinea martin and woolly martin described, ib. *n.*
Mastiff, the, described, i. 392 and *n.*
Mavis or *song thrush*, ii. 139, *n.*
May-bug, the, described, ii. 542, 543 and *n.*
Maximin the emperor, his size, strength, feats, and fortune, i. 180.
Mediterranean sea, its remarkable currents, i. 93; opinion concerning, ib.; how replenished, ib.; its terrors diminished, 94.
Medusa or *sea-nettle*, ii. 375, *n.*
Melton Mowbray, a town in Leicestershire, noted as a fox-hunting station, i. 404, *n.*
Membranes, effect of age on the membranes of the body, i. 205.
Mendip mines, putrefying atmosphere in, i. 36.
Menura or *Lyre bird*, ii. 110, *n.*
Merlin, a species of falcon, ii. 46, *n.*
Meteors or *atmospheric phenomena*, i. 128; remarkable at the pools, 132; at the tropics, 133; at Jamaica, 134; at Quito, 135; seen at Bononia, ib.; beautiful, seen at Quito, ib.; meteors of the polar regions, 136—139; meteoric illusions, 139.
Meteorolites or *falling stones*, account of, i. 141, *n.*
Mico, a kind of monkey, i. 509; one described, ib.
Microscope, its value to the natural historian, ii. 587; Baker's remarks therein, 587, 588; recent improvement of the instrument and the results, 588.
Microscopic Discovery, ii. 587 et seq.; in the mineral kingdom, 588—595; in the vegetable kingdom, 595—602; in the animal kingdom, 602 et seq.
Microscopical Inquiry concerning the minute formations and phenomena of the natural world, ii. 587—622.
Migration of birds, an account of the, ii. 14; observations on the supposed analogy between migratory and hybernating animals, 16.
Miller's Thumb or *bull head fish*, ii. 293 and 320, *n.*
Milo, his strength, i. 180.
Milton, his description of the first sensations of Adam alluded to, i. 202; a parallel to, by Buffon, 202—204; his notion of the cormorant vindicated, ii. 207.
Mind, growth of the human, i. 163.
Mineral Kingdom, discoveries therein by the microscope, ii. 588—595; congelation, 588; of water, ib.; star-like figures produced by congelation of saline fluid, ib.; crystalline figures observed on windows, 589; flakes of snow, their various forms, ib.; crystallization, ib.; distinction between congelation and crystallization, ib.; figures of crystals and their primitive forms, ib.; Hooke's suggestion regarding the formations of crystals, ib.; a more recent theory, ib.; actual crystallization under the microscope, ib.; crystals of common salt, ib.; their formation, ib.; other crystalline structures of salt, 590; method of bringing the crystallizing process under microscopic review, ib.; various chemical experiments exhibiting the crystallizing process under the microscope, ib.; active molecules of matter, 591; how to be observed, ib.; nature of their motion, ib.; singular appearances presented by solution of camphor in turpentine, ib.; theory of molecular activity thence derived, ib.; Ores and minerals, examination of, 592; sands, different kinds of, ib.; particles of the precious stones, ib.; Leuwenhoeck's examination of a diamond, ib.; diamonds discovered in flint, ib.; cavities in gems and mineral bodies, ib.; the two new and singular fluids discovered therein, ib.; inferior minerals, ib.; kettering stone, ib.; minute globules of steel produced by friction of flint and steel, 593; minute petrifactions and fossil remains, ib.; Pritchard's remarks thereon, ib.; insects, fossil remains of, ib.; a singular instance, ib.; Ehrenberg's discoveries of fossil infusoria, ib.; objections thereto anticipated and answered, 593, 594; how layers of rock may be found by accumulation of infusorial remains, 594; Ehrenberg's demonstrative experiments, ib.; vegetable fossil remains of, ib.; Pritchard's remarks thereon, ib.; microscopic examination of fossil woods, 595; the results, ib.
Mines, i. 35; depth of, ib.; noxious atmosphere in, 36. See *Damp* and *Gas*.
Minnows, notice of the, ii. 321.
Mire-drum or *bittern*, account of the, ii. 134.
Missel thrush, ii. 139, *n.*
Mississippi, course of the, i. 80.
Mitchell, James, born blind and deaf, case of, i. 200, *n.*
Mocking bird, American, ii. 143, *n.*, and 146; Barrington and Wilson's description of, 146, *n.*
Mococo, a beautiful monkey, its appearance and habitudes, i. 509, 510.
Modena, country round, remarkable composition of the layers of earth there, i. 100.
Mole, the, described, i. 457—460; its country, ib.; unknown in Ireland, ib.; its legs, teeth and tongue, 460; adaptation of its form for digging, ib.; its eyes, ib.; its prey, 461; sufferings from inundations, ib.; propagation, ib.; abode, ib.; where found, ib.; white ones, ib.; ferocity of the mole, 457, *n.*; moles addicted to

swimming, 458, *n.*; use of the mole, ib.; habits of the, 459, *n.*; shrew-mole, 461, *n.*
Molecules of matter, their activity. ii. 591.
Mollusca, account of the, ii. 375, 376, *n.*, 578—585.
Mona, a monkey, described, i. 506 and *n.*
Monad genus of infusoria, ii. 626.
Monax, the marmout, in Canada, i. 414.
Monpoz, a kind of monkey, i. 510, 511, *n.*
Monitor, a species of crocodile, ii. 393, *n.*
Monkey kind, animals of the, their characteristics, i. 489—491, and *n* ; varieties in the class, 491; ape, ib.; baboon, ib.; monkey, ib.; opossum, ib.; monkey, varieties of the, numerous, 501; their numbers in tropical climates, 502; dispositions, ib.; pests of other animals, ib.; contests with the serpent tribe, ib.; enmity to mankind, 503; with difficulty caught, ib.; pleasure of the Negroes on seeing them killed, ib.; how they injure corn, &c., ib.; and escape pursuit, ib.; discipline of the, ib.; cry, ib.; food, 504; propagation and care of the young, ib.; amusing when tame, ib.; Sir Thomas More's, defended rabbits from a weasel, ib.; their care of Father Carli, ib., 505; those of Africa the most entertaining, ib.; the red of Pennant, its peculiar colour and description, ib. *n.*; collared white eyelid monkey, 506, *n.*; the striated monkey, 508, *n.*; the Entellus monkey, ib.; monkey tribes of India held in veneration, 509, *n.*
Monoculus, or *Water-flea*, described, ii. 463; the cancroid monoculus, ib., *n.*; the four-horned monoculus, ib., 620; its eye, ib.
Monsters, what, described, i. 218; causes of malformation, ib., *n.*; account of one by Malebranch, 219; dwarfs, 220; giants, 222.
Moon, her effect in producing tides, i. 90.
Moose-deer, American name for the elk, its size, i. 333; the gray, ib.; the black, ib.; largest of the family of deer, ib., *n.*; manner of shooting the, 334, *n.* See *Elk.*
Mormyrus, account of the fish, ii. 306.
Morse, the, its description, i. 487; habits, ib.; numbers decreased, ib.; value of their teeth, ib.; great numbers killed by the Greenlanders, ib.
Mosses, microscopic examination of, ii. 600; leaf of bog-moss, 600.
Mother-of-pearl Shells, composition of, ii. 96; whence obtained, 98.
Moths, account of butterflies and moths, ii. 499—505, and *n.*
Mouffion, the sheep in a wild state, its character, i. 287, 297. See *Musmon* and *Argali.*
Mouldiness, plants of, as seen by the microscope, ii. 601.
Moulting season of birds, account of the, ii. 5.
Mountains, inequality of their size, i. 57; theories concerning, ib., 58; uses of, 58; appearance of, 59 and *n.*; some remarkable, 61; the highest, 62; disruptions of, 63; snowslips on, 64; swallowed by earthquakes, ib.; height of, how determined by the barometer, 107.
Mouse, its dispositions, i. 451; timidity and enemies, ib.; extraordinary increase of mice in the royal forests, ib., *n.*; propagation, ib.; fecundity, 452; varieties, ib.; the long-tailed field, described, ib.; short-tailed field, ib.; white mice, ib., *n.*; harvest mouse, ib., *n.*; the shrew, described, 453.
Moustoe, or *White-nosed Monkey*, i. 507.
Mouth, its expression, i. 170.
Mulberry leaves, the best food for the silkworm, ii. 510.
Mules, account of, i. 263 and *n.*, 264.
Mullet, its method of escaping from the seal, i. 486; notice of the, 299, 321, *n.*
Mullus, the fish discriminated, ii. 298.
Multivalve, shell-fish, ii. 373.
Mummies, commerce in, i. 226; supposed medicinal, ib.; method of searching for, ib., 227; in what state found, 228; account of one dug up at Auvergne, ib., 229; conjectures concerning, 229.
Muscardin, a kind of dormouse, i. 453.
Muscles, human, their strength, i. 177; microscopic examination of, 602.
Music, how produced, i. 196; pleasures of, 197; strange instances of the effects of, ib.: case of madness produced by, ib., 198, *n.*; cured by, ib.; bite of the tarantula said to be cured by, 198.
Musk animal, description of, i. 316, *n.*, 318; musk, how obtained, ib., *n.*; quantity exported from Asia, ib., and 317, *n.*; its virtues, ib.; Thebetian musk, 318, *n.*; Indian musk, ib.; Guinea musk, ib.; Ceylon musk, ib.; Brazilian musk, ib.
Musk Bull, account of the, i. 281, *n.*
Musk, pigmy, i. 311.
Musmon, a kind of wild sheep, described, i. 297, 298, *n.*
Musquito Fly, where common, ii. 555 and *n.*
Mussel, the fish and shell, described, ii. 365, *n.*, 366; generation, 367; eggs, ib.; fecundity, ib.; multitudes, ib.; enemies, ib.; afraid of storms, ib.; attaches itself to rocks by filaments, ib.; its instrument of motion, ib.; its furrow in the sand, ib.; mussels sometimes poisonous, 368, *n.*

N

Nails, human, their properties, i. 176.
Narwhal, or *Sea-Unicorn*, its size, ii. 360; its remarkable projecting tooth, ib.; a skull in the Stadhouse having two, ib.; how it uses the tooth, ib.; whether a horn or tusk, ib.; its peaceable disposition, 261; associates with the whale, ib.; distinguished from it, ib.; value of the ivory of its tooth, ib.; the fossil, has given origin to the stories of the unicorn, 262.
Natural world, minute formations and phenomena of, ii. 587—622.
Nautilus, a kind of sea-snail, ii. 364 and *n.*; two kinds, from the colour of the shell, ib.; the shell described, ib.; disengages itself from the shell, ib.; the appearance of the, sailing in the Mediterranean, 364, 365; object of its flight, 365.
Nazareth, bird of, whether the dodo be the, ii. 27.
Neck, the, its use, i. 174.
Needle-fish, described, ii. 290, *n.*
Negroes, vivacity of their infants, i. 161; their treatment of women, 165; of Africa, described, 212; darkness of complexion, 215; some, with white skins, 217.
Ness, river, near Bruges, phenomena of its mouth, i. 99.
Nests of birds, their structure, ii. 10—12, and *n.*; of the sparrow, jay, wren, &c., 10; hanging, of the woodpecker, described, 104—117.
Nettles, sea, star-fish, or anemones, why so called, ii. 561.
Newt, black water, its class, ii. 152; not inconsumable, ib.; absurd remark on the, in the Philosophical Transactions, ib.
Niagara, falls of, on the St Lawrence, i. 81, *n.*, 82.
Nictitating membrane on the eyes of birds, what it is, ii. 3.
Nieper, its course, i. 77.
Niger, account of the, i. 78, *n.*
Night, an African, described, i. 239.
Nightingale, song of the, ii. 146, 147, *n.*; described by Pliny, 146, 147; migrations and habits, 147; its note in England, 148; nest and eggs, ib.; song in confinement, ib.; Gesner's anecdotes of its power of talking, ib.; how taken, 154; and reared, 155.
Nile, source of the, 78, 79, and *n.*; benefits of its inundations, 79, 80; rivers received by, 80.
Nitrogen, a component of atmospheric air, i. 109, *n.*
Nose, its position and form, i. 170; peculiar to man, ib.
Notes, i. 196. See *Tones.*
Notonecta, or *Water-fly*, described, ii. 201.
Numidia, bird of, ii. 76. See *Pintado.*
Nut-hatch, a bird resembling the woodpecker, ii. 107, *n.*; the European nut-hatch, ib., 108, *n.*
Nyl-ghau, a species of antelope, described, i. 314, *n.*, and 544; habits in captivity, 544; manner of fighting, ib.; where indigenous, ib.

O

Oakey-hole, a cavern, description of, i. 33.
Ocean, its extent, i. 83; divisions of, ib.; estimate of its bulk, 84; its uses, ib., 85; parts of, claimed by nations, 85; its bays, &c., minutely known, ib.; saltness of the, ib.; why not putrefied, 86; attempts to deprive sea water of its saltness, ib.; effects of the putrefaction of the, ib., 89; advantages of its saltness, 88; freezes, ib.; luminous appearance of its waves by night, 89; tides of the, ib.; (see *Tides*); circulates round the globe, 92; currents of the, ib.; (see *Currents*); its various motions, 96; its effects on the earth, ib.; lands gained from the, ib., 97; inundations of the,

99; temporary depredations of the, ib.; wonders in the bottom of the, 102, 103; its waters at different depths, 102.
Ocelot, an animal of the cat tribe, described, i. 382 and *n.*
Ocotzimtzcan, or *Mexican Pigeon*, ii. 129.
Odour, not a true test of wholesomeness, i. 201; taste of different nations with respect to, ib.; how varied by distance, ib.; by mixture of ingredients, ib.; by disease, ib.
Oliver, W. a viper catcher at Bath, discovered salad oil to be a cure for the viper's bite, ii. 420.
Ondatra, a kind of musk rat, described, i. 454. See *Rat, musk.*
Ophidium, a beautiful fish, described, ii. 295.
Opossum, animals of the, kind, their relative position, i. 511; the head, &c., described, 512; their bag or pouch described, and how the young accommodated in it, 513 and *n.*; habits, 514; varieties, ib.
Oran-outang, its sizes, i. 491; description of that seen by Dr Tyson, ib.; its resemblance to the human figure, and essential difference, 492; its hair, hands, &c., ib., 493; dispositions, 493; that seen by Edwards, described by Buffon, ib.; Dr Clarke Abel's description of the great oran-outang, 491, *n.*; his account of an oran-outang brought from Java, 493, *n.*; intelligence of two belonging to L. Brosse, 495; smaller tribe, ib.; Le Compte's account of it, ib., 496; the gigantic species, 496; where found, ib.; the African, or pongo, described, ib.; go in companies, ib.; size, strength, &c., ib.; place of the, in the gradation of nature, 497; helplessness of the, ib.; goes on all-fours, ib.
Orb, sea, the, described, ii. 290; lesser, 291.
Ores and *Minerals*, examination of, ii. 592.
Organic productions, classes of, i. 22, *n.*, 25. See *Fossils.*
Oriole, a species of thrush, ii. 143, 144, *n.*
Ornaments of the person, savages admire, i. 173, 174; observations concerning, 174.
Ornithorhynchus, or *duck-billed Platypus*, i. 488, *n.*; the most singular animal of Australia, being a compound of the quadruped and the bird, 561, *n.*; description of, ib. 562, *n.*; habits of the, ib., *n.*
Osprey, or *Ossifrage*, a kind of eagle, ii. 36.
Ostracion, the, a kind of fish, described, ii. 291 and *n.*
Ostrich, its appearance, ii. 19; size, ib.; plumage, ib., 21; its value, 22; spurs, 19; thighs, ib.; internal parts, ib., 20; where found, ib.; habits, ib.; voracity, ib.; incubation and polygamy, 21; habits of the, ib., *n.*; manner of running, 22; how hunted, ib.; domesticated and tamed, ib.; its flesh, ib., 23.
Otter, the, described, i. 475; where found, ib.; prey and manner of fishing, ib.; propagation, 476; its retreats and habitation described, ib.; how caught by dogs, ib.; trained to hunt fish, ib.; countries of the, ib.; sea-otter described, 477, *n.*
Ouarine, a species of monkey, its significant voice, i. 504.
Ounce, confusion concerning the name, i. 380; that of Linnæus, described, 379; disposition of the, ib.; method of taking their prey, ib.; how used in hunting, ib., 380.
Owl, nocturnal, bird of prey, ii. 52; description of the eye and ear of the, ib. *n.*; owls divided into horned and smooth-headed, ib., *n.*; great horned or eagle owl, ib., *n.*, 54; long-eared owl, ib., *n.*, 54; short-eared owl, 53, *n.*, 54; scops-eared owl, 53, *n.*; snowy owl, 53, *n.*, 55; barn or white owl, 53, *n.*; tawny owl, 54, *n.*; little owl, ib.; barn owls at Walton Hall, 55—57, *n.*; the common properties of the owl, 52—54; the appetites, habits, retreats of the class, 55; cry, ib., 56; antipathy of other birds to the, ib., 57; how used to lure the kite, 57; nest of the, ib.; indocility of the, 58.
Ox. See *Cow, Bison*, and *Buffalo;* Indian ox, i. 27, *n.*
Orney Island, produced by the sea, i. 97.
Oxygen, a component of atmospheric air, i. 109, *n.*
Oyster, the, ii. 365, *n.*; its resemblance to the mussel, 368; its shells described, ib.; cannot move its situation, ib.; to what it attaches itself, ib.; by what means, ib.; spawn, ib.; growth, ib.; deposited in beds at Colchester, 369; season for oysters, ib., *n.*; account of those held in most esteem, ib.; method of feeding oysters, ib.; oysters easy of digestion, &c., ib.

P

Paca, its characteristics, i. 445; roots like a hog, ib.; where found, ib.; its numerous enemies, ib.; courage, ib.
Pacific Ocean, constancy of its winds in certain latitudes, i. 117.
Paco, a kind of llama, i. 553.
Paddock Moon, the month in which frogs do not croak, ii. 383; accounted for, ib.
Painters, their observation of the expression of passions by the human body, i. 171.
Paleness, the effect of what passions, i. 171.
Palm, fibres of the, ii. 602.
Pangolin, or *Scaly Lizard*, distinguished from the lizard tribe, i. 468; size and appearance, ib.; its scaly covering, ib.; a sufficient defence against all animals, ib.; but man, ib; harmlessness of the, ib.; its food, ib.; tongue, ib.; preys on ants, ib., 469; its habits, 469.
Panther, the great, i. 376; distinguished from the leopard, 377; its spots, ib.; dispositions, 381.
Paradise, bird of, mistakes concerning the, ii. 108; its characters, 109 and *n.*; the two varieties of the, ib.; the animal described, ib.; where found, ib.; migrations of the, ib.; how shot and preserved, 110; grahle-bird of paradise, ib., *n.*; magnificent bird of paradise, ib., *n.*
Paramœcium genus of infusoria, ii. 631.
Parr, or *Samlet.* See *Salmon.*
Parr, Samuel, his longevity, i. 206.
Parrakeets, what, ii. 114; beauty and talkativeness of the Brazilian, 116; Alexandrine ring parrakeet, 117. *n.*
Parrot, its docility, ii. 113; taught to speak, ib.; Willoughby's story of one belonging to Henry VII., ib.; numerous varieties of the, 114 and *n.*; peculiarities in the toes of the, ib.; in the bill, 115; the tongue and throat, ib.; its climate, ib.; expertness of the, taught in France, ib.; cause, ib.; of the Brazilian, ib.; account of one, ib.; sagacity in a state of nature, ib.; eggs and young, 116; how taken, ib.; flesh of the, ib.; beauty of the Brazilian, ib.; how found and shot, ib.; diseases, 119; varieties, 117—119; family of parrots divided into six different groups, ib., *n.*; ash-coloured or gray parrot, 118, *n.*; ground parrot, 119, *n.*
Partridge, delicacy of the flesh of the, ii. 82; universal diffusion of the, 83; venery, ib.; care of its young, ib.; partridge shooting, ib.; the, never thoroughly domesticated, ib.; bet in partridge shooting, ib., *n.*; varieties of the partridge, 84, *n.*; the mountain partridge, ib.
Passions expressed by the features of the face and attitudes of the body, i. 171.
Patas, or *African Monkey*, i. 505.
Paul, St, de Leon, in Lower Brittany, country round, desolated by a sand storm, i. 127, 128.
Peacock, its beauty, ii. 64; scream, ib.; seen in flocks, ib.; early domesticated, 65; considered a delicacy by the Romans, ib.; in the times of Francis I., ib.; its food, 66; salacity, ib.; flocks of them in Cambaya, ib.; varieties, the Thibet, ib. and *n.*; the Japan peacock, ib., *n.*; the Chinese peacock, ib.; the white peacock, ib.
Peahen, number of her eggs, ii. 66; her age, ib.
Peak, a mountain in the Molucca Islands, swallowed by an earthquake, i. 64.
Pearls, whether a disease or an accident of the oyster, ii. 370; from what fishes obtained, 370; fisheries of, 370—372, *n.*; whence the best, 372; account of the divers for, ib., 373 and *n.*
Peccary, animal of the hog kind, i. 347; description of, ib., *n.*; collared peccary, 348, *n.*; white-lipped peccary, ib.; hoofs, &c., described, 349; herds of the, ib.; food of the, ib.; flesh, ib.; the young of the, ib.; distinct from the hog, 350.
Peewit, or *Lapwing*, described, ii. 194, *n.*
Pegasse, a species of buffalo, described, i. 282, *n.*
Peyn, the Indian Nile, i. 80.
Pelagii, shell-fish of the deep, ii. 355.
Pelican, size of the, ii. 201 and *n.*; account of the pouch of the, and its use, 202; ancient notions of the, ib.; Labat's account of the, ib.; indolence, ib.; except to satisfy gluttony, ib.; female and young, 203; for what purpose killed by the Americans, ib.; Raymond's

account of a tame one, ib.; Faber's, of one that had a taste for music, ib.; age of the, ib.
Penguin, characteristics of the species, ii. 215; wings, 216; legs, ib.; power of diving, 217; Mr Bennet's description of penguins, 216, *n*; the crested penguin, 217, *n.*; description of a penguin rookery, ib.; colour, ib.; Magellanic, ib.; described ib.; food, 218; flesh, ib.; social disposition, ib.; its remarkable nest, ib.; female and eggs, 219.
Penparkhole, a cavern, Captain Sturmy's descent into, i. 33.
Perch, notice of the fish, ii. 298; varieties of the, ib., *n.*; how fished for, 321, *n.*
Perfumes, i. 201. See *Odours*.
Periwinkle, the shell fish so called, ii. 369, *n.*
Persia, dreadful wind in, i. 125; its breed of horses described, 249.
Pesce, Nicola, the diver, account of from Kircher, i. 103, 104.
Petrels, account of the, ii. 210 and *n.*; the stormy petrel, 211, *n.*; the little stormy petrel, ib.
Petrifactions and fossil remains, ii. 593. See *Fossils*.
Phalanger, a pouched animal, notice of, i. 512, *n.* and 515, *n.*
Phatagin, variety of the pangolin, described, i. 469.
Pheasant at first artificially propagated among us, ii. 72; brought from Phasis, ib.; beauty of the, ib.; the animal described ib.; its flesh, 73; manner of hatching, ib.; easily taken, ib.; or shot, 74; how domesticated and reared, 75; a breed between the, and the common hen, ib.; varieties, ib.; pheasants all natives of Asia, 73, *n.*; golden pheasant of China, ib.; other species noticed, ib. and 74, *n.*
Philanger, a species of opossum, how distinguished, i. 515; habits of the, ib.
Pholas or *file fish*, ii. 373; where found and in what situation, 374; shell of the, ib.; the animal described, ib.; power of penetrating hard substances, proved, ib.; perseverance and slowness, 375; numbers meet in the same rock, ib.; where found, ib.
Physiognomy, how marked, i. 167.
Pie kind, birds of the, what class included under, ii. 86; teasing and noxious, ib.; places of building, ib.; republican government, ib.; archness, and capability of instruction, 86, 87; other characteristics, 87.
Pigeon, the, and its varieties, ii. 120 and *n.*; wild-rock pigeon supposed to be the original of all the domestic species, ib., *n.*; the passenger pigeon, ib.; Audubon's description of its habits and mighty flocks, 121, *n.*; ring pigeon or cushet, 122, *n.* and 129; wood pigeon, 123, *n.*; bisset or wild rock pigeon, ib.; management of the dove cot, 124, *n.*; jacobine pigeon, 125, *n.*; collared turtle, ib.; ferruginous ground dove, 126, *n.*; the carrier pigeon, 127, *n.*; different breeds of the common domesticated pigeon, 128 and 129, *n.*; turtle dove, 129.
Pigmy of Tyson, the oran-outang, i. 491.
Pigtail, a kind of baboon, noticed, i. 501.
Pike, the, characterised, ii. 303 and *n.*; its voracity described, 322; mode of catching the, 321, 322, *n.*; saury pike, 304, *n.*
Pilchard, its place of resort, ii. 312; arrival, how known, ib.; great quantities of the, how taken, 313; uses, 315; profits of the fishery of, ib.; general account of the habitudes of the pilchard, 314, 315, *n.*; the pilchard fishery 315, 316, *n.*
Pilori, a kind of musk rat, i. 454.
Pinch, kind of monkey, i. 509.
Pinnock or *Hirling*, a species of sea trout, ii. 321, *n.*
Pintado or *Guinea hen*, its resemblance to the pheasant and turkey, ii. 75; different names of the, 76; feeds in flocks, ib.; the crested, and mitred, ib.
Pipal or *Surinam toad*, its lothesome appearance, ii. 389; eggs sent by internal canals to the back, ib; the male described, 390.
Pipe-fish, account of the, ii, 290; varieties of the, ib., *n.*
Pipits, account of the, ii. 153, 154, *n.*
Pismire. See *Ant*.
Pistil of a flower, as seen by the microscope, ii. 598.
Pithekos of the ancients, the ape, i. 497.
Pivot or *Razor-shell*, ii. 369.
Plague, how caused, i. 113; some places free from, 114; that of 1346, ib.; its progress in England in 1348, ib., *n.*; that in London, 1665, ib., 115.
Plaice, flat-fish, described, ii. 301, *n.*
Planets, comparative sizes of the, i. 1, 2 and *n.*; account of the different planetary systems, 2, 3, *n.*; description of the planetary bodies, 5, 6, *n.*
Plants. See *Vegetables*.
Pleuronectes, the, or flat fish, ii. 299.
Plovers, account of the, ii. 192, *n.*; the golden plover, ib; the dotterel plover, 193, *n.*
Plummet, used to sound the sea, i. 102.
Pluto, gulf of, a chasm, described by Aelian, i. 31.
Poison bag of insects, ii. 620.
Poisers of insects, ii. 617.
Poisonous qualities of some fishes, whence derived, ii. 324.
Poisons sucked out, ii. 388; by the toad, ib. See *Venom*, 416.
Polar regions, descriptions of the earth there, i. 10; voyages for exploring the polar seas, ib., *n.*; description of the ice there, 89; atmospheric phenomena of the, 132, 136—139; the men found round the, described, 209, 210.
Pole-cat, its size, &c. i. 415 and *n.*; distinguished from the ferret, ib.; its fine colours, &c. described, 416; destructive to game, ib.; residence, ib.; infests dove-houses and hives, ib.; its fur, 417; climate, ib.
Pollen, microscopic examination of, ii. 597, 598.
Polynemus, the fish described, ii. 299.
Polypus, description of the, i. 153; pullulation from the, ib.; multiplied by cutting, ib.; general account of polypi, ii. 562—570 and *n.*
Pompey, a lion, age of, i. 366.
Pongo. See *Oran-Outang*.
Pope or *Ruff*, a small fish described, ii. 322, *n.*
Porcupine, its quills described, i. 464; its figure and body, ib.; whether it darts its quills, 465, 466 and *n.*; its method of defence, 466; prey or food, ib.; age, ib.; its escape from dogs, &c., ib.; how hunted by the Indians, ib.; fables concerning the, ib.; when tamed, its fretfulness, 467; varieties of the, ib.
Porpoise, the, distinguished, ii. 264; its agility, 265; method of seeking its prey, 266; destructive to the nets of fishermen in Cornwall, ib.; follows fish up fresh water, ib.; seen in the Thames at London, ib.; how killed there, ib.; oil from the, ib.; fishery on the west shores of Scotland, ib.; young, ib.; age, ib.
Portuguese-man-of-war, a small molluscous animal so called, account of the, ii. 375, *n.*
Pouch of the opossum kind, described, i. 514.
Pouched animals, or *Marsupiata*, i. 511—513, *n.*
Poultry kinds, their utility, ii. 59; characteristics, ib.; habitudes, 59—61.
Prawn, description of the, ii. 331, *n.*
Pregnancy, progress of the embryo during, i. 157—160; a child wonderfully affected by an execution seen by the mother, while in that state, 219.
Prey, beasts of, their habits, i. 239, 240.
Prince of serpents, a beautiful species in Japan, ii. 428; a favourite there, ib.
Propolis, the substance with which bees stop crannies in their abodes, ii. 524; whence collected, 525; manner of using it, ib.
Proportions of the human body, i. 176.
Proteus genus of infusoria, ii. 627.
Ptarmigan or *White Grouse*, ii. 80, *n.*
Puberty, season of, i. 165; its time in different countries, ib.; symptoms of, ib.
Puffin, bill of the, described, ii. 220; legs, ib.; migration for the purpose of hatching, 221; dangers undergone then, ib.; enemies, ib.; dispossesses the rabbit of its burrow at Priesholm, ib.; how taken there, ib.; flesh, ib.; migration, 222.
Puma, the, called the American lion, i. 368; description of the, 375, *n.*
Pupa state of insects, ii. 612.
Python, a genus of reptiles, ii. 429, *n.*

Q

Quadrupeds, classification of, i. 234, 235; their rank, 235; utility, 236; analogies to man, 237; their adaptation to their stations, 238; different structures of their heads, ib.; teeth, ib.; legs, ib.; stomach, ib. their hostilities, 239; seasons of seeking prey, ib.; de-

fences, 240; causes of variety among, 240—242; their comparative size in the different continents, 242; their generation, 243, courage and art in defending their young, ib.; seasons of breeding, ib.; those from the egg, ib.; those covered with scales instead of hair, their distinguishing qualities, i. 467; amphibious their characteristics, 475; observations on the subservience of quadrupeds to man, 561.

Quadrumana, four-handed animals, the monkey kind, i. 489; their comparative advantages, 515. See *Monkey*.

Quagga, a species of the horse, described, i. 264, *n.*

Quail, the, described, ii. 84 and *n.*; account of the migration of the, 85; quail-fighting among the Athenians, ib.; how caught by a call, ib.

Queen bee in a hive, ii. 513; never more than one, ib.; her eggs, ib.

Quito, a city on the Andes, i. 61; its height, 62; appearance of meteors there, 135; the wild-ass how hunted there, 261.

R

Rabbit, stages of generation in the, i. 157; distinct from the hare, i. 434; makes holes for security, ib.; said to be originally from Spain, ib. *n.*; rabbits live in a social state, ib.; care for their young, ib.; love the fields, ib.; sometimes bring forth at a distance from the warren, ib.; description of the apartment in which the female brings forth, 435; the tame, does not burrow, ib.; various colours of the domestic breed, ib.; account of the production and subordination of some domestic ones, ib.; age of the, ib.; flesh, ib.; multiplication of the, in Spain, ib.; prefers a warm climate, ib.; tame, the larger, 436; the Syrian, ib.; none in America, ib.

Race, human, varieties in the, i. 209; difference, small, ib.; classification of the, ib.; several described, ib.; in the polar regions, ib.; the Tartars, 211; Negroes, 212; Americans, 213; Europeans, ib.; diversified by colour, 214, 215; stature, 216; face, ib.; all from one common stock, 217, 218.

Racoon, called the Jamaica Rat, its description, i. 544; abode, ib.; injurious to plantations, ib.; capable of being tamed, ib.; sagacity of the, ib., *n.*

Raesal, his accurate history of the frog, ii. 378.

Rails, account of the birds so called, ii. 197, *n.*; water rail, ib.; land rail, or corn-crake, ib.

Rain, how produced, i. 129, 130.

Rainbow, lunar, seen in the north, i. 136; phenomena of the, 139, *n.*; solar, its appearance in the polar regions, ib.

Rain-fowl, ii. 101. See *Woodpecker*.

Rain-water, its impurity, i. 68.

Ranking, his account of the Indian elephant, i. 522.

Rapacious birds, their adaptation, ii. 28, 29; habits, 29; classification, 30, 31.

Rat, the great, or Norway, or Surmolot, its native country, i. 448; characteristics, ib.; hostility to the black rat, 449; extirpated frogs in Ireland, ib.; its habits of rapacity, ib.; propagation, ib.; its enemies, the dog, cat, and weasel, ib.; black, the common, 448; description of the, 450, *n.*; extraordinary numbers of rats at the horse slaughter-houses of Paris, ib.; where found, 451; black-water, its distinctions and food, ib.; Canada rat, 454, *n.*

—— German, i. 454. See *Cricetus*.

—— *kind*, animals of the, their characteristics, i. 428; multiplication, ib.

—— musk, varieties of the, i. 454; the desman and pilori, ib.; the ondatra, described, ib.; disposition and manner of living, ib.; scent of the, ib.; variously esteemed, ib.

Rattlesnake, the, described, ii. 421; its rattle, ib.; its mortal bite, 422; symptoms, ib.; fatal cases of its bite, ib., and *n.*; remedies, 423; account of its power of fascination, ib.; proof, ib.

Raven, its characteristics, ii. 87, 88, and *n.*; influence of climate on the, 88—92; the white, 92; reclaimed and trained, ib.; habits in the tame state, ib.; in the wild, ib.; reverenced by some, 93; ominous character of the, ib., *n.*

Ray, his classification of animals, i. 231, 232.

Ray kind, fish of the, their properties, ii. 273; characteristics, ib.; the sharp-nosed, ib.; thornback, ib.; fire-flare, ib.; their size, ib.; safety from it, ib.; stories of some of prodigious size, 274; retreats of the, ib.; female and eggs, ib.; fishing of the, how practised at Scarborough, ib.; the Italian method, 275; injurious species, ib.; characteristics of the rays or skate, ii. 276, *n.* See *Skate*.

Razor-shell, its remarkable hole, ii. 369; how taken, ib.

Redbreast, its note and habitudes, ii. 149 and *n.*

Red Sea, nature of its channel, i. 102.

Redshank, the, described, ii. 193, *n.*; spotted redshank, ib.

Red-wing, description and habitudes of the, ii. 144, 138, *n.*, 141, *n.*

Rein-deer, its country, i. 335; usefulness, ib.; change of hair, colour, horns, &c., 336; endeavour to introduce into Britain unsuccessful, ib., *n.*; Lapland, described, ib.; enemies to the, there, 337; how the natives protect it, ib.; the female, its young and milk, ib.; how it spends the winter in Lapland, ib.; said to eat mountain rats, ib., *n.*; dependence of the Laplander on the, 338; the kinds of the, ib.; migrations of the, ib., *n.*; patience of the tame, 339; the milking of the, described, ib.; their age, 340; uses of the flesh, ib.; milk, ib.; skin, ib.; diseases of the, 341.

Relish, on what it depends, i. 201; how affected by circumstances, 202.

Remora, or *Sucking-fish of the Shark*, ii. 272, 292, *n.*

Reptiles, their characteristics and classification, ii. 431—435, *n.*

Respiration on mountains, i. 62; of plants, ii. 597.

Rhine, cataracts of the, 81; a part of, lost in the sand, 83.

Rhinoceros, size of the, i. 529; shape, ib.; horn, ib., 530, *n.*; contends with the elephant, 530; fables concerning the, ib.; account of that described by Parsons, ib.; age, 531; country and haunts, ib.; food, ib. and 530; how taken, 531; varieties, ib.; the double-horned, ib. and *n.*

———— *bird*, account of the, ii. 101, *n.*

Ring-dove, described, ii. 129.

Rivers, comparative purity of the water of, i. 68; opinions concerning their origin, 73, 74; whence supplied, 74; in what manner, ib.; their channels, ib., 75; their current, 75; sinuosities increase as they approach the sea, ib.; some with many mouths, ib.; their rapidity how affected, 76; the largest in Europe, 77 and *n.*; in Asia, 77; in Africa, 78; in America, 80, 81; cataracts of, 81; rivers lost in the sand, 83; quantity of water in, 84.

Roach, how fished for, ii. 322, *n.*

Roc of Arabian writers supposed to be the condor, ii. 39.

Rocks formed of infusorial remains, ii. 594.

Roe-buck, described, i. 330; the haunts of the, ib.; method of running, ib.; constancy of their attachment, ib.; their generation, growth, cry, &c., ib., 331; varieties, 331.

Roller, a kind of jay, ii. 99.

Romans, destroyed the British forests, i. 101.

Rook, the, description of, ii. 90, *n.*; habits of, 91, *n.*; formation of rook's nests, and general character of the community of a rookery, 93—96, and *n.*

Rope-walking, elephants taught, i. 526.

Rud, a small fish, notice of the, ii. 322, *n.*

Ruff, the, described, ii. 190—196; how taken, 197; and served up, ib.

Ruminating animals, the class of, i. 268; their habits, ib.; construction of their stomach and intestines, ib., 269; birds, 269; fishes, ib.; insects, ib.; instance of a man ruminating, ib.; cow kind, ib.; sheep and goat kind, 286; deer kind, 318.

Runner, a name of the corrira, ii. 190.

Rusfiberg, immense projection of the mountain of, i. 63.

Rutting season of the stag, i. 321.

S

Sable, value of its skin, i. 418; its fur described, ib.; its habitudes, 419; country, ib.; scarcity, ib.; hunted, ib.; encouragements to the hunting of, by the Russians, ib.

Sabra, the, or *Trachipterus*, notice of the fish, ii. 298.
Safety-lamp, account of Davy's, i. 28, *n.*
Sagoins, a genus of monkeys, i. 508.
Sai, or *the Bewailer*, a kind of monkey, i. 508.
Sajou, kind of monkey, i. 508.
Saki, or *Fox-tailed Monkey*, i. 508.
Salad-oil, a cure for the viper's bite, ii. 420.
Salamander, ancient notion of the, ii. 399; description of the, ib., *n.*; its appearance, 400; habits, ib.; whether venomous, ib.; gekko and black-water newt species, ib.; internal formation, ib.; viviparous, ib.; produces fifty at a time, 401; amphibious, ib.; changes its skin often, ib.; tenacity of life, ib.; the gigantic salamander, 400, *n.*
Salmon, the, characterised, ii. 301; its habits described, ib., *n.*; how angled for, 322, *n.*; parr, or samlet, 301, 302, *n.*, 321, *n.* [The parr is now proved to be, contrary to what is stated in the note, the young of salmon in its second season.] Salmon trout described, 302, 303, *n.*
Salt, scarcity of, in some countries, i. 86, *n.*; bay and common, i. 87; rock-salt, description of, ib., *n.*; uses of salt, ib.
Saltness of the ocean, opinions concerning the, i. 85; of lakes, ib.; attempts to deprive sea-water of its saltness, 86; advantages of the, 88; another effect of the, 89.
Salt Water, why fishes that live in it will expire in fresh, ii. 309.
Samari Monkey, i. 508.
Sanderlings, account of the, ii. 192, *n.*
Sand-piper, the green, described, ii. 193, *n.*
Sand-storm of Africa, description of the, i. 126.
Santorin, a new island appeared at, 1707, i. 53.
Sarcophagi, or *Stone coffins*, described, i. 227, *n.*
Savages, their barbarous treatment of women, i. 166; their confined aims, ib.; their attention to finery and dress, 173, 174.
Scales and pores of the human skin, ii. 604; method of viewing them under the microscope, 605.
Scales of fishes, ii. 605; of an eel, ib.; of a carp, ib.; hypothesis relating thereto, ib.
Scales on the wings of butterflies, ii. 617, 618; varieties, 618, 619; disposition on the wing, 619.
Scallop, the, remarkable for its manner of motion, ii. 369.
Scaurus Marcus, his exhibition of crocodiles to the Romans, ii. 399.
Sciæna, the, fish noticed, ii. 298.
Scolopendra of the East Indies, described, ii. 466, 467, and *n.*
Scooper, a name of the avosetta, ii. 189.
Scorpion, account of the, ii. 462—466, and *n.*; the black scorpion, 466, *n.*; the African scorpion, ib.
Scotchman, one in the Tower, his endurance of hunger, i. 186.
Scotland, great floods in, in 1829, i. 127, *n.*; red and fallow deer in, 323, 324, *n.*; capercailzie, or cock of the wood, once plentiful in Scotland, now extinct, ii. 78 and *n.*; endeavours to restore it, 79, *n.*
Sea. See *Ocean*.
Sea-bream, a prickly finned fish, ii. 297.
Sea-breezes, i. 123.
Seal, the parts of its body described, i. 481; its size and colour, ib.; characters of the varieties, 482 and *n.*; size of its brain, 482; its tongue, ib.; foramen ovale, ib.; habitation and food, 483; legs, ib.; a social animal, ib.; easily tamed, ib. *n.*; actions in fine weather and a storm, 484; migrates, ib.; propagation of the, ib.; manner of taking seals in Scotland, 485, *n.*; cry, 485; combats, ib.; method of pursuing fish, ib., 486; how caught by Europeans, ib.; by Greenlanders, ib., and 484, *n.*; its skin and oil, 486; flesh, ib.; varieties of the, ib.; the ursine described, ib.; habits and affection, ib.; fights for its station, ib.; and for the female, ib.; the hooded, described, ib.; the bottle-nosed, ib.; food, ib.; gregarious habits, ib.; sluggishness, ib.; those seen by Lord Anson's people, ib.; their flesh, ib.; where found, ib.
Sea-larks, account of the, ii. 192, *n.*
Sea-purses, molluscous animals so called, ii. 376, *n.*
Sea-weeds, microscopic examination of, ii. 601; singular species, ib.
Seeds of plants, and their appendages, ii. 598; how to be microscopically examined, ib.; varieties. ib., 599.
Semen of animals, animalcules in, ii. 633, *et seq.*
Semnopithecus genus of Monkeys, its remarkable characters, i. 508.
Senegal River, in Africa, i. 78; how far navigable, ib.; inundations of, prejudicial, 80.
Sensations of a man newly brought into existence, described by Buffon, i. 202—204.
Senses of man, their comparative extent, i. 200 (see *Hearing*, &c.); mutual aids, ib.; combination of objects of, ib.
Seps, a venomous viper, ii. 423 and *n.*
Sepulchres, Egyptian, described, i. 226, 227; one in France described, 228.
Serpents, general characteristics of, ii. 407, *n.*; why held in detestation, 407; operation of the poison of, 408; uses of the, ib.; where most abundant, ib.; ancient devastations wrought by some not improbable, ib., 409; harmlessness with us, 409; distinguishing marks, ib.; swallow, ib.; organs, ib.; internal parts, 410; number of joints in the back bone, ib.; the ribs, ib.; skin, ib.; scales, ib.; distinctions in size, 411; size of some, ib.; torpidity after feeding, ib.; track of the, ib.; indiscriminate prey, ib.; contests for water, 412; capability of abstinence, ib.; voices, ib.; motions, ib., 413; amphibious in fresh water only, 413; fœtor, by what possessed, 408, 413; distinguished as viviparous or oviparous, 414; as venomous or not, ib.; their defence from their poisonous qualities, ib.; enemies, ib.; means to destroy and charm them, ib., 415; by what nations adored, and how, 415; classification, ib.; incantation of serpents, ib., *n.*; venom, 416; (see *Venomous Serpents*); those without venom, characteristics of, 426; their bite, ib.; manner of attack, ib., 427; varieties, 427, 433, *n.*; serpents in South Africa, 424, 425, *n.*; serpents in Demerara, 426, *n.*
Serpent, Sea, the, or *Elops*, noticed, ii. 299.
Serpent-stone, account of the, ii. 426; how it produces its effects, if any, ib.
Serval, described, i. 381; its resemblance to the caracal, 383.
Sexes, state of the, in different countries, i. 165, 181.
Shagreen, leather from the skin of the wild ass, i. 260.
Shape of man, i. 167; of woman, ib.
Shark, the, its varieties, ii. 269 and *n.*; the blue shark, 269, *n.*; the basking shark, 270, *n.*; the angel shark, ib.; the great white, its voracity, 270; the, described, 271; fins, ib.; eyes, ib.; swiftness, ib.; how it seizes its prey, ib.; depredations, ib.; instance of one biting off a man's leg, ib.; devouring persons let down into the sea, ib.; enmity to man, ib.; how taken by bait, 272; harpooned, ib.; killed by the negroes, ib.; the sucking fish, or shark's pilot, ib.; young of the, ib.; flesh, 273; oil, ib.
Shaving, practice of, in different ages, i. 172, *n.*
Sheath-fish, or *Silurus*, notice of the, ii. 299.
Sheep kind, animals of the, i. 286; nearly allied to the goat, ib., *n.*; distinguished from the goat, 286, 287; qualities and disposition of sheep, 287, 288, and *n.*; habits when tamed, 288; on the continent, follow the shepherd, ib.; their fleece, 289; teeth, 290; their young, ib.; where found in their noblest state, 291; effects of climate on, 293; different kinds of, out of Europe, Iceland, ib.; Merino sheep, account of, 289, *n.*; varieties of British sheep, 291, *n.*; long-woolled British sheep, the old and new Leicester, the Teeswater, the Devonshire nots, the Exmoor and the Heath sheep, ib.; short-woolled sheep, the Dorsetshire, the Wiltshire, the Herefordshire, the South Down, the Norfolk, the Cheviot, &c., ib., and 292, *n.*; Herdwick sheep, dun-faced breed, Hebridean and Zetland sheep, 292, 293, *n.*; breeds of Africa, 293, *n.*; breeds of Asia, 294, 295, *n.*; breeds of Iceland, 295, *n.*; Wallachian breed, 296, *n.*; number of sheep in Great Britain, ib.; the primitive race of, ib.; the musmon, 298 and *n.*
Shell, the, of testaceous fishes, its substance, ii. 347; account of the formation of that of the garden snail, 348; whether formed of the slime of the animal's body, 349; colouring of the, how accounted for, ib.; convolutions of the, depend entirely on the animal, ib.; collections of shells, how polished, 350; pleasures of the occupation, ib.; birds that eat them, 351; shells serve as abodes to other animals, 352; classification of, ib.; Lamarck's synoptical table of, 354—358, *n.*; various places where found, 352, 353; pelagii, or those confined to the ocean, 355; littorales, or those cast

on shore, ib., 356; fresh water, 358; living land shells, ib.; fossil shells, their variety and condition, ib.; see also, i. 22, *n.*; all the spoil of some animal, ib.; historians of this class of nature, ib., 359; uses and value of shells, 358, *n.* See *Conchology.*
Shell-fish, claims to be considered as fish, ii. 326; the two tribes of, ib.; crustaceous, characterised, ib.; testaceous, 347.
Shepherd's dog, described, i. 338; patience and faithfulness of the, ib.; hardiness, ib.
Shores, often a defence against the sea, i. 96; different appearances of, ib., 97.
Short-sightedness, i. 194. See *Vision.*
Shoveller, ii. 185—187. See *Spoonbill.*
Shrew-mole, account of the, i. 461, *n.*
Shrikes. See *Butcher-bird.*
Shrimp tribe, the food of the whale, ii. 253; process of casting its shell, 328, *n.*; shrimps described, 331, *n.*
Siamang, a long-armed ape, i. 498, *n.*
Silk, historical account of, ii. 507, *n.*
Silk-worm, ignorance of the ancients with respect to the, ii. 507; when first brought into Europe, 508; the described, ib. and *n.*; the two methods of breeding the, 509; in the warm climates of the East, 510; in Europe, ib.; form, &c. of the apartment in which it is bred, ib.; provision of leaves, ib.; air, ib.; progress of the worm, ib.; its formation of the silk-cone, 511; the thread described, ib.; its change into the winged state, ib.; male and female, ib.; eggs, ib.; method of unwinding the thread, ib.
Simoom, described, i. 10, *n.*, 126.
Singing-birds, their notes described, ii. 137; American, 146.
Sirli, a species of lark, ii. 151, *n.*
Sirocco wind, notice of, i. 128, *n.*
Siskins, birds resembling the linnets, ii. 158, *n.*
Size of the human body, its varieties, i. 176; variations, ib., 177.
Skate, the, discriminated, ii. 273; characteristics of the rays or skates, ii. 276, *n.*; the long-nosed skate, ib.; the blue skate, ib.; the sharp-nosed ray, 277, *n.*; the thornback, ib.
Skin, effects of age on the human, i. 205.
Skink, a kind of stinkard, described, i. 421.
Skuas, sea-birds, account of the, i. 215.
Slatberg in Iceland, disruption of the mountain of, i. 64.
Sleep increases the weight of the body, i. 177; necessary to all animals, 183; most of all to man, 187; some animals spend much time in, ib.; effects of the want of, on man, ib.; cause of unknown, 188; effects of, ib.; physiology of, ib., *n.*; instances of somnambulism, 189; much required by the studious, ib.; a German student performed his tasks during, 190; story of a sleep-walker, ib.
Slips of mountains, land-slips, i. 63; snow-slips, 64.
Sloth, varieties of the, i. 557; description of the, ib. and *n.*; spends its whole life on trees, ib., *n.*; Waterton's account of the, 558, *n.*; its method of scrambling on the ground, ib.; its structure and habits, 559; whether an unfinished quadruped, ib.; abstinence, ib.
Smelling, an inferior sense in man, i. 200; power of, possessed by some nations, ib.; uses of ib.; the taste of different nations in respect to the objects of, 201 and *n.*; sense of, possessed by birds, ii. 3.
Snail, the garden, its process in forming its shell described, ii. 348; organs of the, 359, 360; horns and eyes on the two uppermost, 360; organs of generation, ib.; coupling, ib.; eggs, ib.; growth of the shell, 361; can mend its shell when broken, ib.; not make a new one, ib.; method of motion, ib.; slime, ib.; appetite, 362; killed by salt, &c. ib.; torpidity, and manner of burying itself, ib.; awakening, and voracity, ib.; varieties of the snail, ib.; the fresh-water, ib.; its peculiarities, ib.; manner of rising to the surface, ib.; viviparous, ib.; brought forth with the stony coat, 363; sea-snails, ib.; manner of impregnation, ib.; want horns, ib.; convolutions of the shell, ib.; the trochus kind, ib.; the nautilus, 364.
——— the sea, whence the name, ii. 289; the, described, 290; account of the garden snail, 359, 360, *n.*
Snake, the black, the largest of English serpents described, ii. 427; not venomous, ib. and *n.*; manner of attack, and how repelled, ib.; prey of the, 428; oviparous, ib.; torpid in winter, ib. See *Serpents.*
Snake-root, Virginian, the best cure for the bite of the rattle-snake, ii. 423.
Sneezing, description of, i. 171, *n.*
Snipes, described, ii. 191, *n.*; the double snipe, ib.; the little snipe, ib.; the common snipe, 192, *n.*
Sobbing, whence it proceeds, i. 171 and *n.*
Solan goose, ii. 208. See *Gannet.*
Sole-fish, described, ii. 300, *n.*
Solfatara, valley of, exhibits the effects of earthquakes, i. 52.
Solon, his opinion of the beauty of the pheasant, ii. 72.
Sound, reflection of, i. 116; transmitted by the undulation of the air, ib., *n.*; how produced, 196; how rendered a tone, ib.; reflected, 198.
Sow. See *Hog.*
Spalax, or *blind rat*, i. 461, *n.*
Spaniards, their value for asses, i. 264.
Spaniel, the large and small water, described, i. 390, 391, *n.* and 394. See *Dog.*
Sparrow, the, its habits described, ii. 135 and 136, *n.*
——— *kind*, birds of the, their abode near man, ii. 130; why they avoid forests, ib.; attachment to places, ib.; accounts of their flights and passages, 131; arts of the bird-catcher to take them, ib.; contentions of the, 132; singing, proper to the male, ib.; the female, nest, and young, ib.—135; paring of the, 135; chastity, described by Addison, ib.; exceptions, ib.; resemblances among the, ib.; classification, 136; slender-billed, ib.; their food, ib.; and song, ib.; thick-billed, ib.; their food, 137; note, ib.; those of passage, ib.; their seasons of migration, ib.
Sparrow-hawk, ii. 46, *n.*
Sparus, a prickly-finned fish, ii. 297.
Spawn of fishes, account of the, ii. 247, 248; estimate of its immense amount, 249, 250.
Speech, acquisition of, by infants, i. 163.
Spermaceti, found in the head of the cachalot, ii. 263; how distributed there, 264; uses of, ib.; how the whole oil of the fish convertible into, ib.; where the whales that yield it, abound, ib. *n.*
Spermatic Animalcules, 638 et seq.; discovered by Leeuwenhoeck and Hartsoeker, ib.; hypothesis concerning, ib.; Leeuwenhoeck's observations, ib.; animalcules in the human semen, ib.; in that of a cod-fish, 639; general discoveries by Leeuwenhoeck in this department, ib.; objections to his discoveries, answered, ib.; Buffon's notions concerning the sperm animals, ib.; Buffon's errors, ib.; Needham's hypothesis, 640; his reasonings regarding the seminal animal of the calmar, ib.; Buffon's remarks thereon, ib.; the fundamental error exposed, ib.; wild speculations concerning the seminal animals, ib.; desirable to elicit more information concerning them, ib.
Spider, the, described, ii. 448—453 and *n.*; construction of its web, 449, *n.*; different kinds of spiders, 455, *n.*; remarkable nest of one, 448 and *n.*
Spinous fishes, how distinguished by their gills, ii. 293; numerous species, ib.; systems ib.; Artedi's, ib.; Linnæus', ib.; Gouan's, 294; particulars of, with descriptions, 294—307; uniformity of their description 307, 308; their bones, ib.; proportion of, to the fins, ib.; live but a short time out of water, 309; exceptions, ib.; passage of some from salt to fresh water, ib.; some from fresh towards salt to spawn, ib.; fishes of passage, ib.; the cod, 310; haddock and mackarel, 310; herring, ib., 311; pilchard, 312—314; their immense numbers, 314; their numbers in the Indian ocean, 318; whether they come from the egg perfectly formed, ib.; white bait, ib, impregnation, ib.; growth, ib.; live on one another, ib.; the dorado, 319; warfare in fresh water, ib.; diffidence of fresh water fish, ib., 320; voracity of the pike, 322; torpidity in winter, ib., 323; diseases, 324; poisonous qualities of some, ib.; how caused, ib.
Sponges belong to the polypi, ii. 564, *n.*; different species of, 570, *n.*
Spoonbill, the, described, ii. 185, 186 and *n.*; the European, 186; the American, ib.; fine colour and uncouth shape, ib.; habits, ib. and *n.*; food, ib.; nest and young, 187; white spoonbill, 186, *n.*; roseate spoonbill, ib.
Spouts, water, one in the Mediterranean described by Tournefort, i. 143; their origin, 144; dreaded by mariners, ib.
Sprat, or *Garvie Herring*, description of the, ii. 317, *n.*

Springbok, a species of African antelope, described, i. 313, 314, *n.*
Spring-water, i. 67; spouting and intermitting springs, 67, *n.*; hot, account of, 68; at Bath, ib.; at St Miguel, ib.
Squash, a kind of stinkard, described, i. 279.
Squilla, or *White Shrimp*, ii. 331, *n.*
Squirrel, an idea of its form, i. 436; the tail and its uses, ib.: varieties of the, ib.; the common described, ib.; the ground squirrel, 437, *n.*; the gray Virginian, 437; the Barbary, ib.; the Siberian white, ib.; Carolina black, ib.; Brazilian, ib.; that of New Spain, ib.; its extensive diffusion, ib.; the varieties differ in disposition and food, ib.; the common, characteristics of the, 438; agility, ib.; food, ib.; its nest described, ib.; provisions of nuts, ib.; propagation of the, ib.; watchfulness, ib.; its nimbleness, ib.; oaks planted by the squirrel, ib., *n.*; abode on trees, 439; migrations of the, in Lapland, ib.; method of crossing lakes there, ib.; domesticated, ib., 440; preference of fixed to revolving cages for squirrels, 439, *n.*; the flying, its class, 440 and *n.*; European flying, where found, ib.; its habits, ib.; female's care of the young, ib.; description of the, and its nature, ib.; its amazing spring, ib.; how adapted for it, ib.; where found, ib.; tamed, ib.
Staffa, description of, i. 33, *n.*
Stag, described, i. 319; its horns, ib., 320; the rutting season of the, 320, 321; size, colour, and habits, 321, 322; hunting of the, 322; laws concerning the, ib., 323; description of stag-hunting in England, 323, 326; hunted in Sicily, 326; in China, ib.; the Chinese stag described, ib.; Corsican, 327; that of Germany, ib.; that of Sardinia, ib.; the American, ib., 328.
Stagnant water, i. 67.
Stamina of flowers, microscopic examination of, ii. 597.
Stare, or *Starling*, its description, ii. 144, and *n.*; voice, ib.; migration and peculiar flight, ib.; the red-winged of America, 145, *n.*
Star-fish, the, described, ii. 561; hard substances found in its stomach, ib.; increases in size, ib.; properties, ib.
Stars, fixed, i. 7, 8, *n.*; falling, what, 139; phenomena of, 140, *n.*
Statues, ancient models of beauty, i. 176.
Stature of the body, how affected, i. 216; of men not diminished, 223.
Stewart, Dugald, his account of a boy born blind and deaf, i. 199.
Stickleback, the, or *Gasterosteus*, described, ii. 293 and *n.*
Stings of insects, ii. 620; poison bag, ib.
Stinkard, fœtid smell of the, i. 420; varieties of the, ib.; anecdote of a, ib., *n.*; the squash, skink, &c., ib.; their fœtid glands described, ib., 421; uses of this odour to the animal, ib.; strength and offensive nature of it when the animal is enraged, ib.; an instance of this by Kalm, 422; kept tame by the Americans, ib.
Stoat, when the ermine properly so called, i. 413 and *n.*
Stock-dove, the original of the pigeon, ii. 125; described, ib.; young, 127.
Stomach of quadrupeds, i. 238.
Stomata of plants, ii. 597.
Stones, precious, whence their value, i. 173; meteoric stones, account of, 141, *n.*
Stork, its resemblance to the crane, ii. 175; distinguishing characters of the genus from herons and cranes, ib., *n.*; the white stork, ib., *n.*, 176; the black stork, 176, *n.*; regular migrations and manner of, 177; food of the, ib.; affection for young, ib.; friendly feeling towards men, ib.; storks held in reverence by the Turks, ib., *n.*
Storm, account of the great storm in Britain, in 1703, i. 126, *n.*; storm of 1783, ib., 127, *n.*; other storms, ib.
Strabism of the eyes, what, i. 194.
Strength of man, i. 177—180; instances of muscular strength, 177, *n.*; some remarkable instances of the, 180.
Strepsicheros, breed of sheep, described, i. 296.
Stromateus, a soft-finned fish, ii. 299.
Sturgeon, its disposition, ii. 283; description, ib.; different kinds and different uses of each, ib.; visits all the seas of Europe, ib.; size of one taken in the Eske, ib.; where most abundant, 284; how caught, ib., 285; temperate and timid, 284; preserved, 285; trade with the roe, ib.; isinglass, ib.; sturgeon fishery, 284, *n.*
Sucking-fish, the, or *Echineis*, ii. 300.
Sun-fish, its size and appearance, described, ii. 287.
Suns, mock, or reflected, seen in the polar regions, i. 139
Surf of the sea, its dangerous nature, i. 97.
Surinam Toad, account of the, ii. 389; (see *Pipal*); serpent, its beauty, 428; considered fortunate by the savages there, ib.
Surmolot, or *great brown rat*, described, i. 448. See *Rat.*
Surmulet, notice of the fish, ii. 298.
Swallow, its migration, ii. 16; peculiarities and varieties of the, 160; characteristics of the, 161; food, ib.; agility, ib.; tail, ib.; its appearance in spring, ib.; difference between the chimney swallow and window swallow, ib., *n.*; nests of the various kinds of the, 162; in China, ib.; how to discard them, ib.; eggs and young, 163; assembling of the, ib.; migration, ib.; seen at sea, ib.; whether all migrate, ib., 164, *n.*; the swift and other varieties, ib., 160; the nocturnal, or goat sucker, ib.; nests of the Chinese, in what estimation held as a delicacy, 162; commercial statistics regarding, ib., 163, *n.*
Swallow, sea, a kind of gull, ii. 210.
Swallows of Ternate, a name of the bird of paradise, ii. 109.
Swammerdam, his persevering inquiries into the nature of shell-fish and insects, ii. 359.
Swan, characteristics of the, ii. 224 and *n.*; the wild swan, 225, *n.*; the black swan, ib.; whether the swan sings, 226; relations on the subject, ib., 227; food of the, ib.; incubation and young, ib.; formerly esteemed for the flesh, ib.; where now preserved for their beauty, ib.
Swift, a kind of swallow, its distinctions and habits, ii. 160.
Swimmers, an order of birds, characteristics of, ii. 201.
Swine. See *Hog.*
Sword-fish, its attacks on the whale described, ii. 255; the, described, 294 and *n.*
Syagush, name of the caracal, i. 381, 383. See *Caracal.*
Syria, animals of, the softness of their hair, i. 359.
Systems of natural history, method of using, i. 230; advantages of, ib.; defects of, 231; Ray's, ib.; Klein's, 232; Linnæus', 233; that followed in this work, 233—235.

T

Tadpole, the spawn of the frog. See *Frog.*
Tajacu, i. 349. See *Peccary.*
Talapoin, a monkey, fine colours of the, i. 507 and *n.*
Tamain, kind of monkey, i. 508.
Tamandua, larger and smaller species of the ant-eater, i. 556.
Tanrec, distinguished from the hedgehog, i. 464; described, ib.; habitudes, ib.
Tapeti, or *Brazilian Rabbit*, an account of the, i. 446.
Tapir, the hippopotamus of the new continent, i. 352, *n.*, 552, *n.*; described, 552; its food, ib.; flesh, ib.; the tapir of Malacca and Sumatra, 553, *n.*
Tarantula, a dance practised in Italy, i. 198, *n.*; a kind of spider, described, ii. 454; its fabled dangerous bite and cure by music, 455.
Tarnassar, the great bird of, supposed to be the condor, ii. 39.
Tartar race of men, described, i. 210, 211.
Tasting, opinions concerning the sense of, i. 201; sensible in children, 202; affected by habit, ib.
Tatou, (see *Armadillo*), i. 469; apara, 471; of Ray, ib.; tatuette, ib.
Teeth, variety of, in animals, i. 174; of quadrupeds, 238; of the cow, 270.
Telescope fish, described, ii. 291, *n.*
Temperate regions, earth in the, i. 11.
Tench, fish, described, ii. 306, 307, *n.*; how angled for, 323, *n.*
Tendrac, the, distinguished from the hedgehog, i. 464; size, movements, and habits, ib.
Teneriffe, peak of, a volcano, i. 44; its height, 62.
Termites, or *White Ants*, description of the, ii. 537, *n.*; singular construction of their nests, ib., 538.
Ternate, how rendered unwholesome, i. 112.
Terns, or *Sea Swallows*, characteristics of the, ii. 212, *n.*
Tethys, the fish described, ii. 299.
Therasia, a new island, i. 53.

Thermometer, i. 69; principle of the, ib.
Thirst, causes and consequences of, i. 185, *n.*
Thoracic fish, what, ii. 294; prickly-finned, 295; soft-finned, 299.
Thornback, a species of skate, ii. 277, *n.*
Thrush kind, birds of the, ii. 137; different species of thrush, their habits, &c. 138, *n.*; their properties, ib.; the song thrush or mavis, 139, *n.*; the missel thrush, its size and distinctions, ib. and *n.*; the punctated thrush, 141, *n.*; the rock thrushes, 142, *n.*; the mocking thrush, 143, *n.*; other varieties, 145; the fieldfare, blackbird, &c. See *Fieldfare*, *Blackbird*.
Thumb-footed shell-fish, account of the, ii. 374.
Thunder, phenomena of, i. 133, *n.*
Thyroid cartilage, seen in men, i. 175.
Tides of the ocean, i. 90; description of the, ib.; precise account of the manner in which they are caused, 90, 91; affected by the channel of the sea, 91, 92; the greatest where, 92; an effect of the, ib.;
Tiger, the, its beauty, i. 369; fierceness, ib.; distinctions of the, ib ; relative position, ib ; where found, ib. and *n.*; tiger hunting in India, 370, 371, *n.*; habits, 371; strength, ib. and 372; combat of one with three elephants, ib.; the three kinds of the, in Sundah Rajah's dominions, 373; scarceness of the real species, ib.; how far tameable, 369; tigress and her young, 373; their skins, 374; clouded tiger, ib., *n.*
Tinea. See *Moths*.
Tipula, the, gnat, described, ii. 553.
Titmice, account of the various species of, ii. 151, *n.*; bottle tit or long-tailed titmouse, 154, *n.*
Toad, the, distinguished from the frog, ii. 334; hideous to the imagination, ib.; resemblance to the frog, ib.; propagation and assistance of the male, 335; food, ib.; account of the habits of one tamed by Arscott, ib.; instance of Germans eating the, without injury, 336; another instance of its wholesomeness, ib.; fables concerning the, ib.; its real character, ib.; torpidity, in winter, ib.; account of several instances of its being found in the heart of trees and stones, ib.; experiments regarding this singular phenomenon, ib., *n.*; account of their sucking cancerous sores, 338; varieties, the water, ib.; the pipal or Surinam, 339; the horned toad, ib.
Tococo, the flamingo, why so called by the natives of Canada, ii. 188.
Tones, how produced, i. 196; their succession in proportion make music, ib.
Tongue or *proboscis of insects*, ii. 615; of the house-fly, ib.; of the honey bee, 616.
Tonquin, extraordinary tides there, i. 92; how accounted for, ib.
Tornado, description of the, i. 125, 126.
Torpedo, a kind of ray, described, ii. 278; its electrical shock described, by Kempfer, ib.; causes ascribed for the effect, 279; its power declines with its vigour, ib.; where the power resides, ib.; other fishes possessed of the same power, 280.
Torsk, a species of cod, described, ii. 300, *n.*
Tortoise, its superiority to the fish tribe, ii. 337; why ranked among them, ib.; land and water, ib.; difference between the, and the turtle, ib., 338; habits of the ib.; shell, ib.; the body described, ib.; various species of, ib., *n.*; internal structure, ib.; its organs described, 339; difficult to be killed, lives with the brains out and the head off, ib.; longevity of the, ib.; account of one at Peterborough which lived above 200 years, ib., *n.*; food of the, 340; motion of its blood, ib.; dormant state, ib.; slowness of all the actions, and changes of the, ib.; eggs, ib.; nest, ib., 341; shell composed of several pieces, ib.; habitudes, ib., 432, *n.* See *Tortoise*, see *Turtle*.
Toucan, account of its extraordinary conformation, ii. 99 and *n.*; of the red-beaked, 100; food or prey, ib. and *n.*; tongue of the, and its use, 101; how it protects its young, ib.; where found, ib.
Touch, sense of, corrects sight, i. 193; its utility, 202; widely diffused, ib.; affected by habit, ib.; where chiefly seated, ib.; importance of, ib.
Trachinus, or *weever*, a kind of fish, described, ii. 295; pain of the sting of its back fin, 324.
Trachipterus, or *sabre*, the fish, noticed, ii. 298.
Trade-winds, i. 117; history and theory of, 118, *n.*; in the Atlantic, 122; off Nova Zembla, &c. ib.
Tragelaphus, the stag of Germany, i. 327.
Transformation of insects, ii. 437.
Tree wasp. See *Wasp*.
Tree-hoppers, Rennie's name for the ancient cicada, how applicable, ii. 476; their instrument of sound, ib.
Trees, formation of, ii. 602.
Trembley, the discoverer of the reproduction of zoophytes from cutting, ii. 567; his classification of the polypus, 570.
Trichoda genus of infusoria, ii. 633.
Trichurus, a prickly-finned fish, ii. 294.
Trigla, properties of the fish, ii. 298.
Trochus, a peculiar kind of snail without mouth, ii. 363; preys on other snails, ib.; all sea-snails liable to its attacks, 364.
Troglodyte, described, i. 491.
Trogons, a family of birds peculiar to warm climates, described, ii. 101, 102, *n.*
Tropics, constancy of winds there, in certain seas, i. 117; hurricanes at the, 125; atmospheric phenomena of the 133—135.
Trout, description of the, ii. 302, *n.*; how angled for, 323, *n.*; the great gray trout of Loch Awe, 302, *n.*; salmon trout, 303, *n.*
Trunk of the elephant, account of the, i. 518.
Tumble-dung, a kind of beetle, described, ii. 546; its sense of smelling, ib.; kings of the class, 547.
Tumbler, a kind of dog, described, i. 394.
Tunny fish, described and tunny fisheries, ii. 297, 298 and *n.*
Turbinated shell-fish, ii. 352—359.
Turbot fish, described, ii. 300, *n.*
Turkey, its original country, ii. 66 and *n.*; the American wild, 67; Prince Charles Lucian Bonaparte's account of the, ib., *n.*; habits in the wild state, ib.; how hunted, ib.; habits, animosities, and antipathies of the tame, 70; cowardice, ib.; female and young, 71; screams and agitation of the female when the young attacked, ib.
Turnstone, described, ii. 194, *n.*
Turtle, the, whence its difference from the tortoise arises, ii. 337; the, described, 341; the great Mediterranean, or coriaceous, its great size and uselessness, ib.; poisonous, ib.; account of one of this species, ib.; of one caught near Scarborough, 342; those of the Indian ocean, the trunk, ib.; the loggerhead described, ib. and *n.*; hawksbill or imbricated, 343 and 342, *n.*; the green, its estimation, 343 and *n.*; qualities of the, as food, 344; why called the green turtle, ib.; its size, ib.; where most numerous, ib.; comes from the sea to fresh water, and to deposit its eggs, ib.; breeding, ib.; eggs, ib.; hatched by the sun, 345; how taken, ib., 347; harpooned, ib ; how taken by divers, ib.; Audubon's account of the habits of turtles and the methods of taking them, ii. 345—347, *n.*
Turtle-dove, its fidelity, ii. 126; collared turtle, 125, *n.*; the bird described, 129; a bird of passage, ib.; nests and food, ib.
Turtle eaters, a people of Ethiopia, described, by Diodorus Siculus, ii. 344.
Tusks of the hog kind, their connection with their venery, i. 352; of the elephant, 519, 520; trade in the, 527, 528.
Typhons, or *water-spouts*, seen at land, i. 144; description of one at Hatfield, 1687, ib.; conjectures concerning, ib.

U

Unau, a kind of sloth, i. 557.
Unicorn, animals found in Africa and Asia resembling the fabulous unicorn, i. 532, *n.*; whence the origin of the stories concerning it, ii. 262; the sea or narwhal, described, 260.
Univalve, or *turbinated shell-fish*, ii. 359.
Uranoscopus, the fish, described, ii. 295.
Urchin, Sea, the proper class of the, described, ii. 373 and *n.* its horns and spines, ib.; its swiftness notwithstanding its many spines, ib.; what sort of food it is, ib.
Urson, distinguished from the porcupine, and described, i. 467.
Urus, white, the, or wild bull, where found, i. 276; described, ib.

V

Vampyre, the American, described, i. 473; blood-sucker, 474; Ulloa's report on this subject confirmed, ib.
Vansire, a kind of ferret from Madagascar, described, i. 415.
Vapours, noxious, in mines, i. 36; (see *Gas*); inflammable, in Persia, 40.
Vari, a kind of monkey, i. 510.
Vascular tissue of plants, ii. 601.
Vegetable Kingdom, discoveries therein by the microscope, ii. 595; Pritchard's remarks thereon, ib., 596; microscope reveals a beauty in vegetable structures not discoverable by unaided sight, 596; Brown's experiments on the pollen of plants, ib.; remarks concerning molecular activity as exhibited both in the mineral and vegetable kingdoms, ib.; circulation of fluids in plants, ib.; Pritchard's account of the cyclosis, 597; aquatic plants in which the circulation is readily observed, ib.; respiration of plants, ib.; the cuticle and stomata, ib.; singular alternate action of plants, ib.; a flower, microscopic examination of, ib.; petals, ib.; absorbents, ib.; stamens, filament, and anther, ib.; the pollen, ib., 598; true farina, 598; pistil, germen, style, and stigma, ib.; pistil, how impregnated, ib.; seeds, their forms and appendages, ib.; seed-lobes, heart, ib.; radicle and plumula, ib.; seeds, how to be microscopically observed, ib.; pappus, or down, ib.; its uses, ib.; ala, or wing, and its uses, 599; poppy seeds, their conformation, ib.; calampelus scaber, seed of, ib.; French marigold, seed of, ib.; theca, or seed-vessel, of moss, ib.; puff-ball, seed of, ib.; seeds of fern, ib.; polypodium of the oak, seeds of, ib.; plant, or tree, leaves, ib.; their composition, ib.; skeleton leaf, ib.; Baker's observations on the leaves of plants, ib.; leaves of stinging nettles, 600; the ferns, their seed-vessels, capsules, sporules, and frond, ib.; the mosses, and septa of, ib.; sphagnum, or bog-moss, leaf of, ib.; algæ, ib.; lichens, 601; fuci, or sea-weeds, ib.; singular species, ib.; confervæ, including chara and nitella, in which circulation is very apparent, ib.; mouldiness, plants of, ib.; fungi, their formation, &c., ib.; old opinions concerning, and remarks thereon, ib.; fungi producing dry rot, smut, &c., ib.; woody formations, ib.; stem, cuticle, bark, liber, sap, pith, ib.; cellular tissue, ib.; woody fibre, vascular tissue, ib.; microscopic examination of these, ib., 602; spiral, annular, and ducted vessels, 602; formation of trees, ib.; aloë, microscopic view of transverse section, ib.; of fibres of the palm, ib.; transverse section of clematis, ib.
Vegetables, their analogies to animals, i. 146; comparative number of vegetables and animals, 147, *n.*; different generative powers of vegetables and animals, 150, *n.*; most useful, 149; few noxious, ib.; organs of generation in, 153, *n.*; fossil remains of, ii. 594.
Venom of the serpent, the bag of, described, ii. 416; appearance of, through a microscope, 417; taste of, ib.; has been drunk without producing a bad effect, ib.; Lucan's observation of this, ib.; how fatal introduced into the circulation, ib., 418; experiment showing the potency of, 418; doubts, ib.
Venomous Serpents, seat of the venom in the animals, ii. 416; fangs, ib.; teeth, ib.; venomous bag, ib.; the fangs and the operation of wounding, ib., 417; appearances and effects caused by the wound, 417; the venom, ib.; habitudes, 418; food, ib.; manner of the attack, ib.
Vessels of vegetables, spiral, annular, and ducted, ii. 602.
Vesuvius, volcano of mount, i. 42; eruption of, in 1707, ib.; one in 1717, described by Berkley, 42—44.
Vibrio genus of infusoria, ii. 629.
Viper, manner of its motion, 412, 413; the, of Great Britain, 418, 419, *n.*; resorts, ib.; properties, ib.; eggs, 420; abstinence, ib.; torpidity during the winter, ib.; how taken, ib.; salad-oil a cure for its bite, experiment showing this, ib., and *n.*; the method of cure prescribed by Celsus, ib.; flesh said to be medicinal, 421; Swedish viper, ib., *n.*
Vision, errors in, i. 192, 193; does not give us an idea of distance without the aid of touch, 193; experiment on this subject, ib., 194; near-sightedness of, 194; at different ages, ib.; rendered indistinct by excessive brightness of the object, ib.; why, ib., 195.
Voices of birds, observations on the, ii. 4; of the various singing birds, described, 137; of American singing birds, 146.
Volcanoes, i. 40 and *n.*; their causes, 40; enumeration of, 41—45; whether they proceed from deep regions, 41.
Volvox genus of infusoria, ii. 627.
Vorticella genus of infusoria, ii. 634.
Vulture, its relative position among birds, ii. 40; distinctive qualities, ib.; varieties, the golden particularized, 40—43; localities of different species of vulture, 41, 42, *n.*; black vulture described, ib.; question whether the vulture is led to its prey by sight or smell, 42, *n.*; parts of the animal, 42; service of, in Egypt, ib.; habits there, ib.; in America, ib.; skill in tearing a body to pieces, and manner of feeding, 43; sloth and voracity, ib.; hostility to the crocodile, ib.; nests, ib.; the king of the vultures described, ib., 44.

W

Wagtails, account of the, ii. 153, 154, *n.*
Walfischoas, the Icelandic name for the food of the whale, ii. 253.
Wall-bees. See *Bee*.
Wanderow, a kind of baboon, an account of the, i. 501, and *n.*
Wapiti, a North American deer, i. 328, *n.*
Warblers, ii. 153, *n.*; pensile warbler, ib.; superb warbler, ib.
Warine, a Brazilian monkey, i. 508.
Washington, bird of, described, ii. 37, 38, *n.*
Wasp, very different from the bee, ii. 528; the, described, ib., 529, *n.*; voracity and fierceness, 529; distinctions of the communities of the, 530; account of the formation of its nest, ib.; materials, ib.; dome, 531; comb, ib.; pillars and stories, ib.; cell, ib.; worms and their processes, ib.; formidable to other insects, and voracious, 532; effects of winter on the, ib.; the solitary wasp, 533; its apartment, ib.; egg, ib.; provisions, ib.; death, ib.; emerging of the young, ib.; account of the wasp of the West Indies, 534; the tree wasp, 533, *n.*
Water, i. 65; its penetrating nature, ib.; absorption of by various bodies, ib., *n.*; its subservience to vegetation, 66; rain-water, ib.; spring-water, 67; river-water, ib.; stagnant, ib.; sea-water, ib.; mineral and medicinal, 68; impurities in, ib.; operation of cold and heat on water, 68—70; compression of, 70; fluidity, ib.; science of, or hydrostatics, 71; paradoxes in, 71—73; its ascent in fine glass tubes, 73.
Water-fowl, characteristics of, ii. 200; toes, ib.; legs and feathers, ib.; oil and skin, ib.; classification of, 201.
Water-hen, the, distinguished from the coot, ii. 197; the bird described, ib., 198; its habitudes, ib.
Waves, velocity of, i. 90, *n.*
Wax, how collected by the bee, ii. 516.
Weasel, its size and proportions, i. 411; description of the, ib.; its noxious nature and habits, ib.; method of stealing and eating its prey, ib., 412; parturition of the, 412; effluvia, ib.; affection for putrefaction, and instance of, ib., 413.
Weasel kind, animals of the, their characteristics, i. 410; fur, ib., 418; method of taming the, 411, *n.*; anecdotes of the, 412, *n.*; their odorous glands, 410; habitudes and shape, ib.; size, 411.
Weaver-fish, ii. 324. See *Trachinus*.
Web of the spider, how formed, ii. 440, 441; of the garden-spider, 441; spun into thread, 442.
Werner, his theory of the earth, i. 17; classification of rocks, 18.
Whale, its greatest size, ii. 250; its amazing appearance, ib., 251; seven varieties of the, 251; the great Greenland, described, ib., 253, *n.*; its skin, 251; tail, ib.; scarfskin, real skin, blubber, 252; cleft of its mouth, ib.; whalebone, ib.; eyes, ib.; ears, ib.; spouts or nostrils, ib.; its internal structure, ib.; fidelity, ib.; female and young, ib., 253; gregarious, ib.; food of the, ib.; inoffensiveness, 254; its enemies, ib.; historical notice of the whale fishery, ib., 255, *n.*; nations that

fish the whale, 255; account of the Irish whale fishery, ib., 256; whales diminishing in numbers, and the effect, 256; the, how killed by the Biscayneers, ib., 258; Scoresby's account of the whale, 256—259, *n.*; maternal affection of the, 259, *n.*; uses of the oil and greaves, 258; barb and flesh, ib.; flesh, by what nations prized, 260; the beluga, or white whale, ib., *n.*; the deductor, or ca'ing whale, 261, *n.*; the spermaceti whale, 262, *n.*

Whale-louse, its injury to the whale, ii. 255.

Whelk, a small shell-fish, ii. 369, *n.*

Whimbrel, described, ii. 194, *n.*

Whip-snake, its appearance, ii. 423; venomous bite, ib.

Whirlpools, i. 96. See *Currents*, the *Maelstroom*, &c.

Whiskers, veneration of the Spaniards and other nations for, i. 173.

Whiston, his theory of the earth, i. 14—16.

White bait, fishery of the, on the Thames, ii. 316, *n.*; found in the Frith of Forth, ib.; general description of, ib.; account of the appearance of, near London, 318; what they are, ib.

Whiting, a species of cod, described, ii. 300, *n.*

Widah, kingdom of, the serpent, how adored there, ii. 415.

Winds, i. 116; how produced, ib.; chiefly by the sun, ib.; difficulty of a history of, 117; steadiness of, in certain places, ib.; causes of, 117—119; history and theory of trade-winds, 118, *n.*; trade-winds, 121; monsoons, 122; some winds peculiar to certain coasts, 123; some change daily, ib.; east, why the most powerful and constant, ib.; on mountains, ib.; varied by the seasons, 124; its currents, how increased, ib.; hot, 125; destructive, ib.; in Persia, ib.; hurricane, ib.; tornado, 126; sand-storm, ib.; storms in Britain, ib.; in France, 127; sirocco, 128.

Wind-gun, account of the, i. 107.

Wings of birds, their conformation, ii. 2, 3; wings and wing cases of insects, 616.

Wistiti, kind of monkey, i. 503.

Wolf, the, distinguished from the dog, i. 398 and *n.*; period of gestation, ib.; size, colour, and disposition, ib.; antipathy to the dog, 390; their untameableness, ib., 400; their generation, 400, 401; strength, 401; suspiciousness, ib.; how hunted, ib., 402; how extirpated from England, 402; where found, ib.; the North American, its tractability, ib., 403.

Wolf-fish, notice of the, ii. 299.

Wolga, the largest river in Europe, what remarkable in the, i. 75.

Wolverine. See *Glutton*.

Wood, fossil, ii. 595.

Wood cock. See *Cock of the wood*.

——— a migratory bird, described, ii. 191, *n.*

Woodpecker, characteristics of the, ii. 101; colonies of the, ib.; green woodspite described, ib.; tongue and its use, 102; how it attacks ant-hills, 103; its nest, ib.; young, ib.; hanging nests of the, in Guinea and Brazil, 104; the gold-winged, account of the confinement of one, 105; ivory-billed woodpecker, 103, *n.*; gold-winged woodpecker, 104, *n.*; red-headed woodpecker, ib., 105, *n.*; downy woodpecker, 106, *n.*

Woodspite, green, ii. 102. See *Woodpecker*.

Woodward, his theory of the earth, i. 14; of earthquakes, 46.

Woody fibres of plants, ii. 601.

Wool, manufacture of, when commenced in Britain, i. 288; that of Merino sheep described, 295.

Worms, their motion, how effected by the spiral muscle, ii. 559; what organs they want, ib.; eggs, ib.; young, ib.; avoid the animals that prey on them, 560; what peculiar in them, ib.; reproduction by cutting, when first observed, ib.

Wrasse, a prickly-finned fish, ii. 296.

Wren, ii. 153, *n.*; golden-crested wren, ib.; willow-wren, ib.; wood-wren, ib.

Wryneck, a bird resembling the woodpecker, ii. 103, *n.*

Wynkyn de Worde, his qualifications of a good greyhound, i. 391.

X

Xiphias, ii. 294. See *Sword-fish*.

Y

Yawning, how produced, i. 170; its sympathetic nature, ib., 171, *n.*

Yellow-hammer, or *Yellow-yeldring*, a species of bunting, ii. 151, *n.*

Young, courage and art of animals in defending their, i. 243.

Youth. See *Puberty*.

Z

Zebra, its beauty and untameableness, i. 265; distinction between the zebra of the plains and the mountain zebra, ib., *n.*; original country of the, 265; its shape and colours, ib.; male described, ib.; instances of its fierceness, 266; reason why untamed, ib.; swiftness of the, 267; instances of female zebras producing mules, ib., *n.*; its food, ib.; voice, ib.; value, ib.

Zeiran, a kind of gazelle, i. 308.

Zeus, or *Doree*, a prickly-finned fish, ii. 298.

Zibet, a variety of the civet, its distinguishing marks, i. 423.

Zoophytes, meaning of the term, ii. 557; what kind of life they have, ib., 558; how distinguished from plants, ib., and *n.*; distinctions of the class, 558; classification, 562—567, *n.*; Blumenbach's description of, 558, 559, *n.*

Zorille, a variety of the weasel kind, i. 421.

DIRECTIONS TO THE BINDER.

SPONGE.—This well-known production of the sea has been in use from the earliest times, and naturalists were long embarrassed whether to give it a place in the animal or vegetable kingdom. Most authorities now place it in the lowest scale of animal life. There are fifty different kinds of sponge. Sponges are found plentifully in the Mediterranean and other seas of warm climates, but diminish in number and deteriorate in quality as they approach cold latitudes. They adhere to rocks in places the least exposed to the action of the currents and waves, and below low water mark. The best sponges come from the Archipelago, where they abound near many of the islands, whose inhabitants subsist entirely by the sponge fishery. At the Cyclades, sponge-diving forms the chief employment of the population. The sea is at all times very clear, and experienced divers can distinguish from the surface the points to which the sponge is attached below, when an unpractised eye could but dimly discern the bottom. Each boat is furnished with a large stone attached to a rope, and this the diver seizes in his hand, on plunging head foremost from the stern. He does this in order to increase the velocity of the descent; thus economizing his stock of breath, as well as to facilitate his ascent, when exhausted at the bottom, being then quickly hauled up by his companions. Few men can remain longer than about two minutes below; and, as the process of detaching the sponge is very tedious, three, and sometimes four divers descend successively to secure a particularly fine specimen. The best sponge is that which is the palest and lightest, has small holes and is soft to the touch. Of old, sponge was regarded as a cure for a long list of maladies. Burned sponge still holds a prominent place among the materials of medici[illegible]

THE PEON, THE RAT, AND THE SNAKE.—One of those singular escapes occurred a few days back, for narrating which old Indians get accused of drawing the most formidable long-bows, when they settle down on their pensions in that portion of the metropolis dedicated to their retirement under the appropriate name of Asia Minor. This, however, is a fact, as doubtless is many a similar story which has made people stare and shake their heads. A peon in the Tannah near the College Bridge, observed a rat run across the floor. He stooped to look after it, having his turban off and his back hair loose. While in this position he suddenly felt as though some one were tugging him back by his hair. He put his hand up, and to his horror found there was a large cobra on his back, struggling to free its teeth from his hair, in which they had got entangled. Probably the reptile had also observed the rat, and had dropped from the roof, imbued with as keen a love of hunting as the peon himself. Be that as it may, the snake ultimately succeeded in getting loose, and escaped to a hole without inflicting any injury on the man. By the order of the chief magistrate the place was pulled down the next day, and there, sure enough, was the snake, with the rat in his stomach half-digested.—*Delhi Gazette.*

WESTERN GIANTS IN THEIR SLUMBER.—The Burlington (Iowa) *State Gazette* says that while some workmen were engaged in excavating for the cellar of Gov. Grimes' new building, on the corner of Main and Valley streets, they came upon an arched vault some ten feet square, which, on being opened, was found to contain eight human skeletons of gigantic proportions. The walls of the vault were about fourteen inches thick, well laid up with cement, or indestructible mortar. The vault is about six feet deep from the base to the arch. The skeletons are in a good state of preservation, and we venture to say are the largest human remains ever found, being a little over eight feet long.

Who are the Longest Lived?

There appears to be a wide difference of opinion between some of our most intelligent and respectable cotemporaries in regard to the subject, who are the longest lived of nations? We copy some of their remarks:

The Americans are the longest lived of people notwithstanding all the humbug about the great age to which the English live, their superior stamina, etc. And the longest lived of Americans are to be found here, in this very New England, although such a mess of stuff is said about the Yankees working themselves to death, being half-starved and depriving themselves of the enjoyments of life thus tending to abbreviate it; and despite the arguments which are based upon the changeability of the climate, the east wind, and all that. These are but windy arguments. Statistics tell a different story.—*Boston Evening Ledger.*

Americans are not the longest lived people, and we much mistake if we are destined to be a long lived nation, even! The Irish, of whom the writer claims to be a descendant, are the longest lived;—but we don't know whether to attribute it to their climate or the simple diet to which the general poverty confines them.—*Charleston (S. C.) Mercury.*

You should have confined yourself, brother *Mercury*, before you delivered that sapient opinion.—Humboldt has placed it beyond a doubt that the mountaineers of Peru can contest the palm with death longer than anybody else.—*New Orleans Picayune.*

That's a lie. Humboldt says no such thing anywhere.—*New York Evangelist.* [Tut, tut, tut.—What language for an "evangelist" to use! Can there be any wonder that naughty boys curse and swear, when they have such examples from such quarters!—*Ed. Life Illustrated*]

Keep cool, gentlemen, or none of you will be long-lived. We believe the greatest age of man to be obtained by the Hindostanees, and refer the curious in such matters to Buffon's interesting account of the people.—*New York Herald.*

Our American friends are having a dispute as to what people present the most numerous instances of advanced age in man. Cold regions we believe to be the most favorable to the prolongation of life but we have nothing to disprove that the Dutch live longer than any other race—too long for their own good, perhaps.—*London Times.*

The London *Times* has been having a fling at the Dutch, referring to the great age to which some of the Mynheers attain, though nothing is mentioned about old Rip Van Winkle. The *Times* is famous for wholesale slurs upon nations, though just now it has not a word to say against its dear neighbor France. If we were asked who lived the "longest of all people, we should say the Patagonians, for numbers of the stand full eight feet high—*Boston Post.*

The Boston *Post* thinks the Patagonians live the longest of all mankind. That may be; but it is certain that the inhabitants of the Himmaleh mountains live the highest.—*Boston Herald.*

That may be, too, neighbor; but a still sure thing is, whether the Yankees live the [illegible] not, they are destined [illegible]

1856

MAN VS. BEAR.—On Saturday last, Sept. 6th, says the Stockton *Argus*, Mr. F. H. Ayres, living on the San Joaquin river, went in pursuit of a bear that had been committing depredations on his swine. Coming up with the animal, he discharged the contents of both barrels of his gun into his body. This incensed, without disabling the bear, causing him to turn upon his assailant, when, with one stroke of his paw, he tore away a portion of his thigh, and, seizing his head in his mouth, crushed it in a fearful manner, breaking in the bones of the forehead and nose, and laying bare a portion of the brain. The brute then left him. He was traced some distance by the blood from the gunshot wounds inflicted upon him, but was not overtaken. Dr. Ryer dressed the wounds of Mr. Ayres, which are of such a severe character as leaves little chance of his recovery.

We never could see the propriety of persons acquainted with the fierce and dangerous nature of the grizzly bear, going out to attack him in the manner Mr. Ayres seems to have done. To this reckless practice, nearly every accident of this class may be traced. This animal is naturally pacific in his disposition, rarely ever attacking man unless provoked by an assault, and even then, as a general thing, he appears to think discretion the better part of valor; retreating, in most cases, rather than engage in a fight. But, when wounded, or closely beset, he never fails to turn and defend himself, and generally with spirit and effect.

He has but a few points fatally vulnerable, even to the rifle ball; hence, the hunter cannot always calculate upon killing, even when he is fairly within range. The heart and the brain are, of course, always vital points when reached by the leaden missile. But it often happens that the bullet, though well directed, strikes the bony covering which protects these parts, at an angle that turns it from its course, causing it to produce no further injury than just sufficient to irritate the object of attack, and bring him upon the now defenceless hunter. It is in this manner that many have heretofore lost their lives, or been terribly crushed and maimed in their encounters with this usually peaceful friend, but dangerous foe. Bruin is by no means a denizen of exemplary habits. He is a night-prowler, lax and unscrupulous in his notions of honesty; a picker up of loose things about a barn yard too, like a city official, preying upon pigs, poultry and offal, left in exposed positions.

We cannot deny that, yet we can hardly recall an instance of deadly conflict between him and his human antagonist, in which he was decidedly the aggressor. In view of his predatory, pilfering, shoulder-striking practices, we don't object to his being attacked and driven from civilized society, but would admonish those who undertake the job, to make ample preparation for defense, as well as attack. Don't go alone, depending on a simple shot or two, but in numbers, well armed, not only with rifles, but also a heavy knife for close quarters, should it come to that. Dogs are often of great service in attacking the grizzly, by worrying and keeping him at bay, thereby giving the hunter a better opportunity to approach and secure a good shot.

Wonders of the Microscope.

The meaning of *Animalculæ* is animals whose figures cannot be discerned without the aid of the magnifying glass. The recent astonishing discoveries of Ehrenberg, a Prussian naturalist, have given a new aspect to this department of animal nature, even in a geological point of view. He has described seven hundred and twenty-two living species which swarm almost everywhere, even in the fluids of living and healthy animals in countless numbers. Formerly they were thought to be the most simple of all animals in their organization; to be in fact little more than mere particles of matter endowed with vitality; but he has discovered in them mouths, teeth stomach muscles, nerves, glands, eyes and organs of reproduction. Some of the smallest animalculæ are not more than the twenty-four thousandth of an inch in diameter, and the thickness of the skin of their stomachs not more than the fifty millionth part of an inch. In their mode of reproductions they produce their young alive, also by eggs, and by buds or gems. An individual of the Hydatina senta increased in ten days one million; on the eleventh day to four million, and on the twelfth day to sixteen million. In another case Ehrenberg says that one individual is capable of becoming in fours days one hundred and seventy billions! Leuwenhoeck calculated that one billion animalculæ, such as occur in common water, would not altogether make a mess so large as a grain of sand Ehrenberg estimates that five hundred million of them do actually sometimes exist in a single drop of water. In the Alps there is sometimes found a snow of red color; and it has been recently ascertained by M. Seutterworth that the coloring matter is composed chiefly of sutusoria, with some plants of the tribe of Algae. And what is most singular is, that when the snow had been melted for a short time, so as to become a little warmer than the freezing point, the animals die, because they cannot endure so much heat. A specimen of meteoric paper which fell from the sky in Courland in 1686, has been examined by Ehrenberg, and found to consist, like the red snow, of *Confrva* and *Infusoria*. Of the latter he found twenty-nine species. Surprising as these facts are, it will perhaps seem still more incredible that the skeletons of these animals should be found in a fossil state, and actually constitute nearly the whole mass of soils and rocks, several feet in thickness, and extending over areas of many acres. Yet this, too, has been ascertained by the same acute Prussian naturalist. 1856

The Golden Era, having a much larger circulation than any other journal in this city, has been awarded by Postmaster Weller the publication of the uncalled for letters in the San Francisco Post Office for 1856.

FIRST EDITION.

SUNDAY MORNING, AUGUST 17, 1856.

A Snake Story---A Live Snake in a Live Man.

A gentleman, whose name we did not learn, arrived in this city from Bird's Hill, on Monday last, for the purpose of procuring surgical advice in relation to the possibility of removing from the stomach a large snake, which has inhabited that locality for the past fifteen years. Exactly at what time the reptile was taken into the stomach, the sufferer is not aware. He first felt its presence in the vicinity of the kidneys many years ago; but the pains experienced, although sometimes acute and troublesome, occasioned no alarm until about two years since, when one day feeling quite unwell, he placed his hands upon his bowels and distinctly felt the snake crawling within him. Since then it has grown enormously, and has attained a length of at least fifteen inches, and a size around the middle of five or six inches. It proportions can be pretty accurately ascertained, as its entire shape is fearfully obvious to the touch. It is quite active, and possesses an insatiable appetite, judging from the amount of food and water consumed by the sufferer, who is continually parched with thirst, and not unfrequently requires from three to four gallons of fluid daily. Through the recommendation of an Indian he has lately found considerable relief from his incessant thirst by drinking water liberally diffused with vinegar.

He has made several ineffectual attempts to dislodge the "varmint" by starvation and the free use of stimulants. On one occasion he abstained from both food and water for three days, in the hope of bringing the occupant to some sort of terms. The first day, the snake became uneasy, the second boisterous, and the third furious, but still the man held out. At the end of the third day, however, his snakeship commenced an attack upon the walls of his prison, with what appeared to be a tolerably full set of teeth, and the result was an immediate supply of food more agreeable to both parties. As may be supposed, the man is reduced to a perfect skeleton under the extreme torture of mind and body preying upon him night and day, but he does not despair of finding a surgeon in the city sufficiently skillful to make an incision in the abdomen and remove the reptile. We have read of similar cases, but this is the first that ever came under our own observation—and we hope it may be the last, for we have felt "all-overish" ever since.

East Indian Jugglery.

Madame Pfeiffer, in her "Second Journey Round the World," gives the following description of certain unexplainable feats of jugglery witnessed by her whilst she was sojourning in the East Indies: "At the close of the entertainment, the performance of Hercules was really curious in its way. He appeared with nothing on but a pair of drawers, and a cord was passed around his neck, and with this his hands and arms were so firmly tied behind him that he could not make the smallest movement. He came to us to have the knots examined, and then he crept under a high covered basket, beneath which various garments were placed; and after the lapse of a few minutes the basket was lifted up, and the Hercules made his appearance completely clothed in them. Then he crept again under the basket, and came out without them, but holding the cord with all its knots fast in his hands, and so forth. All this would, of course, have been nothing in a theatre, where assistance might have been given him, but this was in a meadow, where no assistance was possible. One of the gentlemen present offered him twenty-five rupees for his mystery, but he declined the offer."

The Cashmere Goat—Its Introduction into America.—It is not, as yet, generally known that the Thibet goat, from whose wool the famous Cashmere shawls are made, has been introduced successfully into the United States. This enterprising undertaking was achieved a few years since, after many difficulties, by Dr. J. B Davis, of Columbia, S. C., at that time employed by the Ottoman Porte in experimenting on the growth of cotton in the Sultan's dominions. Dr. Davis succeeded, at vast expense, in securing eleven of the pure breed, which, on his way home, he exhibited in London and Paris. Since that period the goat has been introduced from South Carolina to Tennessee, where it is said to thrive. The value of a flock may be estimated from the fact that no real Thibet goat has ever been sold for less than a thousand dollars. This enormous price, moreover, is not a speculative one, for no fleeced animal has wool of such fineness, softness and durability. The wool of all the Thibet goats in Tennessee, for example, has been engaged at New York, this year, at eight dollars and a half a pound, the purchasers designing to send it to Paisley, in Scotland, in order to be manufactured into shawls.—*Exchange.*

The Vegetable Serpent.—A new organization of nature, being pronounced by naturalists the connecting link between animal and vegetable life, has been found in the interior of Africa, in the form of a serpent with a flower for head. This singular freak of nature is spotted in the body, drags itself along, and the flower forming its head is bell-shaped, and contains a viscid fluid. Flies and other insects, attracted by the smell of the juice, enter into the flower, where they are caught by the adhesive matter. The flower then clooses, and remains shut until the prisoners are bruised and transformed into chyle. The indigestible portion, such as the head and wings, are thrown out by aspiral openings — The vegetable serpent has a skin resembling leaves, a white and soft flesh, and instead of a bony skeleton a cartilaginous frame, filled with yellow marrow. The natives consider it a delicious food.

THE DAILY UNION.

East Indian Archipelago.

A very instructive and readable book has lately been issued from the press, entitled "The Prisoner of Weltevreden, and a Glance at the East Indian Archipelago." The author is Capt. Walter M. Gibson, who was some time ago arrested and imprisoned at Weltevreden, and afterards escaped. Even now he has pending a demand for redress.

The resources of this paradise of earth are but eginning to be developed, owing mainly to the xceeding jealousy with which the Dutch regard he intrusion of outside barbarians. The New York *Commercial Advertiser*, which gives a brief eview of the work, remarks that Capt. Gibson s not a skillful writer—his energy and enthusiasm are more remarkable than his judgment; and to add to the evils of a defective style, he as rendered some portions of his narrative very obscure by the introduction of far-fetched allegory, which the illustrations are scarcely sufficient to explain. Still the book is a very entertaining one, and, for example, read what he says of

THE ORANG-KUBUS, OR HAIRY MEN OF SUMATRA.

I got a glimpse, amid a thick bower of foliage, at a height of about eighty feet, of a dark brown form, seeming to me as large as a human being; and when Bahdoo saw it, he cried out, "orang kubu! orang kubu!"

I raised a shout, and we all cried out at the top of our voices. I struck at some low drooping limbs with the pike in my hand; and then we heard rustles and leaping sounds at other points in the great tree tops near the form we had seen; this one shifted, slid down a limb, came nearer to view, and then we could partly see a very human-like form, holding a little creature with a very human-like face, peering down upon us.

The sailor had raised the carbine and was about to fire, when I bid him stop; it seemed like murder to shoot at that human face, for I had heard something of wild and hairy faces, roaming in the forest not far from the waters of Palembang. I again raised a shout—Bahdoo made a peculiar piercing cry, and again the creature moved; it leaped, others leaped, and the huge tree shook. Downward came the sounds, leaping, rustling, crashing, then dark bodies shot before us, down, plunge into the creek.

We stood with weapons grasped, expecting an attack; but, after hearing a quick flounder and splash in the water, up sprang five or six large creatures, for a moment but dimly seen, then up the bank and away into the thick forest on the other side.

Three-fourths of the day was now gone, and I had seen enough for one day's excursion. The boat was put about, and rowed quickly down the canopied stream—pulled with hands again through the narrow neck, where the leafy tops brushed our backs. Our fatigue felt lightened when we shot out of the leafy cavern into the warm daylight on the main stream we had left; and our increasing fatigue was all forgotten when, upon turning the bend of the stream into the Moosee, we beheld the graceful, golden tipped spars of the Flirt walking up among the towering tree tops.

A light breeze had risen, filling the clipper's main and foretop sail, with which she walked away from the lumbering bark, that crept slowly behind, with all sails set. It was sweet, after the [illegible] and adventure, to sit upon my quarter [illegible] the cool wafts of air that blew [illegible] woods and played with the

ward to me by many Arab and Chinese traders I have met with. The Kubus deposit the gum they collect, and other articles to exchange, in a certain place, when traders are in the neighborhood; then they strike with a club upon a suspended hollow log, called *taboh* by the Malays, making a loud, drum-sound—and run off back into the recesses of the forest. The traders come to the spot, take away the gum, and leave what they think proper. After they have gone, the Kubus cautiously venture out of the thicket, and carry off what has been left for them. Sometimes this mode of barter is reversed—the traders depositing trinkets and cloths—then beat a gong, and retire; whilst the wild men come and take away what has been offered, and honestly and generously leave all that they have got of gum or other articles. Thus the chief material for the purifying incense used in the ceremonial of the Church of Rome is gathered by these rude hands.

Marsden, who resided many years on the western coast of Sumatra, in his account of the aborigines of the island, says that he had heard of two species of people, dispersed in the woods, and avoiding all communication with the other inhabitants; these were the orang Kubu, and the orang Gugar: the former being, as he understood, very numerous on the south-east coast between the Palembang and Jambee territories. He speaks of having heard of several that had been caught and put to work as slaves; and of a young Kubu female that was captured by a man in the Laboon country. He says that the Gugars are much scarcer than the Kubus, differing in little, but the use of some uncouth kind of speech, from the orang utan of Borneo—they being entirely covered with hair. But Marsden is rather skeptical about the existence of these beings of doubtful humanity.

You will have an opportunity when at Palembang, said the Dutch officer, to learn something more definite about these creatures; and may probably see some of them in the possession of the old pensioned Sultan, who resides there. I did learn much more about these wild people at Palembang and at Batavia, which I shall relate in the course of my narrative.

CABIN OF BONES.—In the Placerville *American*, of Saturday, Aug. 16th, we find the following:

1856

On Weber Creek, forty-five miles east of Salt Lake City, is a large cabin literally filled with the bones and carcasses of animals. But how came they there? All will remember the account we gave of a drove of cattle on their way from the States to Salt Lake, last fall, getting snowed in on the mountains, that all but two of the animals and one of the men perished—two men escaping by taking each an animal and making the best of their chances through the deep and rapidly falling snows to Salt Lake.

The third man, after laboring in the snow for a time, determined on returning to the cabin and wait till relief could be sent him, but he perished before it reached him. The starving cattle rushed into the cabin to screen themselves from the cold, and as they fell and died, others made their way in only to perish in their turn and make room for yet others, and this made it what it will doubtless long remain the cabin of bones.

Discovery of Enormous Fossil Eggs. 1857

The Calcutta *Englishman* says :—The *Mauritian* mentions, on the authority of a Bourbon Journal, that a singular discovery has been made in Madagascar. Fossil eggs of an enormous size have been found in the bed of a torrent. The shells are an eighth of an inch thick, and the circumference of the egg itself is two feet eight inches lengthwise, and two feet two inches round the middle. One, which has been opened, contains eight and a half litres, or about two gallons!—What was to have come out of these eggs? Bird or crocodile? The natives seem to be well acquainted with them, and say that ancient tradition is uniform as to the former existence of a bird large enough to carry off an ox. This is only a little smaller than the roc of the oriental fable, which waited patiently till he saw the elephant and rhinoceras fighting, and then carried them of both at one swoop. Some fossil bones were found in the same place as the eggs, but the Bourbon editor says, he will leave it to the pupils off the great Cuvier to decide to what animal they belong. If they should prove to be the bones of a bird of size corresponding with the eggs, the discovery will indeed be an extraordinary one.

THE CALIFORNIA SILK-WORM.—The Saturnia Ceanethi can now be seen to advantage, in all its metamorphoses, from the cocoon, its first, to the full grown caterpillar, its last state, in the grounds of the San Francisco College, on Bush street, between Mason and Taylor streets. There are upwards of one thousand caterpillars, that will shortly be transformed into cocoons and chrysalides. Those of the public who are interested in this discovery may, on proper application to the establishment named, have an opportunity to examine the insects.—*Bulletin.*

THE GRASSHOPPERS.—These insects have made their appearance in countless numbers near this city, and are consuming vegetables with great rapidity. We have been assured that many of the growing crops near the Partera and Cieneguitas have already been quite destroyed by them. They appear to have a partiality for young bean vines and growing grain. The dry season has doubtless favored the development of the destructive insects.—*Santa Barbara Gazette.*

From the Macon Telegraph.

MR. CISBY: There is a negro woman in Bibb county, who has one hundred and nineteen descendants, and is yet in the possession of all her faculties, except sight—she has been blind for six years.

Sixty-seven of her descendants, as well as herself, are now owned by a gentleman in this county. Another heir owns fifty-two in another county.

The name of the woman is Sena. She was one of three slaves inherited by a lady married in Louisville, Jefferson county, Georgia, in 1801.

I mention this as a fact in slave statistics—from which the inference may be drawn, that negroes are not very hardly used in Georgia, or they would not increase at such a rate.

If you feel a curiosity to see the old lady and her descendants, I will take pleasure in showing them to you, as all live within a few hours' travel of each other. Respectfully yours,

BAY GALL.

The Oldest Man in America.

We find the following communication in the Cassville (Ga.) *Standard*, of the 26th inst.:

Mr. Smith: A recent notice in a New York paper, makes Peter Nassau, a colored man, residing at Woodstock, Vermont, the oldest man in America. He has attained the extraordinary age of one hundred and twenty-six years. Albeit, in this era of short lived humanity, this appears a wonderful accumulation of years—there is in our own Sunny South an example of longevity that considerably surpasses it.

There is now living in Murray county, in this State, on the waters of Holley Creek, a Revolutionary veteran, who has attained the age of one hundred and thirty-four. His name is John Hames. He is known throughout the region in w[illegible] by the appellative of "Gran'sir [illegible] for Grand Sire. [illegible] under date of the 12th of February, in relation to is still a proprietor,) writing from Vera Cruz which paper, Mr. Forsyth, our Minister to Mexico, [illegible] Thus a correspondent of the Mobile *Register*, (of [illegible] by partic[illegible] probably well informed.

[illegible] sion, [illegible] he represents the correct version of the treaty, made this [illegible] are inclined to believe is the correct ver- prove mutually beneficial to the two countries, and is simply a commercial arrangement, which will for a sum of money. Another statement is that it of Lower California, and the Department of Sonora of Mexico, together with the cession to this country vides for an American protectorate over the whole ously represented. One statement is that it pronitely known, and its subjects and terms are variance with the Government of Mexico.

The subject matter of this treaty is not yet defation by this Government, are matters of import- ment of its terms at home, and its speedy ratifica- These precautions would indicate that a conceal- [illegible] was ready to convey it to this country.
